The question of an allergic reaction to the antibiotics was never specifically addressed during her emergent stay in the hospital. The emergency room doctors noted erythema and tense swelling of the woman's lower extremities. A serum pregnancy test was positive with a human chorionic gonadotropin (hCG) level of 6124 mIU/ml (2-3 week gestation). She was transported to the intensive care unit in extremis. She was intubated and went into cardiac arrest. She was resuscitated once, but a second cardiac arrest was fatal.

Significant medical history went back approximately one month prior when the woman was involved in a motor vehicle collision and broke her foot. On her two week follow up, her primary doctor asked her if she had had a pregnancy test in the ER at the time of the accident. The woman said yes and that she had been on her menses. A thorough record check did not show a pregnancy test was performed. On the day of the terminal event, she had a tampon in place, noted on the pelvic exam.

The woman's mother reported that her daughter was going through a "mid-life" crisis and acting wildly. She got several new tattoos and was having an affair. The mother stated it was entirely possible she became pregnant while having the affair because her husband had a vasectomy.

At autopsy, the tense swelling and erythema of the lower extremities was noted to be in a trouser distribution. The legs had a crepitus-like feel to them. Internal examination of the pelvis found that the uterus had a slightly purple and erythematous fundus but no perforation. The endometrial cavity was full of hemorrhagic debris but no obvious fetal tissue was seen grossly. Microscopic examination of the debris revealed extensive autolysis with a few fragments resembling placental villi. Blood cultures had been performed at the hospital prior to the cardiac arrest. Despite having received one dose of antibiotics at the medical clinic, one of the blood cultures grew *Clostridium perfringens*, which can produce gas gangrene.

Putting the story together, it appeared the woman got pregnant and either had an abortion or a spontaneous miscarriage with retention of products of conception. There was no history she had been to any doctor

for an abortion. Neither her mother, friends, nor family knew anything about her being pregnant. If the decedent did get an abortion through a clinic or through personal instrumentation, there were complications that were not addressed. If the uterine contents were retained products of conception from a miscarriage, the sepsis would be explained. There is no confirmation of her pregnancy before the last ER visit because a pregnancy test was not performed at the time of her car accident. The sepsis caused a trouser distribution of swelling and erythema of her lower extremities. The crepitus-like feel of the legs may be indicative of gas gangrene from Clostridium. Cause of death in this case is acute sepsis due to uterine infection.

It is important to note that it would be unusual to find identifiable fetal or placental tissue in a case such as this. The time that is required for the development of the sepsis is long enough for all such tissues to autolyze and be unidentifiable under the microscope. Interviews with family and friends regarding medical and social history are very important in understanding the background of the illness. Also helpful, are discussions with other medical examiners with more experience that have seen a few of these cases. Their wisdom is invaluable.

Abortion, Miscarriage, Septicemia

G39 Fatal Rupture of Splenic Artery Aneurysm in a Pregnant Woman With Portal Hypertension

Slobodan Savic, MD, PhD, School of Medicine, University of Belgrade, Institute of Forensic Medicine, Deligradska 31a, Belgrade, 11000, SERBIA AND MONTENEGRO; Djordje Alempijevic, PhD, Institute of Forensic Medicine, Faculty of Medicine, 31 A Deligradska St., Belgrade, 11000, SERBIA AND MONTENEGRO; Irina Damjanjuk, MD, Institute of Forensic Medicine, Belgrade, OR 11000, SERBIA AND MONTENEGRO; Stojan Petkovic, MD PhD, Klinicki Centar Vojvodina, Department of Forensic Medicine, Clinical Center of Vojvodina, Hajduk Veljkova 5-7, Novi Sad, 21000, SERBIA AND MONTENEGRO; and Radmila Stevanovic, MD, Institute of Pathology, School of Medicine, University of Belgrade, 8 Dr Subotica St., Belgrade, 11000, SERBIA AND MONTENEGRO*

By attending this presentation, attendees will learn about important pathological characteristics of splenic artery aneurysms, their causative correlation with pregnancy and portal hypertension, as well as clinical and medicolegal aspects of cases where their rupture leads to a fatal outcome.

This presentation will impact the forensic community by demonstrating how development of splenic artery aneurysm may be connected with pregnancy and portal hypertension; it is a potential source of profuse abdominal hemorrhage and sudden unexpected death, sometimes in previously apparently healthy individuals. Also of importance in this particular case is the patient's intention to hide a known disease from the attending physician, which may cause serious and potentially fatal errors in medical treatment.

Fatal complications of pregnancy and childbirth always attract special public and medical attention and are usually a serious challenge for forensic pathologists, especially if death occurs suddenly and unexpectedly in a previously apparently healthy woman. This case concerns a 30-year-old female, five months pregnant with her first child, who was found dead in her flat. According to the statement of the husband, cited in the initial police report, she had regular check-ups with her obstetrician. During pregnancy she did not complain of abdominal pain or any other discomfort. On the day in question the husband left the flat at 7:00 p.m. while she stayed at home preparing a meal. When he came back one hour later he found her lifeless, lying on the bed in their

bedroom. He immediately called an ambulance; they arrived promptly and attempted CPR but to no avail; she was declared dead at the scene. The cause and manner of death were undetermined and the examining magistrate requested a medicolegal autopsy.

The postmortem examination showed a female of moderate physique, 167cm in height, with external signs of pregnancy in keeping with the gestational age of five months. The skin and conjunctivae were very pale and hypostasis was poorly developed. There was evidence of attempted resuscitation. There was no evidence of external trauma. Internal examination of the cranial and chest cavities revealed only pallor of all organs and tissues, but no other significant pathological findings. Opening of the abdomen showed about 4500 ml of blood in the peritoneal cavity. Examination of the uterus and adnexa showed no evidence of ruptures or other possible source of bleeding. Within the uterine cavity was a dead female fetus, normally developed according to gestational age. The other possible site of hemorrhage was an extremely enlarged spleen, which weighed 780 g, but showed no evidence of rupture. Finally, the source of bleeding was discovered by examination of the splenic artery, which was dilated throughout its course (with a circumference measuring up to 1.5 cm), tortuous, with one 1 cm long fusiform and two big saccular aneurysms, measuring 4 cm and 2 cm in diameter. The larger of the two saccular aneurysms showed a 0.5 cm long rupture, while attached to the smaller of the two was an accessory spleen, measuring 1 cm in diameter. There were several further accessory spleens in the vicinity, with a diameter varying between 0.5 cm and 1.5 cm. The portal vein was almost completely obliterated by an old partly calcified thrombus. Death was deemed natural, caused by exsanguination due to a ruptured splenic artery aneurysm. During interview with the deceased's husband it became apparent that all the above mentioned severe pathological changes involving the splenic artery, spleen and portal vein, with portal hypertension, had been diagnosed both radiologically and clinically two years prior to the fatal outcome. According to the deceased's medical records, this important anamnestic information had not been disclosed to the obstetrician who controlled her pregnancy.

The important pathological, clinical, and medicolegal issues concerning the reported case, mainly the causative relationship between pregnancy, portal hypertension, and splenic artery aneurysm, clinical recommendations regarding pregnancy in women with diagnosed splenic artery aneurysm as well as medicolegal problems connected to patient-physician relationship, and potential accusations of medical negligence and malpractice will be discussed.

Splenic Artery Aneurysm, Pregnancy, Portal Hypertension

G40 How Often is Pre-Existing Disease Found in Child Deaths?

M.G.F. Gilliland, MD, Brody School of Medicine at East Carolina University, Pathology & Laboratory Medicine, Brody Building, Greenville, NC 27858-4354*

After attending this presentation, attendees will be able to describe the frequency of finding pre-existing disease in a group of child death investigations and discuss the potential significance of such findings in individual cases.

This presentation will impact the forensic community by demonstrating why the forensic science community needs a scientific basis for comparison of individual cases to a larger group of child deaths when providing information to triers of fact.

Forensic pathologists are often asked whether injured children have pre-existing diseases when discussing findings in death investigations. Commonly the pathologist is then asked to compare individual case

findings with findings in a larger population of children. The objective of this study was to review a series of child death investigations and determine the frequency of identifying pre-existing disease in the group.

A prospective study focused on the deaths of 169 of approximately 400 child deaths investigated by the Southwestern Institute of Forensic Sciences (SWIFS) in Dallas, TX from 1981-1989. Investigation of these deaths included information about the circumstances of death or collapse, prior medical and social history, autopsy examination with ocular examination, toxicologic investigation, radiography when indicated, and additional investigations when questions remained. The study has been previously described and included: 19 asphyxial, 80 closed head injury, 13 trunk injury, 13 central nervous system disease, 13 sudden infant death syndrome, 21 other natural deaths, and 10 deaths with undetermined cause and manner. The central nervous system diseases included meningitis, seizure disorders, spontaneous intraventricular and subarachnoid hemorrhages, and a brain tumor. The other natural deaths included respiratory tract illnesses, sepsis, congenital heart disease, myocarditis, a volvulus, and a dehydration death. Demographics were similar to the child deaths investigated at SWIFS: 78% were two years of age and under; 98 were white, 51 black, 16 Latino, and 4 other ancestry. Over half, 59%, were boys. Pre-existing disease was defined as diseases found at autopsy whether the disease contributed to death or not. However, children with diseases resulting from cardiovascular collapse were not included in the pre-existing disease group. Bronchopneumonia, myocardial ischemia, or watershed infarcts were found in some of the children who were well until an injury event occurred. These diseases were considered consequences of the collapse event and not included. Analysis of the data regarding bronchopneumonia has previously been reported for this study population. Review of the 169 deaths identified 60 children with pre-existing diseases and 109 without such diseases.

The group was further subdivided by the mechanism of the immediate cause of death. The distribution of pre-existing disease among unnatural, natural, and undetermined causes revealed:

Manner of Death	Pre-Existing Disease Present	Pre-Existing Disease Absent	Total	% of Subgroup with Pre-Existing Disease
Inadvertent	6	30	36	17%
Intentional	16	60	76	21%
Natural	34	13	47	72%
Undetermined	4	6	10	40%

Pre-existing disease was uncommon among injured children. For some of the intentional injury deaths investigation suggested that otitis media or retardation may have been a factor in increasing the caregiver's frustration with the child. The pre-existing diseases did not appear to increase the risk of injury in the inadvertent injury deaths and appeared to be incidental findings. The deaths attributed to natural causes identified diseases sufficient to account for the children's deaths, and, as such, had the greatest frequency of pre-existing disease by the definition used in this study. The 13 with no pre-existing disease included nine of the SIDS deaths which did not have sufficient disease or injury to account for deaths. Review of scene and circumstances, medical records, and search for social service involvement revealed no concerns. In the 1980s such non-suspicious deaths were attributed to Sudden Infant Death Syndrome at SWIFS. The other four natural deaths with no pre-existing disease were diseases resulting from a prior remote injury from which the child had at least partially recovered. Undetermined deaths in this study had neither adequate natural disease nor injury to account for the deaths and suspicious scenes, circumstances, medical records, or social service histories.

Review of a series of child deaths including both natural and unnatural causes and manners of deaths revealed that most natural deaths occurred in children with pre-existing disease and most unnatural deaths occurred in otherwise healthy children. Reporting such findings provides a scientific basis for comparison of individual cases to a larger group of child deaths.

Child Death, Child Abuse, Pre-Existing Disease

G41 Lymphogenic Cardiomyopathy: A Possible Cause of Non-Immune Fetal Hydrops

Antonio Bonifacio, MD, Stefania Zerbo, MD, Cettina Sortino, Pierangela Fleres, MD, and Emiliano Maresi, PhD, Department of Biotechnology and Legal Medicine, Section of Legal Medicine, Via del Vespro, n. 129, Palermo, 90127, ITALY*

After attending this presentation, attendees will gain knowledge of three particular cases of congenital and isolated cardiac lymphangiectasia manifested *in utero* with cardiac failure and hydrops.

This presentation will impact the forensic community by exploring how cardiac isolated lymphangiectasia might represent a new nosological entity that should be included among the primary cardiomyopathies (lymphogenic cardiomyopathy). Consequently, this entity should be investigated among the possible causes of non-immune hydrops foetalis (HF).

It is the intent of this presentation that cardiac isolated lymphangiectasia might represent a new nosological entity that should be included among the primary cardiomyopathies (lymphogenic cardiomyopathy). Consequently, this entity should be investigated among the possible causes of non-immune hydrops foetalis.

HF is an aspecific and terminal sign of many fetal diseases that could be observed at any time during pregnancy. In fully developed HF, there is subcutaneous oedema with fluid accumulations in peritoneal, pleural, and pericardial cavities. The umbilical cord and placenta are also oedematous and there is polyhydramnios. In the early stages of HF, the fluid accumulations are not present in all compartments. HF is caused by three main mechanisms: anemia, hypoproteinemia, and cardiac failure. Most cases fit within this classification, although some cases remain unsolved under the name of "idiopathic HF." Another classification divides HF into treatable (27%) and untreatable (73%) forms. The success of isoimmunization prevention programs demonstrated that most cases of HF are now non-immune and depend on cardiovascular diseases (22%), chromosomal abnormalities (13%), thoracic causes (10%), anemia (homozygous α -thalassemia), monochorionic twinning (6%), infections (5%), miscellaneous (16%), not determined (20%). Cardiovascular HF seems to be more frequently associated with structural and functional abnormalities that cause volume and/or pressure overload on the right atrium such as left heart syndrome, arrhythmias, myocarditis, cardiomyopathies, cardiac tumors, myocardial infarction, and arterial calcification.

Three unusual cases of congenital and isolated cardiac lymphangiectasia (ICL) manifested *in utero* with cardiac failure and hydrops will be presented.

Case 1: A male hydropic fetus with a gestational age of 14.2 weeks without dysmorphia. The mother was 32-years-old and had four pregnancies, one of them resulting in miscarriage due to unknown causes. Ultrasound of the fetus and placenta showed regular heart rate with biventricular hypocontractility and without congenital cardiac and extra-cardiac defects and polyhydramnios. Amniocentesis revealed a normal karyotype.

Case 2: A male hydropic fetus with a gestational age of 19.5 weeks without dysmorphia. The mother was 29-years-old and had a previous miscarriage due to a premature rupture of the placental membranes (acute chorioamnionitis) at the 25th week of gestation. Ultrasound of the fetus and placenta showed regular heart rate with biventricular hypocontractility, without congenital cardiac, and extra-cardiac defects, and polyhydramnios. Amniocentesis revealed a normal karyotype.

Case 3: A female non-hydropic fetus with a gestational age of 22 weeks without dysmorphia, except for the presence of a single head held plica. The mother, 27-years-old, was at first pregnancy. Ultrasound of the fetus and placenta showed light pericardial effusions, regular heart rate with biventricular hypocontractility, without congenital cardiac and extra-cardiac defects, and polyhydramnios. Amniocentesis revealed Trisomia 21.

In all cases, fetal autopsies showed ultrasound findings conducted during pregnancy. At histology, the organs were normally structured except for the heart that showed a “moth-eaten” aspect in the ventricular walls, due to severe, diffuse and transmural lymphangiectasia and interstitial lymphedema. The interposed myocardium resulted compressed, distorted, trabeculated, and with multifocal patchy coagulative myofibrillolysis (contraction band necrosis). The morphological examination in situ of apoptosis highlighted in all cases the presence of frequent apoptotic events in the endothelia of small arteries and veins.

Discussion: ICL is an extremely rare entity and up-to-date the literature reports describe only one case characterized by septal localization of this lesion causing septal hypertrophy and left ventricular outflow obstruction mimicking hypertrophic cardiomyopathy. These cases represent the first report of ICL involving diffusely the heart, causing cardiac failure and hydrops of various degrees. The findings of a marked apoptosis in the endothelial cells of blood vessels suggest that interstitial lymphoedema and lymphatic overload is due to increase vascular permeability of the cardiac blood microcirculation.

Hydrops Fetalis, Lymphangiectasia, Cardiomyopathy

G42 Prolonged Survival Time Following Duodenal Transection in a Child With Abdominal Trauma

Lauren E. Moser, MD, Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201; Mary G. Ripple, MD, 68 Bluebird Road, Port Deposit, MD 21904; and David R. Fowler, MD, Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201*

After attending this presentation, attendees will be able to recognize the symptomatology associated with abdominal trauma and will be able to understand the correlation between symptoms and pathologic injury correlating histologic examination of tissues with a timeline of events.

This presentation will impact the forensic community by providing valuable information about symptomatology associated with blunt abdominal trauma. Seemingly minor external injuries may harbor terminal internal pathology. Recognition of the potential severity of these injuries may prompt clinicians to conduct more thorough patient examinations and pursue imaging studies to identify unexpected internal injuries. In many cases of homicidal blunt force injury, forensic pathologists are asked to estimate the time of injury despite the uncertain circumstantial timeline of case investigation. In this case, a relatively accurate timeline was known. Hence, the correlation with microscopic sections of the injury can provide assistance in the evaluation of previously published timelines for the inflammatory response.

Upon completion of this presentation, attendees will have an appreciation for the clinical symptomatology associated with duodenal transection following blunt abdominal trauma and the importance of histologic evaluation of this type of injury to foster the sequencing of events. Subtle symptoms can dissimilate potentially emergent, life-threatening pathology. This particular case discussion exemplifies prolonged (approximately 24 hrs) survival in a child that sustained a duodenal transection injury after falling from a bicycle. A literature review of comparable cases will also be performed. Case correlation may aid in establishing a time range of survival, which would portend significant clinical value. Clinicians who are knowledgeable about the potential injuries caused by abdominal trauma are more likely to suspect injury despite the absence of suggestive symptoms. Such analysis will likely demonstrate that an official clinical diagnosis of intestinal laceration occurs when an individual's symptoms are more severe (postulating that there is a period of survival status-post injury).

A 9-year-old Hispanic female sustained head and abdominal injuries after falling from her bicycle on 6/27/08 at approximately 1-2

p.m. She was examined and released from a local hospital without having undergone imaging studies. According to the report, later that evening, the child began vomiting and subsequently went to sleep. The next morning, she continued to feel nauseous and vomited in the morning. She went to bed around noon and was found unresponsive at 12:50 pm on 6/28/08. The child was pronounced dead at 1:47 pm on the same day. Investigation revealed no evidence of anything other than unintentional injury. Autopsy revealed a laceration of the head with an underlying depressed skull fracture and focal epidural hemorrhage; focal minor contusions and abrasions of the torso; hemoperitoneum; duodenal transection distal to the pylorus; contusion of the liver; intra-abdominal soft tissue hemorrhage of the ligamentum teres, greater and lesser omentum, and mesentery; petechial hemorrhages of the lower lobe of the right lung; peri-pancreatic soft tissue hemorrhage with bile staining; and minor abrasions and contusions of the extremities. Histologic examination revealed an abundance of neutrophils, fibrinous debris, scattered monocytes, and an absence of hemosiderin laden macrophages, which confirmed the timeline of investigation. The cause of death in this 9-year-old female was head and abdominal injuries sustained after falling from a bicycle.

A common cause of accidental abdominal trauma in grade-school children is due to impact with bicycle handlebars. This injury can mimic homicidal blunt force injury. The importance of histologic examination of injuries in different tissues with a known timeline of events aids in predicting an unknown timeline in homicidal blunt force injury cases. Such trauma commonly causes lacerations of the duodenum, and in many instances, severe internal organ damage is accompanied by a dramatic paucity of significant external injury. Abdominal organ injury has a poor prognosis due to delay in therapy. An appreciation for the potential severity of blunt abdominal trauma, which can provoke more efficient diagnosis of the injury and hastened therapy, may save a precious life.

Duodenum, Trauma, Survival

G43 Role of Scene Reconstruction in the Medicolegal Investigation of Sudden Unexpected Infant Deaths

Richard C. Harruff, PhD, and Pamela S. Ulmer, DO, King County Medical Examiner's Office, 325 9th Avenue, HMC Box 359792, Seattle, WA 98104-2499*

After attending this presentation, attendees will recognize the value of scene reconstruction as a routine component of infant death scene investigation.

This presentation will impact the forensic community by showing how medicolegal death investigators can enhance the quality of their scene investigations and provide valuable information that may be used to prevent or reduce future infant deaths.

Complete investigation of sudden unexpected infant deaths requires scene investigation, full autopsy, and review of the case history. Careful scene investigation is crucial, not only for understanding why one particular infant died, but also for developing valid strategies to prevent future infant deaths. This presentation examines the techniques and value of doing scene reconstruction as part of a rigorous investigation of a sudden unexpected infant death.

The King County Medical Examiner's Office (KCMEO) investigates all sudden unexpected infant deaths using: (1) a standardized scene investigation protocol, (2) a complete autopsy including microscopic examinations, toxicology, metabolic screening, and microbiological cultures when indicated, and (3) review of the case history with police and child protective agencies. For this study, the computerized KCMEO database from 1995 to 2008 was searched for all deaths of children between the ages of one week and three years. These

were then analyzed to group the deaths by manner of death and further subclassify natural death. In addition, the photographic records of KCMEO were individually reviewed to find cases in which scene investigation included scene reconstruction. The cases in which scene reconstruction yielded information important for certifying cause and manner of death were then selected as examples to demonstrate the techniques of this investigative tool and its value for the overall death investigation.

Between 1995 and 2008, 505 deaths of infants and young children from one week to 3 years of age were recorded in the KCMEO database. Of these 505 deaths, 326 of these were classified natural, 107 accident, 2 complication of therapy, 47 homicide, and 23 undetermined. There were 232 deaths that were certified as SIDS. During this time period, 151 deaths were investigated using a doll or similar prop to reconstruct the scene in which the caregiver found the child dead. The scene reconstruction included instances of natural deaths, accidents, and deaths certified as undetermined.

Scene reconstruction is an essential part of the investigation into the death of an infant or young child. Invariably the death scene is disturbed and therefore requires a patient, well-trained, experienced, and compassionate investigator to uncover the details surrounding the death. Using a fabricated, stuffed doll or similar prop, and working patiently with the caregiver is the best means for establishing the location and position in which the child was last seen, the usual position for sleeping, and the position when found unresponsive. Furthermore, this method supports a photographic record that is fairly acceptable to the caregiver(s) and that can later be used to demonstrate the death scene in an emotionally neutral manner. Risk factors and hazards, including bed sharing, present in the child's environment can be readily documented and demonstrated with respect to the specific hazard and the way in which the hazard is responsible for the death. Witness reliability can also be assessed with this technique. As important as scene reconstruction proves to be, there are several obstacles in utilizing this method. Emergency medical personnel frequently disrupt the integrity of the scene by transporting babies that they know are dead to the hospital emergency department; this practice must be strongly discouraged. The death investigator, agency, or otherwise well-meaning individuals may feel that scene reconstruction is too invasive into the caregiver(s) grief and privacy. Training, experience, and compassion are needed to overcome this obstacle. There is the valid concern that a caregiver or witness may not be reliable in reconstructing the scene for the investigator(s). Again, experience has shown that patience and compassion are the most valuable qualities for gaining witness trust and revealing the truth. In conclusion, scene reconstruction provides invaluable information, and therefore, should be considered one of the standards for a quality infant death investigation.

Medicolegal Investigation, Sudden Infant Death Syndrome, Scene Reconstruction

G44 Death by INR: A Case of Vitamin K Deficiency Bleeding Masquerading as Shaken Baby Syndrome

O.C. Smith, MD*, Conscience and Science in Medicine, LLC 9639 Rosemark Road, Atoka, TN 38004; and Jennifer Griffith, MS, Lani Collins, MS, and Linda Williford, PhD, The University of Tennessee Clinical Laboratory Sciences, 930 Madison Avenue, Memphis, TN 38163

After attending this presentation, attendees will understand the need for a deconstruction oriented approach when evaluating Shaken Baby Syndrome cases; realize that differential diagnoses exist for most any medical finding and that superficial observations and failure to develop

the differential can lead to diagnostic errors and wrongful process.

This presentation will impact the forensic community by giving a better understanding of the value of integrated investigations and their ability to serve justice.

A 7-month-old child died at a pediatric hospital of "non-accidental trauma." The chart was given to the pathologist, and conversation from the treating physician indicated intracranial and retinal hemorrhaging. The pathologist recorded a cryptic entry: "INR=1.1." An extensive medical chart dating back to the decedent's third day of life was not disclosed.

The decedent was the twin B of twins born at 35 1/2 weeks, discordant from his twin sister by a birth weight 20% less. Severe reflux disease was present since birth. He required a fundoplication and a feeding tube through the abdomen. At birth he was in the 25th percentile, until his sixth month when it was in the 15th and terminally, had fallen to the 5th. Despite adequate nutritional intake, he no longer absorbed the nutrients and was diagnosed with failure to thrive. Shortly before death, he had the gastrostomy site cauterized for continual bleeding.

The medical examiner ruled Shaken Baby Syndrome. The father was arrested subsequent to his statement that after seeing his son on the floor with his aggressive 13-month-old daughter kneeling on the infant's stomach and her hands at his neck; he separated them and found the infant struggling to breathe. To revive the child, he "shook" it. He was charged with first degree murder. The defense desired a medical review.

Deconstruction revealed two different autopsy protocols, the absence of an adequate neck dissection, the missed presence of prior retinal hemorrhages, and the failure to observe a tongue tumor. The presence of the gastrostomy and fundoplication went unexplained, as did contusions the hospital reported, on the back. Significant hospital laboratory values included coagulation studies with a prolonged prothrombin time (PT) and a normal activated partial thromboplastin time (aPTT). The International Normalized Ratio (INR) was 1.1, within normal range. The timeline revealed an initial retinal examination with hemorrhage in the left eye, hours later both retinas were hemorrhagic. Iron stains of the eyes by the defense were positive, indicating remote hemorrhage. Records of the organ procurement organization indicated the use of vasopressors and anticoagulants, increasing the hemorrhages.

The differential diagnosis when the PT is long and the aPTT is normal is divided between liver disease or a deficiency of vitamin K an essential vitamin that enables the liver to produce coagulation factors. Vitamin K Deficiency Bleeding (VKDB) is a third world disease. The clinician relied upon the INR that no coagulopathy was present because the INR was normal. This is an inappropriate practice as the INR is intended *only* for those patients on coumadin therapy for periods greater than two weeks.

Studies from the University of Tennessee confirm clinicians rely upon the INR as an indicator of normal coagulation status. This practice obscures the initial stages of coagulopathies. Ironically, other studies ordered were not followed up, or were cancelled after death, thus preventing a definitive answer. The pediatricians remained adamant the child was murdered. The defense presented this finding to the prosecution, and settled via diversion.

Shaken Baby Syndrome, Deconstruction, Coagulopathy

G45 Malicious Use of Nonprescription Cough and Cold Medications in Children

Jody L. Green, PhD*, Denver Health Rocky Mountain Poison & Drug Center, 777 Bannock Street, MC 0180, Denver, CO 80204; William Banner, PhD, Oklahoma Poison Control Center, 4822 East 112th Street, Tulsa, OK 74137; Randall Bond, MD, Cincinnati Drug & Poison Information Center, 660 Lincoln Avenue, Cincinnati, OH 45206; Ralph Kauffman, MD, University of Missouri-Kansas City, Department of Pediatrics, 2919 NW 86th Terrace, Kansas City, MO 64154; Anthony Manoguerra, PharmD, University of California at San Diego, School of Pharmacy, 9500 Gilman Drive, MC 0657, La Jolla, CA 92093; Robert B. Palmer, PhD, Toxicology Associates, 2555 South Downing Street, Suite 260, Denver, CO 80210; Ian M. Paul, MD, Penn State College of Medicine, 500 University Drive, HMC; Pediatrics; H085, Hershey, PA 17033; Barry Rumack, MD, University of Colorado, Anshutz Medical Campus, Denver, CO 80045; David C. Winston, PhD, Forensic Science Center, 2825 East District Street, Tucson, AZ 85714; and Richard C. Dart, PhD, Denver Health Rocky Mountain Poison & Drug Center, 777 Bannock Street, MC 0180, Denver, CO 80204

After attending this presentation, attendees will understand the process and outcomes of a systematic evaluation of pediatric deaths associated with nonprescription cough and cold drugs and will gain an awareness of the rare but apparent malicious use of these medications in children.

This presentation will impact the forensic community by increasing awareness of the malicious use of these drugs and encourage more detailed investigations into all pediatric deaths.

The safety of nonprescription cough and cold medication use in children less than 12 years of age has been questioned. To better understand the safety profile of these drugs, an independent expert panel reviewed available death reports of children less than 12 years of age with mention of a cough/cold ingredient that were obtained from three sources: English language medical literature (1949-2007), National Poison Data System (1983-2007) and Manufacturer Safety Records (1980-2007). The panel assessed the causal relationship between each reported drug and death using predetermined definitions for "Definitely Related", "Likely Related", "Possibly Related", "Unlikely Related", "Definitely Not Related", and "Unable to Determine". These definitions were based upon clinical course, drug exposure history, body fluid/tissue analytical evidence, and alternative cause of death. The panel also attempted to categorize the dose ingested (therapeutic/supratherapeutic), intent of administration (therapeutic/non-therapeutic) and potential contributing factors for all deaths determined to be at least possibly related to a cough and cold drug.

Of 227 fatality reports reviewed, 92 (41%) deaths were judged at least possibly related to one or more nonprescription cough and cold drugs. The panel determined that 79 of these involved a supratherapeutic dose of the suspect drug. The dose could not be assessed in the remaining 13 cases. There were no cases for which the panel suspected a therapeutic dose was involved. Of the 92 related deaths, 68 involved an overdose of the suspect drug administered by a caregiver. Ten such cases involved the administration of the drug in a daycare setting. Twenty-four reports (18 - age <2 years, 5 - age 2 to <6 years, 1 - age 6 to <12 years) indicated that the drug was given to the child without an appropriate therapeutic indication (i.e., not for cough or cold symptoms). The panel determined that malicious intent was a contributing factor in 20 cases. These were cases in which the drugs were used to either sedate or intentionally harm the child. Other signs of child abuse including hematomas and healed fractures were evident in some cases.

The incidence of non-accidental child injuries, specifically death, resulting from the misuse of nonprescription cough and cold medications or other drugs is unknown, in part because there is no standard laboratory testing during pediatric fatality investigations. Postmortem drug

concentration levels are rarely reported because appropriate specimens are not routinely collected during autopsy. These body fluid/tissue drug levels are often difficult to obtain due to limited specimen and analytical challenges. They are also difficult to interpret due to postmortem effects including redistribution as well as limited peer-reviewed reference ranges for the pediatric population. Interpretation of drug levels should be done with pharmacokinetic parameters and must not rely on published ranges which do not take into account the elapsed time since administration of the drug. Those performing investigations of pediatric deaths, especially in children less than 2 years of age, should consider overdose of cough and cold medications and other drugs, including instances of malicious use of these drugs by parents or caregivers.

Pediatric Deaths, Nonprescription Medications, Drug Toxicity

G46 Wrongful Convictions and Pediatric Forensic Pathology: The Canadian Experience

Jeffrey R. Manishen, BA*, Ross & McBride LLP, 1 King Street West, 10th Floor, PO Box 907, Hamilton, L8N 3P6, CANADA

After attending this presentation, attendees will understand of how inadequate training and supervision, difficulties in the communication of opinion evidence, and problematic areas in pediatric forensic pathology may result in wrongful convictions. Those in attendance will enhance their understanding of the ways to improve the interaction between forensic scientists and the criminal justice system.

This presentation will impact the forensic community by exploring the recommendations of the Inquiry into Pediatric Forensic Pathology conducted by appellate court Justice Stephen Goudge in Toronto, Ontario, Canada, which are likely to have a significant impact on the prevention of miscarriages of justice on an international level.

As a result of the identification of serious errors in the postmortem reports and testimony of Dr. Charles Smith, a pathologist called by the prosecution in several child homicide cases in Ontario, Canada, the provincial government convened a public inquiry to address systemic issues in order to prevent the recurrence of such tragedies. Between November 2007 and February 2008, the Commissioner heard from government officials, prosecution and defense counsel, police officers, judges, and law professors as well as the internationally recognized forensic pathologists who were involved in the review of the specific cases. Research papers on a variety of topics were received and policy roundtable discussions conducted. Dr. Smith himself also gave evidence regarding his efforts and explanations.

The investigation of suspicious deaths in children presents many complex challenges for all concerned, including the need for proper training and certification of the forensic pathologist, evolving and sometimes controversial issues in pediatric forensic pathology, the difficulty in choosing appropriate language to characterize the level of certainty of an opinion regarding cause of death and the dangers of "tunnel vision."

Evidence at the inquiry identified a variety of approaches to address these problems. The implementation of a comprehensive postmortem report format detailing all opinions and the basis for same ensures a standardized methodology for the timely communication of autopsy findings. A vigorous peer review process prior to the release of such reports contributes significantly in validating the conclusions. The principles of evidence-based medicine provide an important standard to implement and ensure the requisite degree of reliability for a court considering opinion evidence on issues involving pediatric forensic pathology. Appropriate measures of accountability are necessary to identify and deal with those circumstances in which the pathologist's practices may be deficient. Continuing education for counsel and

experts will assist in avoiding misunderstanding of their respective roles and participation in the trial process.

While the inquiry received considerable publicity in Canada, the lessons which may be learned from these unfortunate events should be shared with the international forensic community in order to achieve the objectives of fairness and justice for those charged with criminal offences.

Forensic, Pediatric, Pathology

G47 The Possibilities and Limitations of Neuropathology in Exhumation Autopsies

Jan E. Leestma, MD, 1440 North Kingbury Street, Suite 210, Chicago, IL 60622*

After attending this presentation, attendees will understand important opportunities in difficult situations which commonly surround exhumation autopsies.

It is often assumed that exhumation autopsies will yield only marginal information, least of all to permit in-depth neuropathological examinations. This presentation will impact the forensic science community by demonstrating how five cases prove otherwise. This information should be valuable to pathologists and the general forensic community,

Five cases are presented that offer a range of forensic/medical issues in the context of exhumation autopsies. Four cases involved civil or criminal litigations and one case was done for personal reasons of a family of a suicide victim.

The durations of burial ranged from two to more than 18 years. All individuals had been interred in either wooden or metal caskets, usually within concrete burial vaults. All had been arterially embalmed. At issue were the nature of the injuries or processes leading to death that usually involved head trauma, but in one case involved possible Marchiafava-Bignami syndrome.

Three of the cases had not been autopsied before, but two had. In general, preservation of the head, brain, and other organs was good to excellent and permitted satisfactory case analysis both grossly and microscopically.

The opportunities and limitations of exhumation autopsy neuropathology will be presented.

Exhumation, Neuropathology, Autopsy

G48 Pathology/Odontology: The Team Approach to a Forensic Autopsy

John E. Filippi, DDS, 1325 North 127th Avenue, Omaha, NE 68154; and Mary H. Dudley, MD*, Jackson County Medical Examiner's Office, 660 East 24th Street, Kansas City, MO 64108*

After attending this presentation the attendees will understand the "dual role" the pathologist and odontologist have in determining the cause of death and the development of a positive identification.

The presentation will impact the forensic community by increasing the awareness of the medical legal system and law enforcement agencies regarding how the coordination of these two forensic sciences can support the investigation.

A forensic pathologist performs autopsies to determine the cause and manner of death in situations falling under the jurisdiction of the Medical Examiner/Coroner Office. After the forensic autopsy is completed, the forensic odontologist examines the dental structures, and through a comparison analysis between the antemortem dental and the postmortem dental records, can render a "rapid onset" positive identification. When working together, both forensic professionals, can

provide concordance, to the issuing of a prompt death certificate for the next of kin, and can also be called upon to be an expert witness in a court of law.

This presentation will increase the awareness of the forensic community and law enforcement agencies, in the attempt to show, how both fields can work together in the forensic autopsy. The focus of this case presentation will highlight the forensic investigation of a high profile dual homicide case illustrating the forensic team approach. The difficulty of the case stems from the young age of the two related victims, the cause and manner of death, the history behind that investigation, and the final court decision. The presentation will include how forensic anthropologists recovered the buried remains, how forensic pathologists determined the cause and manner of death, and how forensic odontologists determined the chronological dental age and the final rendering of a positive identification.

Skeletal remains were discovered in a shallow grave in a wooded area in Missouri. Forensic Investigators first surveyed and photographed the scene. A forensic anthropologist was then called to assist with the excavation. Two juvenile skeletal remains along with clothing fragments and projectiles were placed into evidence. The forensic pathologist determined that both children were shot in the back of the head, from an indeterminate range, which was the cause of death. The skeletal remains were further examined by the forensic anthropologist, who determined estimates of height, weight, and race. After procuring antemortem dental records, a positive identification was made by the forensic odontologist. In addition, bone samples were collected and stored for DNA analysis.

Discussion of the dental (oral) autopsy will reveal how the actual dental x-ray comparisons were made for a positive identification. Specific reference will be made to the use of special dental technology, such as digital dental radiographs and the WINID dental charting software program. These same dental protocols can also be developed in the SOP's and applied by a medical examiner/coroner's office, for future multiple deaths or a mass fatality incident.

Although this was a high profile homicide case, the routine utilization of a forensic odontologist can provide additional evidentiary value to many cases involving skeletal, decomposed, or fragmented remains. Forensic dentistry can provide support evidence for positive identification, when other modalities, such as fingerprints or time sensitive DNA analysis are not utilized.

In conclusion, the ability to blend the two forensic sciences, pathology and odontology, during a forensic autopsy, can be invaluable to a medical examiner/coroner office in the investigation process, criminal trial and for final closure for the victim's families.

Pathology, Odontology, Positive Identification

G49 Making the Best of Death

Chantal Ferraro, PhD, Long Island University, Sociology/Anthropology, CW Post, Brookville, NY 11548; and O. C. Smith, MD, Conscience and Science in Medicine, Atoka, TN 38004*

The goals of this presentation are to: (1) evaluate the existing notion of social autopsy, (2) modify and expand it both conceptually and methodologically, and (3) integrate findings of physical and social autopsies in order to establish a bridge between the forensics of the dead and the forensics of the living.

This presentation will impact the forensic community by providing a model that is applicable to any population in any community, the understanding of which will make the study of the dead a powerful tool of death prevention for the living.

The term autopsy most commonly refers to the postmortem examination of a deceased for medical or forensic reasons. In that context, autopsy is synonymous with necropsy. Etymologically, however, autopsy translates into "to see for oneself." Recently, the addition of modifiers, such as social or psychological, to the term reflects

the attempt to define new fields of inquiry based on the broader latter meaning. A psychological autopsy examines the mental state of a deceased at time of death, and may contribute to the determination of the manner of death, especially in cases of suicide. The concept of social autopsy is more confusing since its two applications belong to entirely different spheres. According to Rick Lavoie (2005) a social autopsy is a pedagogical strategy to help a learning disabled child to see for himself the cause/effect relationship between his social behavior and the reactions of others. But for sociologist Eric Klinenberg, who studied the 1995 lethal heat wave in Chicago, a social autopsy is a way to identify the social risks of a dependent population factors that led the isolated, the old and the poor to die by the hundreds. Although valid and useful in their own right, these definitions are not adequate for us.

The model of social autopsy being discussed originates in the longitudinal study of child death which was presented at the 2002 AAFS meeting. The original study was based on the autopsy reports of the Shelby County (TN) Medical Examiner's office where over 1,500 cases of child death were investigated, inclusive of all manners, over a period of ten years. The "Swiss Cheese" concept elicited by the Human Factors Analysis and Classification System (HFACS) was incorporated where defects in the layers of latent and active responsibilities, permit lethal latent and active failures within individuals, society and cultures to be identified. This presentation will focus on homicidal deaths from 0 to 4 years of age and accidental deaths from 0 to 18. Subsequent sociological and anthropological research of the community in which these deaths occurred allowed us to "see for oneself" the levels of failure and the failures within levels. From this evolves an understanding of what produces not just the death of each individual but identifies patterns that anticipate future trauma or death, with its human and societal costs. These patterns represent a framework of behaviors that must be altered or remedied by the community. It is the contention of the investigators that a social autopsy is defined by its ability to reveal such patterns and to highlight the line of failure. The necropsy exists to identify this "tip of this iceberg" the social autopsy defines its magnitude.

Social Autopsy, Necropsy, Prevention

G50 Building the Communication/Language for Collaboration Between the Forensic Pathologist and Funeral Director/Embalmer

Vincent E. Hill, MD*, Mortuary Medical Services, 3003 Van Ness Street, North West, Suite 106, Washington, DC 20008

After attending this presentation, attendees will be familiar with the language and techniques used in the funeral industry.

This presentation will impact the forensic community by arming the forensic pathologist with the words to scientifically describe a body that has been embalmed.

This presentation will expose the forensic pathologist to the language and embalming procedures used in preserving the dead body. The presentation will be useful to forensic pathologists who are members of FEMA's Disaster Mortuary Operational Response Team (DMORT) or work in jurisdictions where cemeteries are subject to flood waters.

Forensic pathologists are known for their skill in turning the visual into words. They are able to explain orally and in writing the most complex surgical procedures despite the fact that they are not trauma surgeons, orthopedic surgeons, neurosurgeons or gynecologists. But, when it comes to the postmortem surgical procedure known as embalming, the forensic pathologist lacks knowledge of the words and technical procedures used by the funeral director/embalmer. Michael M. Baden, MD mentions, in Chapter III, Part 4, "Exhumation" (Medicolegal Investigation of Death, 4th edition), "The entire exhumation and autopsy

process should be well documented by words and photographs ...". As stated above, forensic pathologists know the words of their fellow surgeons but are not trained in the words of the funeral director/embalmer despite the fact that autopsies are performed on embalmed bodies prior to interment and after disinterment. Since the conception of DMORT in the early 1980's, national forensic teams have been deployed to 24 mass disaster events. Three of these events exclusively involved cemetery floods, one involved a crematory, and three involved floods that secondarily caused local flooding of cemeteries. With disinterred remains the primary focus of the forensic team is not in determining the cause of death but in finding positive identification. With disinterred embalmed bodies, the presence of embalming artifacts may be one of the main physical findings the DMORT forensic pathologist will have for positive identification. If the forensic pathologist is unable to adequately describe the postmortem embalming changes that occur during arterial and cavity embalming he or she could exclude or misinterpret a useful identifier. If the forensic pathologist knows that the body was embalmed using a single-point injection through the right common carotid artery with right jugular vein drainage or was embalmed by use of the restricted cervical method, this level of knowledge would help expedite the identification process when the local funeral director/embalmer compares their embalming reports with the autopsy report. Since 29% of DMORT's mass fatality events involve disinterred remains, the affected community would be better served by having forensic pathologists who are able to speak and write the language of the local funeral director/embalmer.

Forensic, Pathologist, Embalming

G51 Sickle Cell Trait Associated Deaths: A Case Series With a Spectrum of Clinical Presentations

Christopher Wilson, MBBS, Jon R. Thogmartin, MD*, Noel A. Palma, MD, and Susan S. Ignacio, MD, Medical Examiner's Office, District 6, 10900 Uilmerton Road, Largo, FL 33778; Barbara C. Wolf, MD, and Wendy A. Lavezzi, MD, Office of the Medical Examiner, District 5, 809 Pine Street, Leesburg, FL 34748; and Mark J. Shuman, MD, Miami Dade County, Medical Examiner Department, Number One on Bob Hope Road, Miami, FL 33136

After attending this presentation, attendees will be educated with respect to the wide variety of clinical presentations persons with sickle cell trait manifest including clinical symptoms, laboratory abnormalities, and gross anatomic and microscopic findings. This study also seeks to show how simply the diagnosis can be made by the astute clinician or forensic pathologist if only he or she will consider it in the differential diagnosis.

This presentation will impact the forensic community by showing that sickle cell trait is a condition which is not restricted to conventional ethnic boundaries of Afro-Americans and that the diagnosis needs to be seriously considered in individuals living in geographic locations in which the natural environment plays a prominent role in the manifestation of the disease. Early recognition of the disease in such individuals can possibly result in a decline in mortality.

At the conclusion of this presentation, attendees will be educated with respect to the wide variety of clinical presentations persons with sickle cell trait manifest including clinical symptoms, laboratory abnormalities, gross anatomic and microscopic findings. This study also seeks to show how simply the diagnosis can be made by the astute clinician or forensic pathologist if only he or she will consider it.

This presentation will hopefully have a significant impact on not only the forensic community but also on humanity by showing that sickle cell trait is a condition which is not restricted to conventional ethnic boundaries of Afro-Americans and that the diagnosis needs to be

seriously considered in individuals living in geographic locations in which the natural environment plays a prominent role in the manifestation of the disease. Early recognition of the disease in such individuals can possibly result in a decline in mortality.

As many as one in three Africans living in areas where malaria is indigenous and approximately one in twelve Americans with African ancestry have sickle cell trait. The affected individuals are generally asymptomatic and many are not even aware that they carry the gene. The general consensus of the public is that sickle cell trait is a relatively benign condition and affected persons are at no increased risk of morbidity or mortality because of their condition. However, the forensic community is cognizant that under the proper set of circumstances, sickle cell trait can be potentially fatal.

This study presents a series of 11 individuals with sickle cell trait and one with hemoglobin SC disease who died during various circumstances. All of the victims were subject to the warm and humid climate of Florida. The onset and/or duration of symptoms varied from a few to several hours with many displaying a prolonged lucid interval with stable vital signs. Despite seeking medical treatment, sickle cell trait related micro-occlusive crisis was never considered in the differential diagnosis. Several cases were associated with sudden death. In those deaths which were delayed, high anion gap and uncompensated metabolic acidosis were typical. Also characteristic were large increases in creatine phosphokinase, alanine aminotransferase and aspartate aminotransferase along with myoglobinemia. Although the antemortem diagnosis of rhabdomyolysis was made, the underlying cause was never deduced by the clinicians. Of particular interest was a case of a fatal splenic crisis due to sickle cell trait in a Caucasian and a victim with hemoglobin SC who died from a combination of mild traumatic injuries and prolonged bodily inversion. In some cases, sickle cell trait was not even considered in the original death certification.

In conclusion, this study demonstrates the varying characteristics and presentations of 11 cases of sickle cell trait and one case of hemoglobin SC related deaths and shows that such deaths can be sudden or delayed. Conventional racial delineation of the sickle cell hemoglobinopathies should not deter one from considering it in the differential diagnosis especially if the patient is subjected to environmental and physical stressors which can potentiate the disease. Furthermore, failure to consider sickle cell trait related crises as a diagnosis can result in improper death certification. Greater efforts to educate the public especially athletes and coaches on the possible hazards of exercise induced sickle cell trait related micro-occlusive crisis hopefully will result in less morbidity and mortality.

Sickle Cell Trait, Exertion, Metabolic Acidosis

G52 Commotio Cordis: A Forensic Science Perspective

Ariel Goldschmidt, MD*, Steven T. Hensley, and Mary H. Dudley, MD, Jackson County Medical Examiner's Office, 660 East 24th Street, Kansas City, MO 64108

After attending this presentation, attendees will have an enhanced understanding of the prevalence, pathophysiology, and important forensic science issues related to commotio cordis and the ability to apply this knowledge to their practice should it become necessary.

This presentation will impact the forensic community by providing a broad and thorough review of the current literature and scientific knowledge about commotio cordis, with particular emphasis on key issues relevant to forensic scientists. Included in the discussion will be several published case examples of commotio cordis, as well as several case examples of commotio cordis investigated in the State of Missouri.

The presentation will begin with detailed criteria for what type of

deaths do and do not constitute commotio cordis. Mention will be made of the prevalence of commotio cordis and common involved activities, with specific published case examples involving sports activity and a low speed vehicle collision. Case reports resulting from a retrospective search of cases in Missouri will be presented.

Attention will next be focused on animal models used for the study of the pathophysiology of commotio cordis. The theory of "mechano-electric coupling" of myocyte stretching and the opening of potassium/ATP channels will be discussed. Lessons learned from various experiments using animal models will be presented, including the importance of hardness of sports objects and effectiveness of chest protectors.

The presentation will include several issues of particular interest to medicolegal investigators and forensic pathologists. Typical as well as atypical case histories of commotio cordis will be presented, stressing the importance of proper scene investigation and obtaining medical history. There will be a review of possible autopsy findings seen in cases of commotio cordis. Finally, controversies regarding manner of death in atypical cases of commotio cordis will be discussed.

Commotio Cordis, Precordium, Manner of Death

G53 Corpora Amylacea and Sudden Death: A Case of Adult Polyglucosan Body Disease Diagnosed at Forensic Autopsy

Timothy L. Williams, MD*, and R. Ross Reichard, MD, New Mexico Office of the Medical Investigator, MSC11 6030, 1 University of New Mexico, Albuquerque, NM 87131-0001

After attending this presentation, attendees will learn about a case of adult polyglucosan body disease diagnosed at forensic autopsy.

This presentation will impact the forensic community by educating them about the first reported case of adult polyglucosan body disease presenting as sudden death and diagnosed at forensic autopsy.

Adult polyglucosan body disease (APBD) is a rare neurodegenerative condition characterized by typical onset in middle age, progressive neurological impairment that is heterogeneous between those affected, and death within 1-14 years of diagnosis. The histopathological hallmark of the disease is massive deposition of corpora amylacea (designated polyglucosan bodies in this context) in the central nervous system, and variable deposition of similar material in other sites. While the cause of the disease is as yet unknown, recent research has identified mutations in proteins involved in glycogen metabolism in a subset of cases. Some of these mutations are similar to mutations identified in cases of glycogen storage disease type IV (GSD IV), a disease that classically is present in the first year of life, is of very heterogeneous manifestation, and is also characterized by massive deposition of corpora amylacea. The genetic and histopathological similarities between these two conditions have lead to speculations that APBD may represent an adult form of GSD IV.

In this presentation, a case of sudden death is presented wherein APBD was diagnosed at forensic autopsy. Scene details, relevant medical and social history, and autopsy and histopathological findings are presented and richly illustrated with supporting images.

The case provides an excellent example of a prolonged and enigmatic presentation involving a complex interplay of medical, social, and forensic issues. The histopathology is particularly illustrative of this rare disease, showing massive deposition of corpora amylacea in the central nervous system, and marked accumulation of similar material in the heart. The latter was determined to be the mechanism of death (cardiac arrhythmia) with APBD the underlying cause.

This presentation represents the first case of APBD reported in a forensic context. APBD is reviewed and its relationship with other

diseases characterized by massive deposition of corpora amylacea is outlined. The role of forensic autopsies in the diagnosis of rare conditions is discussed.

Neuropathology, Corpora Amylacea, Sudden Death

G54 Trends in Forensic Investigations Into the Missing: Observations From the ICRC

Morris Tidball-Binz, MD, Ute Hofmeister, MA, and Shuala M. Drawdy, MA, International Committee of the Red Cross, 19 Avenue de la Paix, Geneva, 1202, SWITZERLAND*

After attending this presentation, attendees will gain awareness of trends identified in the application of forensic medical sciences to investigations into the whereabouts and fate of persons missing as a result of armed conflict, internal violence, or catastrophes, as observed by the forensic unit of the International Committee of the Red Cross (ICRC). Attendees will also learn about the steps taken by the ICRC to meet challenges posed by these trends.

This presentation will impact the forensic community by outlining emerging challenges posed to the wider forensic community by investigations into persons gone missing as a result of armed conflict, internal violence or catastrophes, as observed by the ICRC. The trends and challenges identified in this paper will assist in the design of strategies for effective and efficient contribution to this emerging field by forensic practitioners, institutions, and service providers.

In February 2003, the ICRC organized an International Conference on The Missing in Geneva, Switzerland. Recommendations were adopted to prevent and resolve the tragedy of persons unaccounted for as a result of armed conflict and internal violence. These included recommendations on forensic best practices for the recovery, management and identification of the dead in challenging contexts, including: roles, duties, responsibilities and applicable ethical standards for forensic practitioners and teams; guidelines for the recovery and storage of human remains; criteria for forensic human identification; principles for ethical, effective and efficient information management; and advice on the relationship between forensic practitioners and bereaved families and communities.

Following the International Conference, the ICRC established a forensic unit to help implement the recommendations worldwide. Since its inception, the forensic unit has witnessed a sustained increase in the application of forensic medical sciences to the search for The Missing and has observed the following trends:

- Growing awareness and understanding of the tragedy of The Missing in armed conflicts and catastrophes;
- Growing recognition of the importance of proper management and identification of the dead in armed conflicts and catastrophes;
- Growing needs for experienced forensic practitioners for investigations into The Missing;
- Incorporation of recommendations from the 2003 International Conference on The Missing into international standards and national legal and institutional frameworks related to The Missing;
- Awareness of the need for sustainable local forensic capacity to investigate The Missing;
- A role-shift from medicolegal practitioners (i.e. coroner, medical examiner, forensic doctor) towards multidisciplinary forensic teams in the recovery and identification of The Missing;
- Growing reliance on forensic DNA analysis;
- Demands for professional standards of best practice and quality assurance and control from practitioners and institutions involved in investigations into The Missing;

- Increased incorporation of investigative practices regarding The Missing into scientific literature, research and training; and
- Growing expectations from bereaved families and the general public for swift and positive results from forensic investigations into The Missing.

These trends pose challenges and inherent opportunities for the forensic community, including:

- Helping to meet growing needs worldwide for forensic practitioners, institutions, and service providers for investigations into The Missing. These should conform to standards of professional best practice, quality assurance and control required for these investigations. Local capacity building and ownership should be prioritized;
- Empowering communication, coordination and cooperation, at regional and worldwide levels, between forensic practitioners, institutions and service providers involved in and available for investigations into The Missing;
- Supporting swift access to indispensable forensic know-how, technology and tools by practitioners and institutions operating in under-resourced contexts; and
- Sustained efforts in public awareness raising about the role, scope, value and limitations of forensic sciences applied to investigations into The Missing.

The clarification of the whereabouts and fate of The Missing in armed conflicts and catastrophes is a humanitarian priority that requires a global and concerted effort, including from the forensic community. Based on trends observed and lessons learned, the ICRC offers recommendations for addressing the challenges identified in this paper and also for building on the opportunities which these challenges offer to the forensic community.

Missing Persons, Humanitarian Identifications, International Committee of the Red Cross

G55 Evidence-Based, Medical-Legal Documentation of the Postmortem Anogenital Examination

Sharon R. Crowley, MN, FCNS, 122 Emeline Avenue, Santa Cruz, CA 95060*

After attending this presentation, attendees will understand how to incorporate an evidence-based methodology for the documentation of the postmortem genital examination. Attendees will also be able to facilitate incorporation of a previously proposed taxonomy, germane to the postmortem anogenital examination, in order to improve medical-legal documentation and able to incorporate a theoretical framework for sexual murders, as a basis for the methodological examination of the suspected sexual homicide victim.

This presentation will impact the forensic community by augmenting and enhancing the forensic examiner's diagnostic acumen in this arena. Helping to avoid ambiguity among examiners in the interpretation of clinical findings and improve documentation and ultimately contribute to a better understanding of the etiology and manifestations of fatal sexual violence against women.

The interpretation of genital findings in the deceased remains a vital and timely issue. Until recently, a paucity of information existed on the nature and appearance of the anogenital tissues during the postmortem interval. Because the traditional genital examination consists of gross visualization, subtle findings were not easily detected. These findings may constitute injury due to sexual assault, concomitant changes in the anatomy due to postmortem processes of decomposition, or a combination of both. The theoretical framework for this proposed methodological documentation format is founded on:

- Sexual activity by the offender that culminates in the death of the victim.
- Current, ongoing baseline clinical studies on the nature and appearance of the anogenital anatomy during the postmortem interval.
- Previously presented methodology for postmortem genital examinations (Crowley, JFS, 2004).
- Previously described taxonomy for the description and classification of the appearance of the tissues during the postmortem anogenital examination.

Currently, a wide variation exists in methodology for examination of both antemortem and postmortem sexual assault victims. Postmortem challenges vis-à-vis protocols and procedures may pose even greater significance, because there is no surviving victim to recount details of the assault, including sexual acts, threats, and other behaviors of the offender(s).

Currently, no standardized state, regional, or national form exists for the accurate and complete documentation of the postmortem anogenital examination. The clinical evaluation of the sexual homicide victim forms the basis for all related medical-legal reports.

- The question of exam authorization may be an area of concern. However, no separate authorization should be needed, as these examinations fall under the jurisdiction of the Coroner or Medical Examiner. In addition, they are medically non-invasive procedures.
- The postmortem genital examination record is not a complete medical record, as with other forms used to document the sexual examinations of *living* sexual assault victims, e.g., California Office of Emergency Services, forms 923 and 930. Therefore, supplemental medical and/or gynecological records may be of benefit for further review.

The meaning and performance of the acts committed during a sexual murder varies with the offender. Salient features of the crime may be evident, which may give information about the offender's sexual motivation. A systematic, evidence-based approach to documentation is part of a consistent, methodological approach to the evaluation of this population.

Scrupulous documentation should provide as much data as is known about a given case. This includes the following general categories: salient case and demographic data, disposition of the body, available history, general physical assessment, clothing, toxicology, evaluation of nongenital trauma, components of the sexual assault evidence kit, the genital and anal examination, and colposcopic examination. It is important to clarify where the primary responsibility for a portion of the examination and/or the documentation was *not* assumed, e.g., in the evaluation of nongenital trauma by a forensic nurse.

Select cases of fatal sexual violence provide actual examples of traumatic injuries, consistent with blunt force trauma to the anogenital tissues. Injuries can be categorized as to type, number, and anatomic site. In addition, normative studies of baseline controls were evaluated, using the sequential methodology for the postmortem genital examination with colposcopy, *SART-TO-GO* (Crowley, JFS, 2004). A previously presented taxonomy was developed to describe the nature and appearance of the postmortem genital anatomy (Crowley & Peterson, AAFS, 2004) and to develop a standardized classification system for these previously undescribed findings. This taxonomy is incorporated in the proposed protocol for the documentation of the medical-legal examination of sexual homicide victims.

The postmortem genital anatomy worksheet consists of the same anatomic sites that are routinely examined in the living sexual assault victim. These include the peri-urethra/peri-clitoral area, labia majora, labia minora, posterior fourchette, fossa navicularis, hymen, vagina, cervix, perineum, anus, and rectum. Supplemental documentation is included for both the adult male and the pre-pubescent child.

All examination techniques and any adjuncts should be recorded, such as use of balloon-covered swabs (Crowley, 1999), labial traction, or

labial separation, in addition to routine speculum examination and anoscopy.

Appropriate and complete chain-of-custody must be documented and is included within the tool. A copy of the tool should be placed within the sexual assault evidence kit for the criminalist.

A supplemental narrated summary or dictation is recommended, to complement the standardized form. It also places events in chronological order, incorporates more uniformly understood language, and clarifies roles and responsibilities. The emphasis on teamwork and evaluation is crucial in an event that requires multi-disciplinary cooperation.

The taxonomy for postmortem genital examinations has proved to be a useful classification system during clinical examination, case documentation, and database entry. This taxonomy has been incorporated into the proposed medical-legal form, in order to differentiate postmortem artifact from concomitant findings that might be suggestive of sexual trauma, i.e., blunt force injury, including lacerations, ecchymoses, and abrasions. This capacity is pivotal. Just as in living victims, it is essential to be able to distinguish benign gynecological conditions from traumatic findings.

Data to date from the analysis of ongoing, baseline controls has yielded useful information for the development of a template for documentation. It is important to carefully describe the nature and appearance of salient anatomic sites. Analysis of research data has reinforced the need for the examiner to avoid working in a vacuum. The examiner whose sole prior experience lies in the antemortem arena may confuse normal postmortem artifact with traumatic findings. Common benign gynecological findings, such as labial adhesions and punctate lesions, are often present. Other findings, such as postmortem mucosal shedding at various sites within the anogenital tissues, have occurred with sufficient frequency during the postmortem control study to warrant recognition as normal postmortem artifact.

The ultimate goal is to better visualize and improve the understanding of what is normal in anogenital anatomy during the postmortem interval. To this end, careful scrutiny and meticulous documentation will both add to individual case yield and enhance the overall body of knowledge within this area.

Postmortem Anogenital Examination, Sexual Homicide, Colposcopy

G56 Postmortem Recognition of Sickle Cell Trait

Kathryn H. Haden-Pinneri, MD, and Sara Nunez-Doyle, MD, Harris County Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054*

After attending this presentation, attendees will gain a better understanding of the importance of recognizing the incidental autopsy findings related to sickle cell trait and the implications this diagnosis may have on surviving family members.

This presentation will impact the forensic community through knowledge gained about sickle cell trait and from insight regarding the importance of notification of surviving family members.

Sickle cell trait is defined as the heterozygous condition of having one gene for sickle cell hemoglobin and one for normal hemoglobin. Patients with sickle cell trait tend to lead normal lives, without serious complications; therefore it is not regarded as a disease state. In certain conditions; however, complications not only occur, but they may be fatal. Deaths due to exertional sickling involving young athletes have made headline news on multiple occasions. When an individual with sickle cell trait becomes hypoxic, acidotic, dehydrated, or hypothermic, the typically silent sickle cell trait transforms into a syndrome that resembles sickle cell disease with widespread sickling and subsequent vaso-occlusion.

The presence or absence of intravascular sickled red blood cells in tissue specimens depends on the degree of oxygenation of the sample

prior to fixation. Intravascular sickling may occur due to terminal hypoxemia in the setting of sickle cell trait. It is almost impossible to determine the role sickled cells may have played by the presence or absence of intravascular sickling in autopsy specimens.

The events surrounding a death due to exertional sickling will assist the pathologist in this diagnosis. Individuals with sickle cell trait who die without a history of intense exercise prior to death may pose a challenge to physicians in determining if the death is or is not related to their genetic condition. A third possibility exists in which an individual may not be known to carry the sickle cell trait until sickled cells are seen in biopsy or autopsy specimens.

Three decedents autopsied at the Harris County Medical Examiner's Office, ranging in age from 28 to 49 were found to have sickle cell trait. None of the individuals were known to have the trait and when family members were contacted, only one had any knowledge that this condition existed in their family. The sickle cell trait was found to be purely incidental in two of the three decedents and may or may not be related to the cause of death in the third individual.

Two of the decedents were black males who were found unresponsive at work, one outside and one at a desk. One was 39-years-old and the other was 49-years-old. Both had enlarged hearts with coronary artery atherosclerosis. Microscopic examination revealed sickled cells in the heart, liver, lungs, kidney, and brain of both men. Hemoglobin electrophoresis performed on postmortem blood revealed the presence of hemoglobins A, S, F, and A2 in levels suggestive of sickle cell trait with an underlying beta+ thalassemia.

The third case involved a 28-year-old morbidly obese black female (body mass index of 54.1) who became unresponsive shortly after complaining of shortness of breath and abdominal pain. Autopsy findings included bilateral pulmonary thromboemboli, deep venous thromboses, gallstones, and clear bile. Microscopic examination revealed sickled cells in the kidney liver and brain. Hemoglobin electrophoresis results are pending at this time. Family members were contacted and reported knowledge of sickle cell trait in a sibling, but not in the decedent.

All family members contacted were grateful for the information and most were planning a follow up visit with their physician to obtain testing for sickle cell trait. With the exception of possibly the pulmonary emboli, the finding of sickle cell trait was incidental to the determination of the cause and manner of death; however, the information was extremely important for the family members of the decedents. This finding underscores the responsibility of forensic pathologists to perform autopsies with the intent of complete and thorough documentation of all findings, not just determination of cause and manner of death.

Autopsy, Sickle Cell Trait, Incidental

G57 An Angel Dies on the Needle: Fatality After Injection Sclerotherapy for Prolapse Rectum in a Child

Abraham T. Philip, MD, Onondaga County Medical Examiner, 100 Elizabeth Blackwell Street, Syracuse, NY 13210; and Jeanna M. Marraffa, PharmD, Upstate New York Poison Center, 250 Harrison Street, Syracuse, NY 1302*

After attending this presentation, attendees will be made aware of the toxicity of phenol, a product with multiple clinical applications that resulted in a fatality during a non-invasive surgical procedure.

This presentation will impact the forensic community by increasing its awareness about a previously unreported complication of use of phenol as a sclerotherapeutic agent for prolapse of rectum.

The goal of this presentation is to discuss the findings in a case of toxicity due to phenol toxicity that resulted in the death of child fatality after a surgical procedure for a non-life threatening condition.

Prolapse rectum (PR) or protrusion of the rectum beyond the anus occurs frequently in populations at both extremes of age. In the pediatric population, PR is usually diagnosed before the age of three years, and in adults, the peak incidence of PR is after the fifth decade of life. The etiology of PR in developing countries is usually related to diarrheal illnesses, parasitic infestations, and malnutrition. In the developed world, a common cause is cystic fibrosis. Surgeons have shown considerable ingenuity in the search for the ideal operation for PR. Over 200 different procedures have been employed, suggesting that the ideal surgical solution has remained elusive. Treatments include conservative management, resection and fixation, levator ani repair, presacral packing, Thiersch's wire suture and injection sclerotherapy. The last is considered an attractive treatment option because it is minimally invasive.

The case presented is of a 2-year-old female child, with PR, cystic fibrosis, and Ebstein malformation of the tricuspid valve. Due to refractory PR, the decision was made to treat her with injection sclerotherapy, using phenol as the sclerotherapeutic agent. In the operating room, and shortly after the injections, the baby had a sudden cardiac arrest, and received CPR for approximately 2 hours. She developed anoxic encephalopathy, rhabdomyolysis, non-hyperthermic elevated creatine kinase (CK) levels, and disseminated intravascular coagulopathy (DIC). She died approximately 4 days after the surgery. An antemortem urine specimen submitted on the day after the surgery had a total phenol concentration of 240mg/L. Phenol concentrations, done as part of workplace testing, in unexposed and chronically individuals should be below 10 and 30 mg/L.

At autopsy, the baby's external appearance and internal organs were appropriate for age. There was a reddish discoloration around the anus, and separate reddish brown discoloration to the buttocks. Internally there were multiple punctuate hemorrhages on the mesentery and capsule of internal organs. There was intraparenchymal hemorrhage within the lungs and spleen, and red blood cell casts within the renal pelvis. The anal canal was infarcted. The evaluation of the heart (48.2 grams) confirmed the Ebstein malformation. The muscle biopsy revealed nonspecific congenital myopathic changes with decreased myophosphorylase and glycogen. The section of liver showed PAS & PASD negative vacuolization of the hepatocytes. Examination of the brain revealed cerebral edema with acute hemorrhagic infarct of the left occipital cortex, and multifocal subarachnoid, cortical, and cerebellar hemorrhages.

A variety of sclerosing agents have been used with varying success rates. Phenol preparations have been used in dermatology and plastic surgery for the treatment of acne and during chemical face peels. During cutaneous application of phenol, absorption of the chemical has occurred with deleterious systemic effects, including cardiac arrhythmias have been reported. The publications about the value of the use of Phenol as sclerosing agent for PR have been mixed. One report indicated 90 to 100% cure rates after one or two injections and no complications. Another report indicated complications, including mucosal sloughing and perianal fistulae, in 27% of cases. No cases of fatality due to phenol toxicity after injection sclerotherapy have been reported in the medical literature.

This case report describes the steps taken to establish the diagnosis of phenol toxicity, and eliminate the other causes of sudden death suggested by the initial differential diagnosis. The forensic community should be aware of the toxicity of phenol as it has multiple clinical uses, and can result in fatality.

Prolapse Rectum, Injection Sclerotherapy, Phenol Toxicity

G58 MDMA Neurotoxicity

Irene Riezzo, MD, Viale Degli Aviatori, 1, Department of Forensic Pathology, University of Foggia, Foggia, 71100, ITALY; Vittorio Fineschi, PhD, Chair Forensic Pathology, University of Foggia, Ospedale Colonnello D'Avanzo, Foggia, I-71100, ITALY; Carmela Fiore, MD, and Stefano Derrico, MD, University of Foggia, Department of Forensic Pathology, Viale Degli Aviatori 1, Foggia, 71100, ITALY, and Steven B. Karch, MD*, PO Box 5139, Berkeley, CA 94705-0139

After attending this presentation, attendees will gain knowledge on how to characterize MDMA neurotoxicity in rat brain.

This presentation will impact the forensic community by demonstrating how the results of even one single administration of MDMA can significantly alter the brains cellular antioxidant defense system and produce oxidative stress in both the striatum, and frontal cortex. Thus one possible mechanism of MDMA neurotoxicity appears to be a direct toxic effect of MDMA or its red-ox active metabolites

3, 4-Methylenedioxymethamphetamine (MDMA or "Ecstasy") is an increasingly popular psychoactive and hallucinogenic drug of abuse. It acts on the CNS by increasing the release of serotonin and other catecholamines in addition to preventing their reuptake. MDMA has been shown, in both man and animal, to damage serotonergic and dopaminergic nerve terminals and to cause neurodegeneration in multiple areas of the brain, including the cortex, hippocampus, striatum and thalamus. The closely related drug, methamphetamine (METH) and its derivates have been shown to produce long-lasting depletion in dopamine and its metabolites, as well as dopamine reuptake sites in the rat and primate striatum, but not in other dopamine rich areas such as the nucleus accumbens and the prefrontal cortex, in contrast to the neurotoxic effect of dopamine to striatal DA terminals. Two other important aspects of MDMA neurotoxicity have been identified: hyperthermia and neurodegeneration. The former appears to be a direct action of MDMA, while the later is due to the production of reactive oxygen (ROS). Mounting evidence suggests that MDMA-induced 5HT neurotoxicity is due to the increased production of free radical induced oxidative stress. Attempts were made to clarify the mechanisms of MDMA in rats' brain by administering a single dose of the drug and studying the effects using combined toxicological, biochemical and immunohistochemical analysis.

Fifty rats were used for the study, each weighing 200-250 grams. Twenty-five rats were used for the histopathological and toxicological examination. They were divided into three experimental groups of seven animals each and administered one 20mg/Kg dose of MDMA intraperitoneally. The four controls were injected with saline. The first group of animals was sacrificed six hours after injection, the second at 16 hours, and the third at 24 hours. Plasma samples obtained immediately after sacrificed, stored at -80°C and then analyzed for MDMA/MDA with gas chromatography/mass spectroscopy (GC-MS). Histological sections of the brains were also obtained and immunohistochemical stains were used to localized MDMA and its metabolites, MDA and MDEA, within the various areas of the brain. Other immunohistochemical stains were used to localized growth associated protein 43 (GAP43), tryptophan hydroxylase (TrypH), markers of synaptic plasticity of the serotonergic innervation and the vesicular monoamine transporter -2 (VMAT2) as a stable marker of striatal dopaminergic terminal integrity. Microglial activation and damage were measured using a different immunohistochemical stain for glial fibrillary acid protein (GFAP), Heat shock proteins (Hsp 27, Hsp 70 and Hsp 90) and beta-amyloid precursor protein (β APP). Apoptosis was measured using the tunnel assay, which identified apoptosis via DNA fragmentation. For the evaluation of oxidative stress, the others twenty-five rats, divided into three groups of seven male albino rats weighing 200-250 g were used to analyze the effect of MDMA administration (20 mg/Kg, i.p) on rats' brain. Hippocampus, striatum, and frontal cortex were removed 3 and 6 hours after treatment and analyzed for the activity

of antioxidant enzymes (super oxide dismutase, SOD; glutathione reductase, GR; glutathione peroxidase, GPx). Reduced and oxidized glutathione (GSH and GSSG) were measured using a spectrophotometric assay. Ascorbic acid (AA) levels were determined reverse-phase HPLC method. Finally, lipid peroxidation was measured by quantitating the release of malonaldehyde (MDA) using UV-HPLC.

The acute administration of MDMA produces a decrease of GSH/GSSG ratio and oxidative stress in all of the brain areas examined. SOD activity was significantly reduced after 3 hours in hippocampus (-60.7%) and after 6 hours in striatum, hippocampus, and frontal cortex (-43.3%, -86.1% and -23.4% respectively). GR and GPx activities were reduced after 3 hours (-22%) and after 6 hours (-33.3%) in frontal cortex. AA levels strongly increased in striatum, hippocampus and frontal cortex after 3 (+159%, +84% and 17.6%) and 6 (+162%, +154% and +23.4%) hours respectively. High levels of MDA respect to control were measured in striatum after 3 hours (+276%) and 6 hours (162%); in hippocampus (71.8%) and in frontal cortex (+18.22%) after 6 hours.

The results of even one single administration of MDMA can significantly alter the brains cellular antioxidant defence system and produce oxidative stress in both the striatum and frontal cortex. Thus one possible mechanism of MDMA neurotoxicity appears to be a direct toxic effect of MDMA or its redox active metabolites.

MDMA Neurotoxicity, Immunohistochemical, Oxidative Stress

G59 Levorphanol, Dextromethorphan, and a Case of (Probable) Mistaken Identity

Philip Croft, MD*, Sparrow Health Systems, 1215 East Michigan Avenue, Lansing, MI 48912; Joyce L. de Jong, DO, Sparrow Forensic Pathology, 1215 East Michigan Avenue, Lansing, MI 48909; Michael A. Markey, MD, Sparrow Hospital, Sparrow Forensic Services, 1215 East Michigan Avenue, Lansing, MI 48909; and Michael Smith, PhD, Sparrow Health Systems, 1215 East Michigan Avenue, Lansing, MI 48912

After attending this presentation, attendees will recognize that levorphanol and dextrorphan, a metabolite of dextromethorphan, are stereoisomers that cannot be distinguished from each other by routine toxicology testing, and that forensic pathologists and others in receipt of toxicology reports should be cognizant of this when interpreting toxicology results.

This presentation will impact the forensic community by raising awareness among both forensic pathologists and toxicologists of the laboratory's limitations regarding levorphanol and dextrorphan discrimination, thereby leading to improved communication between pathologists and the laboratory along with a reduction in instances of misinterpreted toxicology results involving these compounds.

Appropriate evaluation of toxicology results within the context of a forensic autopsy is vital, and relies, in part, on a laboratory's ability to detect, differentiate, and report individual compounds contained within specimens collected during a postmortem examination. The existence of pharmacologically active stereoisomers poses an additional challenge to both toxicologists and pathologists, as they cannot be differentiated in the laboratory by routine methods. This is the case with levorphanol, a relatively potent prescription narcotic, and dextrorphan, the active metabolite of the commonly used over-the-counter antitussive dextromethorphan.

A case involving a 70-year-old man with pneumonia and a history of chronic ethanol abuse is presented to illustrate the importance of recognizing the laboratory's general inability to differentiate levorphanol from dextrorphan. Laboratory testing in this case showed a relatively high level of levorphanol along with other medications commonly found in over-the-counter cold medications. The presence of levorphanol was unexpected within the context of the case, as the decedent was taking no prescription medications and had not seen a physician for years. The

levorphanol was initially considered a significant contributing factor in the man's death.

Re-evaluation of the toxicology findings, spurred by a second case with similar toxicology results under equally incongruous circumstances, uncovered the difficulty posed to toxicology testing by the structural similarity between levorphanol and dextrophan. Given this insight, the circumstances of both of these cases suggested that the compound originally reported to be levorphanol was considered more likely to be the metabolite of dextromethorphan. Subsequently, "levorphanol intoxication" was discounted as a factor contributing to death in the first case. The original toxicology reports were amended to reflect the inability to distinguish between levorphanol and dextrophan.

Subsequent review of in-house case files since 1999 revealed 13 more cases in which levorphanol was reported to be in blood and/or urine along with other compounds often admixed with dextromethorphan in over-the-counter cold medications. These findings suggest that some, if not all, of these earlier cases were more likely to represent the detection of dextrophan and not levorphanol.

Toxicologists and pathologists should be aware that levorphanol and dextromethorphan's metabolite dextrophan are stereoisomers, and that their structural similarity renders them indistinguishable by routine laboratory testing. An understanding of these limitations is critical to the interpretation of toxicology results that may indicate the presence of one or both of these compounds.

Levorphanol, Dextromethorphan, Isomers

G60 Fentanyl-Related Drug Deaths in Virginia (2000-2006)

William T. Gormley, PhD, Office of the Chief Medical Examiner, 400 East Jackson Street, Richmond, VA 23219; and Anna Noller, PhD, Virginia Department of Health, Office of the Chief Medical Examiner, 400 East Jackson Street, Richmond, VA 23219*

After attending this presentation, attendees will recognize the growing contribution of fentanyl to drug deaths, especially in combination with other drugs and alcohol.

This presentation will impact forensic scientists, primary care physicians, pharmacists, and patients by demonstrating the danger of combining fentanyl with other medications, street drugs, or alcohols.

Fentanyl is an opiate analgesic with about 81 times the therapeutic effect of morphine. Initially used mostly in hospital settings, fentanyl is increasingly used for outpatient management of chronic pain, especially delivered transdermally or through mucous membranes. Over the past years fentanyl has appeared more frequently in toxicology screens associated with drug deaths.

All deaths investigated by the Virginia Office of the Chief Medical Examiner between January 1, 2000 and December 31, 2006 in which fentanyl was detected on toxicological examination were received. Cases where fentanyl was used therapeutically in natural deaths were excluded from this analysis. Cases where fentanyl was present but the cause of death was a traumatic injury were excluded.

Analysis demonstrated a progressive increase in number of cases from three in 2000 to 51 in 2006. Deaths involving fentanyl typically occurred in the 3rd and 4th decade of life (average 40 years). There was a slight male predominance (about 60%), and 97% of the victims were white. There was significant geographic disparity in the data. There are four District Offices in Virginia, each office serving approximately 25% of the population. The relatively rural Western District had 51% of the fentanyl-associated death cases. The more urban Central, Eastern, and Northern Districts had 15%, 19%, and 15% of the cases respectively. Most of the deaths were classified as accidental (88%) with 10% suicidal and 2% undetermined.

Only 12% of the deaths in this study were caused by fentanyl alone. In the remaining cases other drugs were present and contributed to the death. The other drugs included prescription medications, street drugs, over the counter medications, and alcohol. Prescription medications were involved in 85% of the cases and included analgesics, muscle relaxants, and mental maintenance drugs. Prescription drugs were overestimated in this study since medications which may have been obtained illegally (i.e., oxycodone and methadone) were classified as prescription drugs. Morphine was classified as prescription unless 6-acetylmorphine was also present. Street drugs were involved in 14% of cases, over-the-counter drugs (acetaminophen, antihistamines, and dextromethorphan) in 8% and alcohol in 13%.

This analysis documents the marked increase (17-fold) increase in fentanyl-related deaths over the last six years. The observation that most of the deaths are associated with other drugs suggests a role for increased caution by physicians in prescribing fentanyl, especially in combination with other medications. Increased education of patients is essential with emphasis on the critical importance of using the medication as directed. Patients should also understand the danger of mixing fentanyl with non-prescribed substances such as street drugs, alcohol, and sedating over-the counter drugs.

Fentanyl, Drug Death, Epidemiology

G61 Deaths Involving Stress

Jeffery J. Gofton, MD, 901 North Stonewall, Oklahoma City, OK 73117-1218; and Wendy M. Gunther, MD, Office of the Chief Medical Examiner, Tidewater District, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510-1046*

After attending this presentation, attendees will learn characteristics of traumatic and natural lesions identified in a series of cases presenting for medicolegal autopsy in which the medical examiner determined that stress played a role in death; will be able to evaluate the role of toxicology, history, and time course in determining the cause and manner of death in such cases; and will be able to evaluate impact of such characterization of cause and manner of death on courtroom testimony.

This presentation will impact the forensic community by demonstrating how to utilize a case format series to evaluate the common factors which should be present in order to assign stress a role in certification of medicolegal death. Discuss the appropriate manner in each of several cases of stress-related death.

Although most deaths presenting for medicolegal autopsy fall readily into the categories of natural, accident, suicide, and homicide, some deaths from natural disease appear to be influenced by stress, which raises the question of whether a manner of accident or homicide should be assigned to a death that is primarily from natural causes.

Stress as defined in these cases may include participating in an altercation, whether verbal or physical; suffering trivial injury, or nontrivial injury which is nevertheless not fatal; being afraid for one's life; fearing catastrophic outcomes to oneself or another; losing valued personal property during an assault; or undergoing poisoning with varying substances to a degree which should not be fatal, while under emotional stress from other causes.

Stress is a vaguely defined word which has been used in the media, in lay discussions, in psychology, in research, and in forensics. It has multiple overlapping meanings more than one of which may be utilized in a discussion, resulting in decreased communication clarity. Nevertheless the death of an individual during an emotionally violent incident from what appears to be natural disease, without sufficient trauma to explain death, may be difficult to describe without using the word stress.

Medical examiner opinion on the role of stress in such deaths varies. Some take the position that an influence as difficult to measure

as stress should not play a role in death certification. This series of cases from a five-year period in the Tidewater district of the Commonwealth of Virginia illustrates examples of deaths which the medical examiner felt were best certified with some reference to stress. The manner of death in these cases, as well as the relevant history, toxicology, autopsy findings, and scene investigation, is reviewed with an eye to developing some common factors which belong in the evaluation of a death that is at least partly attributed to stress.

Stress, Altercation, Death

G62 Investigation of Acute Oxymorphone (Opana® ER) and Ethyl Alcohol Intoxication

Andrew W. Sexton, DO*, 24 Regency Park Drive, Agawam, MA 01001

After attending this presentation, the attendees would appreciate the significant impact of coordinated interdisciplinary approach in determining an acute oxymorphone (Opana) and ethyl alcohol intoxication.

The presentation will impact the forensic science community by reporting the limitations of ELISA methodology for screening detection of oxymorphone (Opana®).

Scene investigation, circumstantial information together with thorough autopsy/toxicology and ancillary studies constitute the triad of a competent medicolegal death investigation. Herein is described the death investigation of a 28-year-old Caucasian male, whose cause of death would be classified undetermined, had the systematic aforementioned principles not been applied. The case is characterized by astute police investigative efforts, competent scene recovery and awareness of synergistic drug effects between Opana®ER (oxymorphone) and ethanol. The decedent, accompanied by friends, participated in a celebration at a local bar prior to a major social event. Following a period of marked ethanol consumption, the decedent returned to a friend's house and retired. Approximately 6.5 hours later, attempts to awake the decedent were unsuccessful; he was found to be apneic and in asystole. Resuscitative efforts were initiated and ACLS protocols followed as the decedent was transported to a nearby emergency room. The decedent was pronounced shortly after arrival.

Autopsy findings revealed a well nourished, well developed 28-year-old Caucasian male, measuring 71 inches long and weighing 160 pounds. No external or internal evidence of trauma was detected. All body organs revealed weights within normal limits, with the exception of heavy lungs indicating severe pulmonary edema. Initial postmortem toxicology indicated non-fatal concentrations of ethanol at 0.11%, 0.14%, and 0.25% respectively in blood, vitreous humor, and urine. The scene investigation did not indicate an unsafe sleeping environment. Gross and microscopic examinations were negative for gastric contents or foreign body aspiration.

The cause of death remained undetermined until a second review and reassessment of the police investigation, including witness testimonies, raised suspicion for a drug-related event. In the area where the decedent had been sleeping, a broken 40 mg tablet of Opana®ER was found in a prescription vial on a shelf. The decedent's friend stated to police he never crushed or broke the prescription tablets. Further, the friend stated that on past occasion the decedent requested his medication for experimental use. The friend denied compliance with previous requests and no inquiry was made by the decedent the night of the party.

Additional toxicological studies included directed analysis for synthetic opioids by GCMS/SIM in blood and urine. The analysis revealed oxymorphone concentrations of 95 ng/mL and 214 ng/mL in blood and urine, respectively. The UMass Forensic Toxicology Laboratory employs ELISA technology, which includes a specific assay for oxycodone, in front line presumptive screening of postmortem blood.

Oxymorphone, a metabolite of oxycodone, exhibits limited cross reactivity in this assay (at a 50 ng/mL positive cut-off concentration for oxycodone approximately two and one-half times that concentration, or 130 ng/mL oxymorphone, is needed to elicit a positive response). The ELISA result for oxycodone was therefore negative.

The cause of death was certified as acute oxymorphone and ethyl alcohol intoxication. Most notably, the drug's manufacturer cautions contemporaneous use of alcohol since oxymorphone plasma concentrations may increase as much as 270% and causes fatal overdose. Similar to OxyContin®, crushing or breaking Opana®ER tablets defeats the extended release formulation and precipitates delivery of the drug's full dose into the blood.

This case underscores the significance of a coordinated, interdisciplinary approach to competent death investigations. Absent or superficial scene investigations, cursory or incomplete autopsy examinations, and inadequate toxicological studies can undermine accurate cause of death certifications.

Toxicology, Synthetic Opioids (Opana), ELISA

G63 Deaths During Police Chases

Jeffery J. Gofton, MD*, 901 North Stonewall, Oklahoma City, OK 73117-1218; and Wendy M. Gunther, MD*, Office of the Chief Medical Examiner, Tidewater District, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510-1046

After attending this presentation, attendees will: (1) learn characteristics of traumatic and natural lesions identified in decedents presenting for forensic evaluation after dying during police pursuit, (2) will be able to evaluate the role of toxicology, behavioral history, and time course in determining the cause and manner of death, (3) and, will be able to distinguish injuries inflicted by police from accidental or suicidal injuries incurred during the course of police pursuit and evaluate impact of such recognition on courtroom testimony.

This presentation will impact the forensic community by assisting participants in recognizing significant characteristics of trauma and other features of deaths during police pursuit by analysis of a case format presentation.

Deaths occurring during police chases require special attention at forensic autopsy. A number of issues may be raised by death during police pursuits which are relevant to the cause and manner of death. Even issues which are not directly relevant to cause and manner may influence subsequent court decisions on police actions.

The primary issue in many cases is whether police actions directly caused death. In cases of police shootings, this is obvious; in car crashes, it may be far from obvious, so much so that the question has gone as far as the United States Supreme Court. In addition, the medical examiner may be presented with a decedent who was not the person police were chasing; passengers, innocent bystanders, and pedestrians have all been killed during police pursuit.

Death during pursuit is by no means only due to motor vehicle related trauma or police shootings. A decedent whose cause of death is clearly a gunshot wound may not have sustained it at police hands. Sometimes more than one officer has shot a decedent and the question arises of which bullet is most responsible for death. In cases where gunshot wounds are not responsible, the cause and manner of death may vary widely. Blunt force trauma or sharp force trauma such as canine bites may be identified. These injuries may have been inflicted by police, by accident, or by another. Such blunt trauma may be primary in death, contributing, or irrelevant. Other accidental means of death may supervene over police-inflicted injuries when suspects flee. The time course from initiation of police chase to death is also significant and may not always be what is expected. Deaths have occurred after police chase was called off that may nonetheless be related to the history of police pursuit.

In examination of all deaths during police pursuit, careful photographic documentation is essential along with a number of other methods of documentation only some of which are routine. Collection of trace evidence may require a higher level of care than is applied in routine cases. The medical examiner's experience and judgment as well as observations are essential to separate trauma significant in death from trauma not relevant to death, and to determine the likely origin of both kinds of trauma. For example, the medical examiner is called on to identify injuries inflicted directly by police from injuries sustained by accident or at other hands. Natural disease, intoxication with drugs and alcohol, and history of behavior such as previous flight from police or suicidal ideation prior to the incident, may all be relevant; each is likely to require careful assessment during the course of forensic evaluation. Familiarity with a variety of traumatic lesions that have occurred during police pursuits ending in death assists the medical examiner with resolving questions of police responsibility and authority, and with cause and manner of death.

This series of deaths during police pursuit provides a review of accidental, suicidal, natural, and directly police-inflicted deaths occurring over a five-year period in the Tidewater district of the Commonwealth of Virginia. The causes of death include single gunshot wound, multiple gunshot wounds, motor vehicle collision-related trauma, and drowning. The documentation of injuries and disease and the process of medical examiner reasoning which resulted in the determination of cause and manner of death are presented for each case.

Police Chase, Death, Forensics

G64 Variations on a Theme: Inhalant Abuse Related Fatalities in Central New York — An 11 Year Review

Abraham T. Philip, MD, Onondaga County Medical Examiner's Office, 100 Elizabeth Blackwell Street, Syracuse, NY 13210*

After attending this presentation, the attendees will be made aware of the epidemiology of the inhalant abuse related fatalities evaluated by the Onondaga County Medical Examiner's Office from 1998 to 2008.

This presentation will impact the forensic community by examining the variations in inhalant abuse related fatalities, and dispute the notion that it is usually a juvenile behavioral problem.

Inhalant abuse is the intentional or deliberate inhalation of chemical vapors, often a household product, to achieve intoxication. The commonly used chemicals are volatile solvents, aerosols, glues, paints, and lighter fluids. In inhalant abuse there is a progression from "Sniffing" - inhalation of vapors from an open container, to "Huffing" - inhalation of vapors holding a piece of cloth that has been soaked in volatile substance against the nose and mouth, to "Bagging" - inhalation from a plastic bag containing the desired substance. The prototypical inhalant abuser is a young male, between 10 and 15 years of age, indulging in inhalant abuse during school vacation times.

A study was conducted examining the inhalant related fatalities evaluated by the Onondaga County Medical Examiner's Office from 1998 to 2008, to obtain data about demographic characteristics; circumstances of the deaths; major autopsy findings; toxicology test results; and cause and manner of death (COD & MOD) formulations of these cases.

There were nine possible cases identified by the initial searches, of which two cases were deleted as not suitable for this study. Of the remaining seven cases (three female; four male) the mean age was 32.0 years and the median age was 21. There were three cases in 2002, two in 2007, and one each in 2005 and 2008. There was one case each in the months of January, February, April, June, and August and two cases in July.

Of the seven cases only one was the so-called prototypical inhalant abuser a 13-year-old male found with evidence of direct inhalation. The three female victims were aged between 18 & 21, while the remaining male victims were in the 4th and 5th decade of life. Besides the one case of direct inhalation, three cases had spray paint residue on the face, two cases had strong circumstantial evidence of inhalant abuse and in one case there was a past history of inhalant abuse. All cases below the median age had issues with scholastic performance and or depression. The cases above the median age had histories of illicit drug and alcohol abuse or psychiatric issues.

Toxicology was confirmatory in five (71%) of the seven cases. In one case the testing was limited by decomposition of the victim and in another case specimens were not submitted for an inhalant abuse test panel. The inhalant panel tests revealed 1-2 aromatic or halogenated hydrocarbons and or ketones including the following compounds with the following frequency noted in parenthesis: benzene (1), toluene (3), difluoroethane (1), and methyl ethyl ketone (2). Illicit drugs of abuse were identified in one case, lead was identified in the gasoline direct inhalation case and multiple medications (predominantly psychiatric) were identified in four (57%) of the seven cases.

In one case each the listed COD was: complications of solvent abuse; inhalation of toxic products of combustion and thermal injury; multiple drug intoxication; and laceration like incised wounds to the neck due to circular saw. In three cases the COD was: asphyxia due to (1) inhalant abuse, (2) spray paint, and (3) drowning as the cause of death. Inhalant abuse was listed in the contributory conditions of the drowning and neck trauma victims. The MOD in six cases (85.7%) was accident and one was suicide. A further review of the autopsy report determined that inhalant abuse (or variant terms) was mentioned in the summary of diagnostic finding. The cases in which the inhalant abuse was not mentioned included the victims of fire, drowning, and multiple drug intoxication.

Education and preventive efforts focused not just on teenagers, but targeted to older at risk adults, are required if inhalant abuse related fatalities are to be eliminated. Furthermore, clinical services should consider these findings to identify the at risk individuals.

Inhalant Abuse, Huffing, Bagging

G65 A New Framework for Guiding Research in Forensic Entomology: Improving the Science Relevant to PMI Estimates

M. Eric Benbow, PhD, University of Dayton, Department of Biology, 300 College Park, Dayton, OH 45469-2320; and Jeffery K. Tomberlin, PhD, and Rachel Mohr, MS, Department of Entomology, Texas A&M University, 2475 TAMU, College Station, TX 77843*

After attending this presentation, attendees will increase awareness of specific basic research needs essential for refining estimates of the period of insect activity (PIA) on human remains. Furthermore, attendees will be introduced to a needed differentiation of semantics intended to improve communication among forensic entomologists, other professionals of the forensic science community, members of the judicial process, and the general public.

This presentation will impact the forensic science community by presenting a new framework for describing the aspects of entomological activity associated with human remains. After attending this presentation, the attendees will understand the need for additional research examining neglected study foci related to the PIA, specifically the interval of activity prior to physical colonization. This presentation will raise attendee awareness to specific basic research needs essential for refining estimates of the PIA on human remains.

A major component of the nature and practice of forensic entomology is assisting investigators in determining the postmortem interval (PMI). To date, the initial time of colonization that begins the defined post-colonization interval (post-CI), and includes arthropod occupation and use of the remains, has been the most relevant information for entomologically-based PMI estimates, which is concisely defined as the PIA; however, the time between death but before initial insect colonization is also a portion of the PIA and is important for cases that require accurate estimates within hours after death. For this presentation, this portion of the PIA is defined as the pre-colonization interval (pre-CI).

The pre-CI encompasses the portion of the PIA from time of death until initial physical colonization and use by insects for consumption or oviposition. Most studies that address the pre-CI have focused on nocturnal oviposition, but few have addressed other processes that influence initial insect contact and early colonizer oviposition; most notably measurable behavioral characteristics that are influenced by both biotic and abiotic factors in the environment. In addition, there is tremendous variation in the length of time and faunal succession characteristics of insect activity on a body. The interface of the pre-CI and the post-CI is defined by the time when arthropods physically colonize and begin using the human remains as a resource; as an oviposition site, habitat for finding prey or primary consumption of tissues. This interface is preceded by an acceptance phase defined by behavioral patterns of body detection and evaluation for full colonization. The acceptance phase of the pre-CI has been all but unstudied to date, but can affect estimates of the PIA. In the current state of knowledge regarding the PIA, limited scientific information can lead to interpretative differences among forensic entomologists.

The pre-CI in general, and the acceptance phase in particular, are broad areas of forensic entomology research that have been neglected, and require more rigorous and repeatable experimental design necessary to improve the entomological information relevant to total PIA, and consequently further refinement of PMI estimates. However, a common language and framework among forensic entomologists is necessary to facilitate and guide this research. To this end, a new conceptual framework is introduced to identify areas of needed forensic entomological research and propose standard terms when discussing entomological data used in investigations involving PMI estimates. This framework divides the PMI into logical components from death to body discovery including but not limited to the following: death to initial insect detection of the decomposing body (pre-CI exposure phase); the time from detection to location of the body (pre-CI detection phase); the time from body location to first oviposition (pre-CI acceptance phase); and, the time from insect colonization of the body to discovery of the remains (post-CI).

This framework identifies specific areas of research within each of these entomological phases that involve the behavioral and physical stages of insect activity on a body, and suggests which abiotic and biotic factors influence these entomological processes that can be of focused and applied studies. It is the intention of the authors to facilitate a common language and conceptual structure to improve the science of forensic entomology, an important consideration for aiding criminal investigations involving estimates of the PMI. Accordingly, this platform is used as a method for developing a common path leading from basic to applied research in the field of forensic entomology.

Forensic Entomology, Arthropod, Insects

G66 The Activity of *Calliphora vicina* (Diptera: Calliphoridae) Can Alter the Morphology and Presumptive Chemistry of High Impact Bloodstains

Amanda Fujikawa, BS, University of Nebraska-Lincoln, 202 Entomology Hall, Lincoln, NE 68583-0816; Larry Barksdale, MA, Lincoln Police Department, 575 South 10th Street, Lincoln, NE 68508; and David O. Carter, PhD, University of Nebraska-Lincoln, Department of Entomology, 202 Entomology Hall, Lincoln, NE 68583-0816*

After attending this presentation, attendees will have a better understanding of fly artifacts, their importance when interpreting and reconstructing a crime scene, and practical applications in locating and identifying fly artifacts.

This presentation will impact the forensic community by increasing knowledge of outside influences, specifically *Calliphora vicina*, on crime scenes and the means of using this knowledge to make more accurate scene reconstructions.

The study being presented examined the effect of *Calliphora vicina* on high impact bloodstain patterns and to test presumptive blood tests that could be used to differentiate between blood spatter and fly artifacts.

The experiments were conducted in microscenes (.46 m³ wooden boxes) that had two walls of glass and a ceiling of plexiglass to facilitate observation and photography. Interchangeable inserts were made to allow for surface changes in the microscenes. Surfaces used in this study were combinations of indoor materials commonly found at crimes scenes. Combinations of white linoleum with white textured and painted walls (Combination 1), wood floor laminate with a wallpapered wall (Combination 2), and mid-grade carpet with light hued paneling (Combination 3) were used to demonstrate surface texture and its effect on the flies' ability to feed and deposit artifacts. High impact bloodstains were made from fresh (within 5 minutes of drawing) human blood on two walls and a pool was formed on the floor. The flies were placed in holding cages that attached to the microscene. This design provided an opportunity for the flies to choose to enter the microscene. Flies entered the microscene within 30 minutes with combinations 1 and 2. They entered the microscene within 60 minutes with combination 3. The flies remained in the microscenes for 48 hours. After they were removed, measurements, photo documentation, and presumptive chemical tests were performed. Four commonly used presumptive blood tests were used: phenolphthalein, Hemastix®, leucocrystal violet, and fluorescein.

The deposition of artifacts was evenly distributed between floor and wall surfaces within a microscene. Both male and female flies fed on the blood and deposited artifacts. Artifacts could range from completely clear, consisting mainly of water, to completely opaque, consisting mainly of blood. Regurgitation was the most common method of deposition, but defecation did occur. Regurgitated artifacts were generally small, 1-2 millimeters, with little or no tail. Defecated artifacts were of similar size to the regurgitated but generally had a tail from a few to over 20 mm in length.

There was no difference in reaction time between blood spatter and artifacts when using phenolphthalein, Hemastix®, and fluorescein. The reactions times with leucocrystal violet were generally similar although increased reaction time was seen in some instances. Artifacts that consisted of less blood fluoresced under a blue/green light when viewed through an orange filter without chemical enhancement.

Forensic Entomology, Insect Artifacts, Blow Fly

G67 Rehydrating Dried Blow Fly Larvae to Reclaim Their Usefulness in Forensic Investigations

Michelle R. Sanford, MS*, Jennifer L. Pechal, MS, and Jeffery K. Tomberlin, PhD, 2475 TAMU, Department of Entomology, Texas A&M University, College Station, TX 77843

After attending this presentation, attendees will learn methods for rehydrating dried larval insect specimens. The impact that initial preservation coupled with drying and rehydrating of larval specimens on their length and weight as it relates to estimating period of insect activity also will be discussed.

This presentation will impact the forensic community by demonstrating how studies on methods development in forensic entomology can benefit the forensics community by being used to define protocols and standard operating procedures that can be cited and used in legal proceedings.

Ethanol is commonly recommended for preserving larval blow fly specimens in forensic investigations. Alcohol is a volatile preservative that can evaporate over time resulting in the dehydration of larval specimens or the creation of *crispy maggots* which are difficult to identify and unreliable for measurements for age estimation. In this study methods recommended for rehydrating dried museum specimens were adapted and applied to *crispy maggots* of three common North American blow fly species (*Phormia regina* (Meigen), *Cochliomyia macellaria* (Fabricius), and *Chrysomya rufifacies* (Macquart)). Length and weight of the specimens were documented throughout the process. The effect of initial preservation method was also observed by collecting replicate samples and preserving in 80% ethanol, 70% isopropyl alcohol, or with fixation by hot water killing followed by preservation in 80% ethanol. Third instar larvae were collected over the course of nine months from different animal carcasses used for teaching the Texas A&M University forensic entomology course. Individual third instar larvae from each species (n = 90/species) were measured and weighed before the preservative was allowed to evaporate. Rehydration was attempted by soaking overnight in 80% ethanol, a commercial trisodium phosphate substitute solution, or 0.5% trisodium phosphate solution after which specimens were again measured and weighed. Analysis of length and weight data with analysis of variance showed that for each species the impact of rehydration and the impact of the interaction between initial preservation and rehydration treatment significantly affected final rehydrated length and weight among the different species.

For all specimens, soaking in any of the rehydration treatment solutions restored a portion of the original larval length (mean percent difference initial–final across all species and preservatives: 80% ethanol: -10.6%; trisodium phosphate: -2.9%; trisodium phosphate substitute: 1.1%) but none of the solutions were able to restore original larval weight. The original larval length and the final rehydrated larval length were used to estimate larval age using published data sets. These estimates agreed within a few hours in many cases with individual preservation by rehydration treatment combinations more closely agreeing for some species than others. A comparison between the length-based larval age estimate and the known duration of the exposure of the animal carcasses revealed that there were large differences (percent difference between estimated and actual exposure: *P. regina*: 74% lower than actual; *C. macellaria*: 51% lower than actual; *C. rufifacies*: 150% higher than actual) which probably reflect delays in, and barriers to, colonization coupled with differences in tissue types used in published studies and this experiment.

Overall the data show that *crispy maggots* can be rehydrated and suggest that their length can be measured to obtain a length-based age estimate for period of insect activity estimates. Knowledge of the initial preservation method might also aid in selecting the most appropriate rehydration method.

Studies on methods development in forensic entomology can benefit the forensic sciences community by being used to define protocols and standard operating procedures that can be cited and used in legal proceedings.

Diptera, Method, Length

G68 Patterns of Adult Blow Fly Attraction to Carrion Over Time

Rachel M. Mohr, MS*, and Jeffery K. Tomberlin, PhD, Department of Entomology, Texas A&M University, 2475 TAMU, College Station, TX 77843-2475

After attending this presentation, attendees will better understand about the length of time between the exposure of carrion to adult blow flies and the onset of fly attraction to that carrion. Attendees will also learn about the physiological age profile of adult flies attracted to carrion over time.

This presentation will impact the forensic community because it helps better quantify the length of time between exposure of a cadaver and the onset of insect colonization.

This presentation is intended to educate attendees about the length of time between the exposure of carrion to adult blow flies and the onset of fly attraction to that carrion. Attendees will also learn about the physiological age profile of adult flies attracted to carrion over time.

This information is significant for the forensic sciences community because it helps better quantify the length of time between exposure of a cadaver and the onset of insect colonization.

Forensic entomology's most common application is to calculate the length of time that a cadaver has been deceased, the total postmortem interval (PMI). Most commonly, what is actually calculated is the duration of immature insect inhabitation of the cadaver, based on the known growth rate of particular insect species - what the authors are terming the post-colonization interval (post-CI). Little attention has been paid to the time between exposure of a body to insect activity and the onset of oviposition, and in this research, termed as the pre-colonization interval (pre-CI). However, under appropriate conditions such as a very fresh cadaver, or when high temperatures lead to rapid decay, the pre-CI may represent a substantial portion of the total PMI. Adequately characterizing the behavior of the adult fly, particularly as a function of cadaver age and ambient temperature, could greatly assist entomologists in calculating the total period of all insect activity on a cadaver.

Insects arrive at a cadaver in relatively predictable succession patterns. Blow flies tend to arrive very early in the succession pattern, often within 24 hours postmortem. Adult flies found around a very fresh cadaver are usually presumed to oviposit shortly after locating it. However, since most blow flies require a protein meal in order to produce eggs, young flies may visit a cadaver long before they are capable of ovipositing. The process of producing eggs by depositing vitellin (yolk protein) into the immature ovarioles allows the physiological age of flies to be determined. By determining the ovarian status of flies, and the patterns of the groups' relative carrion usage, it can be accurately assessed how long postmortem oviposition-ready flies are found at a cadaver. The rate of ovarian development is largely dependent on fly metabolism, which in turn is significantly influenced by temperature. The higher the temperature, the faster ovaries develop, so long as the fly has obtained adequate dietary protein. Therefore, temperature is an important factor to track when estimating either the rate of ovarian development or simply the overall physiological age.

Experiments were performed evaluating the attractiveness of carrion to the common early-arriving blow flies, *Cochliomyia macellaria* (Fabricius) and *Chrysomya rufifacies* (Macquart). Pigs were killed by cranial stunning, and placed in an open field within one hour of death. At hourly intervals between dawn and dusk of the next 72 hours, ambient

temperature observations were made, and adult flies were collected from the carcasses. Flies were identified to species and sexed. All flies were weighed and placed in different weight classes. Female flies were dissected, and their ovarian developmental status determined in order to place them into five separate age groups. The post-CI and behavior pattern was evaluated for each group. The post-CI of each age group will be discussed in relationship to temperature. Complicating or retarding environmental factors will also be discussed, as well as the limitations of the findings. However, the results of this study are expected to be useful in improving the accuracy of entomologically derived postmortem intervals. Furthermore, this research shows the importance of collecting adult insects as well as immatures at a body recovery site.

Forensic Entomology, Blow Flies, Postmortem Interval

G69 The Effect of Soil Compaction on Pupation Depth of *Lucilia sericata* in Soil

Jonathan A. Cammack, BS*, and Peter H. Adler, PhD, Department of Entomology, Soils, and Plant Sciences, Clemson University, 114 Long Hall Box 345315, Clemson, SC 29634; Jeffery K. Tomberlin, PhD, Department of Entomology, Texas A&M University, TAMU 2475, College Station, TX 77843-2475; Yuji Arai, PhD, Department of Entomology, Soils, and Plant Sciences, Clemson University, 270 Poole Agriculture Center, Clemson, SC 29634; and William C. Bridges Jr., PhD, Department of Applied Economics and Statistics, Clemson University, 243 Barre Hall, Clemson, SC 29634

After attending this presentation, attendees will understand the effect that soil compaction has on the burrowing ability of post-feeding third instar larvae of *Lucilia sericata* (Meigen) (Diptera: Calliphoridae) searching for a pupation site.

When paired with information from post-feeding larval dispersal studies, this information will impact the forensic sciences community by aiding investigators in locating entomological evidence at a body-recovery scene.

After attending this presentation, attendees will understand the effect that soil compaction has on the burrowing ability of post-feeding third instar larvae of *Lucilia sericata* (Meigen) (Diptera: Calliphoridae) searching for a pupation site. When paired with information from post-feeding larval dispersal studies, this information will impact the forensic science community and humanity by aiding investigators in locating entomological evidence at a body-recovery scene. Information from this study also can be used to decipher the relationship between ambient temperature and soil temperature to better determine development of insects that have dispersed from human remains and burrowed into the soil to pupate. This information will allow for a more precise estimate of the period of insect activity (PIA) as it relates to the time since initial insect colonization, or post-colonization interval (post-CI).

Locating the oldest insects that develop on human remains is crucial for accurate analysis of entomological evidence. If the remains are in a late stage of decomposition, fly larvae from the first sere of succession might have left the remains and pupated in the surrounding soil. If this has happened, a PIA estimate based on fly larvae collected from the remains will not accurately represent the post-CI. Therefore, investigators must be able to locate flies that have pupated in the soil to obtain an accurate post-CI.

In this study, post-feeding third instar larvae of *L. sericata* were allowed to burrow into soil of different compactions. After adult emergence, the depth in the soil of empty puparia was recorded. Time from egg to adult emergence also was recorded. Results from this research will generate a standard operating procedure for collecting fly puparia in soil at a body recovery scene, as well as evaluate development

times of these insects in soil when using development data from previous laboratory studies.

The utility of *L. sericata* in forensic entomology has long been recognized. It is an early colonizer of decomposing remains, occurring in the first sere of succession. Due to its nearly cosmopolitan distribution, it has been widely studied in many locations worldwide, and can be considered a laboratory model for forensic entomology research. *Lucilia sericata* has been studied for its forensic implications in the context of temperature-related development, entomotoxicology, molecular identification, and now pupation behavior.

Entomology, Pupation, Soil

G70 Feeding Patterns of American (*Periplaneta americana*) and German (*Blattella germanica*) Cockroaches on Pig Skin

Lindsay A. Bright*, 1500 Olympia Way #12, College Station, TX 77840; and Jeffery K. Tomberlin, PhD, and Roger Gold, PhD, Department of Entomology, TAMU 2475, College Station, TX 77843-2475

After attending this presentation, the attendees will understand the characteristics of *Periplaneta americana* (Linnaeus) (Blattodea: Blattidae) and *Blattella germanica* (Linnaeus) (Blattodea: Blattellidae) feeding sites on epidermal tissue.

This presentation will impact the forensic sciences community by educating attendees about cockroach feeding on human remains and variables that can affect their associated feeding behavior.

Cockroaches are voracious consumers of a wide variety of organic material and debris. They are also commonly found in and around human dwellings. Consequently, it is not uncommon to discover human remains exhibiting signs of cockroach feeding. Because cockroaches tend to feed on just the top layers of epidermis, their bites and feeding sites closely resemble second degree burns or abrasions. Postmortem injuries caused by cockroach feeding are often misinterpreted as antemortem injuries which can lead to the suspicion of foul play even when none exists.

The American and German cockroaches are two of the most common species of cockroach found in residential areas. The differences in feeding behavior between these two species of cockroach have not been characterized. Consequently, it is currently not possible to determine which species fed on a given set of remains. Furthermore, no information is available about the effects of temperature or population size on the feeding habits of either species.

Studies were conducted to observe the effects of temperature and population size on the feeding behavior of both American and German cockroaches. Pig epidermal tissue was used as a substitute for human epidermis. All cockroaches were starved for 24 h prior to the study and cockroaches not used in previous trials were obtained for each replicate. In order to understand the effects of population size on feeding behavior, 100, 150, or 200 American and German cockroaches were exposed to a 124.63 cm² area of pig epidermis for 48 h. The experiment was conducted at 27°C RH 80±10% and a photoperiod of 12:12 [L:D] h. Pig epidermal tissue exposed to each species was examined individually and not in mixed cultures. The effects of temperature on feeding behavior were tested using groups of 150 American or German cockroaches. One hundred and fifty individuals of each species were kept in growth chambers maintained at 15°C, 21°C, or 27°C. All growth chambers had RH 80±10% and a photoperiod of 12:12 [L:D] h. Pictures of the pig skin from both studies were taken with a digital camera every 6 h for 48 h. Feeding sites were identified and measured using SigmaScan Pro 5, and percent area damaged due to cockroach feeding was determined.

According to these studies, the amount of epidermis damaged due to cockroach feeding was positively correlated to both density and temperature. Epidermis that was exposed to 200 of either species of cockroach was damaged far more than skin exposed to lesser densities. Both American and German cockroaches showed very little feeding activity at 15°C, suggesting a minimum temperature for feeding. At 27°C, both species of cockroach consumed the most area. It is anticipated that the outcome of these studies will be useful in better identifying and understanding the interactions between anthropophagous roaches and humans in forensic investigations.

Cockroach, Insect Feeding, Epidermis

G71 Attraction of Two Forensically Important Fly Species: *Chrysomya rufifacies* (Macquart) and *Cochliomyia macellaria* (Fabricius) to Inter- and Intraspecific Eggs

Adrienne L. Brundage, MS*, Texas A&M University, 2001 Cobblestone Lane, Bryan, TX 77807; and Jeffery K. Tomberlin, PhD, Texas A&M University, Department of Entomology, TAMU 2475, College Station, TX 77843-2475

The goal of this presentation is to elucidate the attractive mechanism of inter- and intra-specific eggs to two forensically important fly species: *Chrysomya rufifacies* (Macquart) and *Cochliomyia macellaria* (Fabricius). The evolutionary relationship between the two species will also be discussed, as well as the potential for this information to elucidate mechanisms used to initiate colonization of a resource by blow flies at the conclusion of the pre-colonization interval (pre-CI) which is described below.

This presentation will impact the forensic sciences community by: (1) explaining the importance of the pre-CI when attempting to estimate time of colonization, (2) examining the biology of, and interactions between, two forensically important fly species, *Chrysomya rufifacies* and *Cochliomyia macellaria*, and (3) investigating one possible mechanism triggering and/or inhibiting their oviposition on a resource.

Carrión represents a temporary and ever-changing habitat and food source for a wide variety of organisms. Previous studies indicate the first macrobiotic decomposers to discover ephemeral resources include blow flies (Diptera: Calliphoridae). However, their arrival does not necessarily translate into immediate colonization of the remains. Therefore, the period of insect activity (PIA) is broken into two portions. The pre-CI is from the time of death until arrival of arthropods on the corpse. The post-colonization interval is from colonization of the remains until discovery. Colonization can be defined as utilizing a resource as a habitat or for offspring development.

Blow flies arrive in predictable patterns and are present for a predictable time interval depending on abiotic and biotic factors. These primary colonizers may colonize carrión within hours of death. The act of colonization starts a “biological clock” and given the collective knowledge of blow fly biology, it is possible to determine the post-CI of the PIA. Since the majority of blow fly species do not colonize living tissue, exposure interval of the remains may be synonymous with the post-CI or minimum postmortem interval (PMI). In some instances estimates of the post-CI are analogous to the PMI.

The accuracy of estimating the pre-CI along with the full PIA may provide greater understanding of the period of exposure of the remains and more accurate estimates of the PMI. While a great deal is known about a few species of forensically important arthropods, much more research is needed. The community of necrophagous insects differs between habitats and between geographical areas. These differences mean that general successional and life history studies may be of some use to all forensic entomologists, but accurate PIA is dependent upon

intimate knowledge of the community makeup, specific successional patterns, and life histories of forensically important flies common in the area of the crime.

Ten forensically important species have been collected in Brazos County, Texas, USA and deserve further investigation: *Calliphora livida*, *C. vicina*, *Cynomyopsis cadaverina*, *Lucilia cuprina*, *L. eximia*, *L. coeruleiviridis*, *Cochliomyia macellaria*, *Chrysomya rufifacies*, *C. megacephala*, and *Phormia regina*. Of these, *Cochliomyia macellaria* and *Chrysomya rufifacies* dominate the maggot mass during the warmer months, and are therefore important in time of colonization estimates.

Recent studies have characterized an ovipositional phenomenon in a family closely related to blow flies. Female *Musca domestica* (Linnaeus) (Diptera: Muscidae) utilize bacterial volatiles present on conspecific eggs to mediate oviposition preference. Due to the ubiquity of bacterial symbionts in the insect realm and the related life histories of Muscidae and Calliphoridae, this same oviposition mechanism may be present in forensically important blow flies, and may therefore be important to the post-CI. The current study was designed to test volatiles emitted from Calliphoridae eggs.

In this study, the attractiveness of inter- and intraspecific eggs to adult flies was investigated. A y-tube was used to present individual males and females of each species with a choice between egg clusters of each species and blank controls, and the preference recorded. The results help elucidate the mechanism for oviposition choice and timing, and help characterize the pre-colonization interval.

Entomology, Diptera, Calliphoridae

G72 Effects of Resource Age and Sterilization on the Attraction of *Cochliomyia macellaria* (Fabricius) and *Chrysomya rufifacies* (Macquart)

Francisco I. Ortiz, BS*, 1818 South 2nd Street, Apartment 62, Waco, TX 76706; and Jeffery K. Tomberlin, PhD, Department of Entomology, TAMU 2475, College Station, TX 77843-2475

After attending this presentation, attendees will understand the attraction of two forensically important blow flies, *Cochliomyia macellaria* (Fabricius) and *Chrysomya rufifacies* (Macquart) (Diptera: Calliphoridae), to different resources. This presentation will also serve to educate attendees about the roles bacteria on dead tissue serve to attract flies.

This presentation will impact the forensic community by demonstrating the need to exercise caution in estimating the period of insect activity (PIA) because of the different rates of colonization by different species. By understanding differences in colonization between species, more accurate period of insect activity (PIA) estimates may be developed.

C. macellaria and *C. rufifacies* are two species of forensically important blow flies whose interaction is important to understanding both their behavior and their impact as evidence in forensic investigations. When both species are present on decomposing animals or bodies, *C. rufifacies* larvae commonly prey on *C. macellaria* larvae. Furthermore, studies on carrión succession suggest that *C. macellaria* is a primary colonizer of carrión, while *C. rufifacies* is a secondary colonizer. However, these studies have all provided only anecdotal conclusions about their colonization behavior.

Blow flies locate carrión primarily through odor signals given off by the decomposing tissue which combine with visual cues to attract flies to a resource. Female flies use these signals to locate the most suitable oviposition location. The aim of this study was to examine the preference of *C. macellaria* and *C. rufifacies* for resources at different

ages of decomposition; to determine if fly preference is due to the microbial content of the resource; and to determine if bacteria isolated from the resource is attractive to blow flies.

A Y-tube olfactometer was used in these experiments. In the first experiment, males and females of both species were allowed to choose between fresh and 3-day old beef liver. The second experiment consisted of testing the preference between sterile and non-sterile beef liver of different ages. In the final experiment, both species were given the choice between sterile nutrient agar and agar colonized with bacteria from the liver. Initial choice, choice after 5 minutes, and residence time at each resource was recorded in each experiment.

Chi-square analyses of the data indicate no significant preference in either species to a resource based initial response. Therefore, final response (i.e. after 5 minutes) was tabulated. *C. macellaria* and *C. rufifacies* exhibited significant preference for fresh liver and 3-day old liver, respectively. Closer analyses of the data indicate males of both species demonstrated a significant preference, but females did not. For experiment two, neither initial nor final choice showed a significant difference between species. Finally, neither species exhibited a significant preference between sterile agar and agar treated with bacteria.

T-test analysis of residence time provided similar results to those determined with the Chi-square tests. Both species spent a significant amount of time at a particular resource. *C. macellaria* resided a significant amount of time on fresh liver while *C. rufifacies* had a greater residence time on 3-day old liver. Additionally, both species spent a significantly greater amount of time on the bacteria and agar than on the sterile agar.

The results from the first experiment support the assumptions that *C. rufifacies* is a secondary colonizer and *C. macellaria* is a primary colonizer. While only anecdotal information was previously available, the data collected in these studies provide a better understanding of the behavior of these blow flies. In some cases, succession data are used to estimate the PIA. For instance, these data are useful in the case of predicting sequence of colonization by *C. macellaria* and *C. rufifacies*. Data from the studies indicate that odors from decomposing remains as well as associated bacteria might be regulating attraction and colonization by these species.

Forensic Entomology, Blow Flies, Period of Insect Activity

G73 Factors Affecting the Rate of Decomposition of Pig (*Sus scrofa*) Carcasses During a Period of Drought in Southern-Western Australia

R. Christopher O'Brien, MFS*, Faculty of Science, UOIT, Oshawa, ON L1H 7K4, CANADA; Ian Dadour, PhD, Centre for Forensic Science, University of Western Australia, 35 Stirling Highway, Nedlands, 6009, AUSTRALIA; Jan Meyer, PhD, Mailbag M309, 35 Stirling Highway, Crawley, 6009, AUSTRALIA; and Shari Forbes, PhD, University of Ontario Institute of Technology, 2000 Simcoe Street North, Oshawa, L1H7K4, CANADA

After attending this presentation, attendees will have an understanding of the factors which affect the rate of decomposition of pigs in southwestern Australia. These decompositional data can be used to better understand the factors which affect decomposition of a human body.

This presentation will impact the forensic sciences community by illustrating the factors which will affect the time since death estimations used by law enforcement agencies. These factors will significantly affect a body exposed to environmental variables for any amount of time in Western Australia. The experimental methodology can be utilized in other parts of the world to determine the impact of local environmental factors on the rate of decomposition.

Estimation of time since death is an important factor in forensic investigations and the state of decomposition of a body is a prime basis for such estimations. Environmental factors have been shown to have a significant influence on the rates of decomposition; these factors can include temperature, solar radiation, rainfall, humidity, physical placement, coverings, and scavenging activity. Many studies have documented and quantified the influence of such factors on the decomposition stages of human bodies and pig carcasses which serve as models of human bodies in North America. However the application of these types of investigations to an Australian environment is still rare. This study provides a quantitative analysis of the impact of environmental factors on the rate of decomposition of exposed pig carcasses in the southern region of Western Australia surrounding the capital city, Perth. Pig (*Sus scrofa*) carcasses of approximately 45 kg were placed in four different environments including native bushland and suburban agricultural land. The carcasses were not protected and had trauma from the headbolt or rifle shot to the skull. The decompositional process was monitored using time-lapse image capture from an infrared camera. Monitoring was conducted for 24 hr cycles until the carcasses reached the skeletonization stage of decomposition. The images were viewed to determine the stage of decomposition and to identify any animal necrophagric activity. Weather data were collected for each location which included temperature and rainfall. This research found that temperature was the most influential factor in determining rates of decomposition with summer having significantly faster rates than any other season. While winter had the slowest rates of decomposition it was also the season with significantly higher levels of rainfall. Scavenging by native and introduced animals significantly affected the rate of decomposition in the cooler months of the year but had no significant impact in the warmer months. The lack of rainfall in all seasons except winter made statistical analysis inconclusive as to the significance of rain on the rate of decomposition. During these experiments, southwestern Australia was experiencing one of the greatest periods of drought in recorded history. Therefore the research examines both the decompositional rates in Western Australia and these rates in periods of drought.

This presentation will include methodology which can be used in other locations throughout the world to replicate the experimentation as well as the results of the study illustrating the importance of such research.

Decomposition, Taphonomy, Western Australia

G74 Associative Learning of *Cochliomyia macellaria* in Response to Larval Resource: Inter- and Intraspecific Resource Interaction, and Presence of Inter- and Intraspecific Larvae on a Resource

Stacy A. Boatright, BS*, 2304 Cornell, College Station, TX 77840; and Jeffery K. Tomberlin, PhD, Department of Entomology, TAMU 2475, College Station, TX 77843-2475

After attending this presentation, attendees will understand the concept of associative learning as it pertains to the blow fly, *Cochliomyia macellaria*. Experiments assessing adult blow fly response to its larval food resource, exposure of both intra- and interspecies to a food resource, and the presence of both intra- and interspecies larvae on a food resource were examined.

This presentation will impact the forensic science community by being the first to assess the importance of blow fly biology as it pertains to the pre-colonization interval (pre-CI) in a forensic investigation.

The pre-CI is the portion of the period of insect activity (PIA) prior to colonization of a food resource. The location phase begins when the insect detects a body and is more than likely governed by volatile odors

not only from the corpse itself, but also from other adult blow flies and their larvae present on the corpse. The acceptance phase begins when the insect first makes physical contact with the food resource. Understanding blow fly behavior under various conditions might allow for more concise estimates of the pre-CI of a body; the current study assesses *C. macellaria*'s behavioral response to three such conditions.

The first experiment addressed whether *C. macellaria* adult flies will be more attracted to food resources on which they were raised. An abundance of *C. macellaria* eggs was gathered from pre-existing colonies and randomly distributed between bull testicles and beef liver and kept under the same conditions. Once the flies reached the adult stage, they were only provided with water and a powdered milk and sugar mixture *ad libitum*. Beginning on the seventh day post-emergence, seven testicle-fed males and seven testicle-fed females were placed individually in a Teflon dual-choice olfactometer and their response to the resources provided recorded; likewise, seven liver-fed males and seven liver-fed females were examined under the same circumstances. Testicles were placed in containers connected to the dual-choice olfactometer, while liver was placed in the other. Resources were rotated between arms with each replicate. The olfactometer was also cleaned between sessions. This regime lasted for five consecutive days. The goal was to determine whether or not adult flies would associate with the odors of the source on which they were raised, thus "choosing" that particular resource.

The second experiment determined whether *C. macellaria* flies are equally attracted to a food resource that has been exposed to adults of the predatory species, *Chrysomya rufifacies*. An equal number of male and female *C. macellaria* were kept in one cage, while an equal number of male and female *C. rufifacies* were kept in a second cage, under the same conditions. Containers of beef liver were introduced to each cage, and one from each of the cages was removed every 24 hours for five consecutive days. Once one 24-hour exposed container was removed from each cage, they were connected to separate arms of the dual-choice olfactometer. Five female and male *C. macellaria* adults were tested to see whether they were deterred from the liver that had been exposed to *C. rufifacies*. Other containers of liver were exposed to each of the fly species colonies for 72-hour time intervals, at which point they were also used in the olfactometer. All *C. macellaria* adults used in this experiment were reared on beef liver.

The third experiment assessed whether the presence of intra- and interspecies larvae affected *C. macellaria*'s attractiveness to a food resource. This study is applicable to forensics because it addresses whether or not *C. macellaria* adults are less likely to lay their eggs on a cadaver that has already been infested with the predatory species, *C. rufifacies*. A similar experimental design with the olfactometer as described previously was used in this study. One container of beef liver containing third instar *C. macellaria* maggots and one container of beef liver colonized by *C. rufifacies* maggots were placed at the arms of the olfactometer. Five *C. macellaria* adults from each sex were tested for five consecutive days.

These experiments are the first to assess the importance of blow fly biology as it pertains to the pre-CI in a forensic investigation. In other words, the current experiments take into consideration a variety factors which may influence the colonization of a food resource by the blow fly, *C. macellaria*.

Forensic Entomology, Period of Insect Activity, Associative Learning

G75 Attraction and Repellance of Blow Flies to Intra- and Interspecific Fecal Bacteria

*Melinda K. Dooley**, and *Jeffery K. Tomberlin, PhD, Department of Entomology, TAMU 2475, College Station, TX 77843-2475; and Adrienne L. Brundage, MS, 2001 Cobblestone Lane, Bryan, TX 77807*

After attending this presentation, attendees will have a greater understanding of the conspecific and interspecific interactions of blow flies: specifically, the role of fly feces and related bacteria on the attraction and repellence of forensically significant blow flies (Diptera: Calliphoridae).

This presentation will impact the forensic community by improving understanding of factors that can affect attraction and oviposition of two of the most common blow flies in the summer in the southern United States, *Cochliomyia macellaria* (Fabricius) and *Chrysomya rufifacies* (Macquart).

The most important duty of the forensic entomologist in a death investigation is to provide an estimate of the time of colonization, or period of insect activity (PIA) which translates into a minimum postmortem interval (mPMI). Blow flies are the most significant insects in death investigations because known patterns of larval development allow entomologists to determine how long a corpse has been colonized. As blow flies generally only oviposit on a body after death occurs, the amount of time that has passed since eggs were laid is the minimum length of time for which the victim has been dead. However, flies may not oviposit immediately at the instant of death. Rather, there are elements that delay oviposition, especially in *C. rufifacies*, which has been observed to arrive at the scene of death first, but only oviposit after other species such as *C. macellaria*. These elements may include quality or decomposition of the resource, the presence or lack of certain bacteria, or conspecific and interspecific signals left in the secretions of flies.

In this study, fly specks were gathered from recently emerged *C. macellaria* adults. A saline solution of the fecal matter was grown on nutrient agar, and the resulting bacteria were cultured and used in preference testing via Y-tube olfactometry. Based on odor alone, fecal bacteria do not produce volatiles strong enough to attract or repel adult flies of either species. However, certain signals must be present to trigger the beginning of oviposition of these two species on their respective timetables.

C. macellaria are typically one of the first species to colonize a resource in the southern United States. However, a few days after death, the majority of maggots on a body may be *C. rufifacies*. Although this species is often one of the first to arrive at a scene of death, adult females will wait to oviposit until after other fly species have begun to colonize the resource. It is possible that the presence of maggots of primary colonizers such as *C. macellaria* somehow prepares or alters the resource, improving the viability of the later-colonizing *C. rufifacies*. The adult *C. rufifacies* may be waiting for some signal that the resource has been colonized by other species before beginning oviposition, and this study investigates the role that *C. macellaria* feces and related bacteria may play in that signaling process.

By increasing understanding of what delays and triggers oviposition on a body, improved estimates of pre-colonization intervals will lead to more accurate estimates of the PMI.

Blow Fly, Postmortem Interval, Oviposition

G76 Three Dimensional Polygonal Model Visualization of *Lucila sericata* From SEM and Stereomicroscopic Data

*Jeffrey R. Christiansen, BS**, Halff Associates, 1201 North Bowser Road, Richardson, TX 75081; and Jeffery K. Tomberlin, PhD, Department of Entomology, TAMU 2475, College Station, TX 77843-2475

After attending this presentation, participants will be able to understand how a true color, three dimensional polygonal model visualization of *Lucila sericata* can be produced from SEM and stereoscopic photomicrograph data.

This presentation will impact the forensic sciences community by providing a tool for better anatomical training methods of forensically important insect species.

Blow flies (Diptera: Calliphoridae) are a cosmopolitan group of insects and often the first to colonize human remains. Therefore, they are often collected as evidence. Analysis and prediction of their age often is interpreted as the period of insect activity (PIA). However, in order to utilize any insect collected from human remains as evidence, they must first be identified. Skills necessary for identifying these insects are gained primarily through courses taken while in college, graduate school, or workshops. Primary information utilized for identifying these insects is found in texts or research publications. These sources contain detailed taxonomic information about each of these species which enables their identification. However, few resources are available that provide three-dimensional imagery for teaching or identification purposes. For this reason, a highlydetailed three-dimensional polygonal model of the species has been created. The creation of an anatomical training tool that can be utilized by any age group would significantly increase the awareness of discipline-specific species. While utilizing two different diagnostic microscopes (i.e. scanning electron microscope (SEM) and dissecting microscope), a better understanding of the anatomical characteristics and landmarks can be understood. The issue becomes, who else can benefit from the data acquired? Usually the investigator is the only individual to benefit. From this stereoscopic data, an accurate three dimensional polygonal model was created using computer software forming the basis of the three dimensional investigational/visualization tool. By combinatorial investigation, a tool can now be utilized by everyone in the form of three-dimensions, true color, high-definition imagery and movies. This proposed model is the first investigational process utilizing both stereoscopic photomicrographs and SEM data to generate a specie-specific three-dimensional polygonal model. *Lucila sericata* is a green bottle fly that is common throughout the United States during the warmer months of the year and has been used in many studies to understand the biology and ecology of blow flies in general. Therefore, this species was selected for the study.

This study is also important because it allows forensic entomologists to better communicate blow fly anatomy to a wide array of sciences including but not limited to pathology. The end result, a three dimensional visualization of the blow fly, offers a compelling tool for teachers at all levels to introduce entomology in the classroom. This concept will continued to be investigated for a further detailed polygonal model, and to include other forensically significant species.

***Lucila sericata*, Visualization, SEM**

G77 An Unusual Case of Homicidal Chest Trauma Using a Golf Club as a Weapon

Carlos F. Chavez-Arias, MD, Puerto Rico Institute of Forensic Sciences, PO Box 11878, Caparra Heights Station, San Juan, Puerto Rico 00922-1878; Javier Serrano, MD, Puerto Rico Institute of Forensic Sciences, Calle Maga Esquina Casia #9, Urb. Reparto Metropol, San Juan, PR 00921; Dario Sanabria, MD, Puerto Rico Institute of Forensic Sciences, Department of Pathology, PO Box 11878, Caparra Heights Station, San Juan, Puerto Rico 00922-1878; and Jose F. Rodriguez, PhD, Institute of Forensic Science of Puerto Rico, Calle Maga Esq. Casia, Urb. Reparto Metropolitano, San Juan, PR 00922*

The goal of this presentation is to describe and discuss an unusual case of homicidal chest trauma caused by a single blow to the chest with a golf club that was used as a weapon.

This presentation will impact the forensic sciences community by demonstrating an unusual mechanism of chest trauma and death produced by a golf club head without penetration of the thoracic cavity by the weapon.

Different accidental injuries from golf equipment have been reported for adults and children. The vast majority of these reported cases were accidental blows to the head from clubs and balls. To this date there are no reported cases in the literature of homicidal chest trauma using a golf club as a weapon. Golf clubs are potentially lethal weapons when used inappropriately. A golf club is particularly designed to hit a golf ball. The club head is capable to accelerate to a great speed. This speed is produced by body motion swinging the club in vertical, circular, and horizontal directions.

This witnessed case involved an 18-year-old, black Hispanic healthy man who received a single blow to the chest in the presternal region with a club head during a fight. Immediately after he was hit he collapsed at the scene. Minutes later he was pronounced dead on arrival at the emergency room.

At autopsy the body corresponded to a well-developed and well-nourished lean male. He was 67 inches tall and weighed 118 pounds. External examination of the anterior torso, disclosed the presence of two well-defined brown-tan abrasions in the medial aspect of the left pectoral region separated by a 1" by 1" inch contused area. One of the abrasions was lateral and higher compared to the other. It measured 3/4" by 1/2" and had a rectangular shape. The other abrasion measured 5/8" by 5/8" and had a triangular configuration. The contused area had a triangular shape with a vertex pointing to the medial aspect of the thorax. The body had no other external signs of trauma. Upon reflection of the skin of the anterior thorax, a localized 1 1/4" by 1" hemorrhagic area was involving the presternal soft tissue and was associated to linear non-displaced fractures of the anterior aspects of the left 5th and 6th ribs at the costosternal junction. The right pleural and pericardial spaces had 1000 ml and 30 ml of liquid blood respectively. The pericardium had an extensive laceration associated with two parallel transmural lacerations of the anterior right ventricular wall, slightly parallel to the heart axis. There was no other cardiac involvement by trauma. The rest of the thoracic and abdominal organs had no lesions. Additional autopsy findings were remarkable for right lung collapse and brain edema. Toxicological evaluation was negative for alcohol, cocaine, opioids, and cannabinoids.

Chest trauma is traditionally described as blunt or penetrating. The trauma is classed as blunt when the chest wall remains intact and as penetrating when the integrity of the chest wall is breached. Blunt trauma is more common than penetrating chest injury, accounting for more than 90% of thoracic injuries. Two mechanisms occur in blunt trauma: by direct transfer of energy to the chest wall and thoracic organs and by differential deceleration, experienced by thoracic organs at the time of the impact. A direct blow to the thoracic wall produces crush and shear injury associated with fractures of bones and soft tissue damage. Ribs may be fractured at the point of impact and damage the underlying

thoracic organs by producing contusions or punctures. This case represent blunt chest trauma in which a great amount of energy was applied over a small body surface causing a penetrating injury of the heart by fractured ribs. An important feature of this injury is that the fractured ribs were not found displaced at autopsy examination. A temporal displacement of these ribs could explain the nature of the heart injury.

Factors such as golf club design and physics of chest trauma are keys for understanding the mechanisms of trauma involved in this unusual homicide case.

Golf Club, Chest Trauma, Homicide

G78 Non-Chemical Suffocation Deaths in Forensic Setting: A Six Year Retrospective Study of Environmental Suffocation, Smothering, Choking, Traumatic, and Positional Asphyxia

Silvia Tambuscio, MD, Legal Medicine for the Court of Padova, Via Rezzonico, 24, Padova, LA 35131, ITALY; and Anny Sauvageau, MD, Lab de Sciences Judiciaires et de Medecine Legale, 1701, Parthenais Street, 12th Floor, Montreal, Quebec H2K 3S7, CANADA*

After attending this presentation, attendees will be afforded a six-year review of forensic autopsies of non-chemical suffocation deaths in the province of Quebec, Canada.

This presentation will impact the forensic community by providing evidence-based data to support common knowledge on non-chemical suffocation deaths.

Suffocation has been the object of several papers but mainly case reports or cases series. Studies of subsets of suffocation deaths, limited to a specific scenery or category, have also been reported, such as suffocation in motor vehicle crashes, lethal crush/traumatic asphyxia, fatal entrapments in on-farm grain storage bins, suffocation by plastic bags, coffee thrombosis deaths, or overlaying and wedging deaths in children. However, no systematic study has ever portrayed non-chemical suffocation deaths in forensic setting. A six year retrospective study of all non-chemical suffocation cases in the laboratory in the forensic victim population aged of more than one year will be presented.

In the province of Quebec (Canada), a single centralized forensic laboratory covers the entire 7.5 million province population. Over a six year period (2000-2005) all autopsy cases performed at this laboratory were retrospectively reviewed for non-chemical suffocation deaths in the forensic victim population aged of more than one year. For each case, the type of suffocation, manner of death, gender, and age were compiled. In the case selection, cases of suffocation occurring in association with another type of trauma, such as sharp or blunt weapon, were excluded. Cases of suffocation in association with another category of asphyxia, such as hanging combined with suffocation by a plastic bag overhead were also excluded.

During the six year study period (2000-2005), a total of 96 non-chemical suffocation cases were autopsied in the forensic laboratory of the two Lab Sciences Judiciaies. This represents 2.3% of all forensic autopsies for the same period. Overall, cases were aged from two to 90-years-old (mean \pm standard deviation, 46 \pm 19), with similar averages for men (46 \pm 19) and women (48 \pm 24).

Type of suffocation: Traumatic /positional asphyxia ranked as the leading type of non-chemical suffocation, with over half cases (54%). Smothering and choking followed, in 30% and 14% of cases respectively. Entrapment/ environmental suffocation, on the other hand, was found in only 2% of cases.

Gender and Age: Overall, a strong male predominance was observed, with two-thirds of male victims. Traumatic

/positional asphyxia remained the leading type of non-chemical suffocation in male victims. However, the type distribution of non-chemical asphyxia differed in female victims, smothering being the most common type (64%), relegating mechanical/positional asphyxia to second position (32%). Choking occupied third position in both gender, with 16% and 5% in males and females respectively. As for age, the average in each type of suffocation did not seem to differ significantly.

Manner of death: Taken as a whole, manner of death in non-chemical suffocation is generally ruled as accidental (73%). In fact, all entrapment/ environmental suffocations and traumatic/ positional asphyxia deaths were accidental, as well as the vast majority of choking (85%). Smothering, in contrast, is associated with a higher variability of manner of death between cases: though suicide makes up the main core (17 cases), manner of death was ruled differently in 12 cases, including six homicides and five accidents. The most common form of smothering was from a plastic bag overhead (69%), with all suicidal smothering cases being related to this method.

In the last 15 years, evidence-based medicine has been advocated as a new paradigm, proclaiming that evidence from research is the best basis of clinical decisions and practice. In this global context, forensic pathology is no exception and is increasingly becoming a science and decreasingly an art. Nevertheless, there are still several areas of forensic pathology mainly based on tradition, with textbooks describing common knowledge that is not supported by modern research data. The present study is intended to contribute to evidence-based data on non-chemical suffocation deaths. Despite several case reports, case series and a few studies on suffocation subsets, this is the first time non-chemical suffocation deaths are systematically studied. Taken as a whole, the outcomes of this study corroborate the literature data, thus supporting the common knowledge with evidence-based data.

Asphyxia, Suffocation, Manner of Death

G79 Death by Electrocution: Unusual Findings in a “Love Nest”

Sandra Cornetta, MD, Sezione di Medicina Legale - Università di Bari, piazza Giulio Cesare, 11, Bari, 70124, ITALY; Fiorenza Zotti, PhD, Section of Legal Medicine, Place G. Cesare, Bari, 70124, ITALY; Roberto Gagliano-Candela, AS, University of Bari, Cattedra Tossicologia Forense, Policlinico, Piazza G. Cesare 11, Bari, 70124, ITALY; Andrea Marzullo, MD, Sezione di Anatomia Patologica - Università di Bari, piazza Giulio Cesare, n.11, Bari, 70124, ITALY; and Alessandro D. Erba, Sezione di Medicina Legale - Università di Bari, piazza Giulio Cesare, n.11, via Prospero Petroni, n.37, Bari, 70124, ITALY*

After attending this presentation, attendees will realize the significance of a complete forensic examination of each case in order to understand the real cause of death. Sometimes the evidence found at the crime scene could lead examiners to misunderstand the cause of death, but only by collecting pathological, toxicological, immunological, and histological findings, you can be sure to correctly solve a case.

This presentation will impact the forensic science community by showing some unusual findings observed in an apartment that seemed to be a quiet love nest. Some of these findings seemed to suggest a different cause of death from the real one that was obtained through histological examinations.

A 63-year-old married man with two children was found dead in an apartment in a suburb of Bari, Italy. The apartment turned out to be a “love nest” of sorts, complete with nude pictures on the walls, erotic books, and pornographic videos and magazines. A large quantity of condoms and various types of sex toys were discovered in the drawers

throughout the premises. None of the family members of this man were aware of this apartment.

The body was found completely nude, lying prone on the floor of the kitchenette with the knees and pelvis in a flexed position. On the wall were exposed electrical wires from the thermostat of the boiler, a tool drawer on a shelf, and screwdrivers and pliers scattered on the floor around the cadaver. External inspection of the body showed no presence of any significant traumatic lesions except for some oval, slightly depressed, yellowish, grazed areas on the back of the right hand and on the external malleolus of the right ankle which resembled parchment.

An autopsy revealed a diastasis between the IV and V cervical vertebrae with light hemorrhage of the soft tissue which probably happened just before the moment of death (*limine vitae*) due to the anomalous position assumed by the cervical roots after the victim fell to the floor into a very confined space. It was later discovered that the victim suffered from pre-existing cervical arthrosis. Immunological investigation was carried out on the suspicion that the death may have been the result of anaphylactic shock, but the findings were negative. Toxicological investigation showed the presence of nontoxic levels of Sildenafil (the principal active ingredient in Viagra®), along with high levels of some components of a cutaneous disinfectant used in the sterilization of medical surgical instruments.

These findings, which seemed quite curious, were attributed to the possible transrectal absorption of the substance, most likely used in the disinfection of some of the autoerotic instruments discovered in the apartment. In the end, the definitive diagnosis of the cause of death was arrived at by means of histological verification carried out on fragments of skin taken from the grazed areas of the right hand and ankle which showed signs of the passage of electrical current. In particular, it was the coagulative changes of the epidermis (i.e., cytoplasmic hyperesinophilia, lengthening of the nuclei) and congestion of the small blood vessels which suggested that the subject died of electrocution.

Electrocution, Sex Toys, Transrectal Absorption

G80 A Fatal Case Due to a Pitchfork Penetrating Head Injury

Margherita Neri, PhD, Santina Cantatore, and Cristoforo Pomara, PhD, Department of Forensic Pathology University of Foggia, Viale degli Aviatori 1, Foggia, 71100, ITALY*

After attending this presentation, attendees will have a better understanding of an unusual fatal case of penetrating cranial stab injury due to pitchfork.

This presentation will impact the forensic community due to the rarity of the deaths by pitchfork, the particular features of eye and intracranial lesions caused by the tool, and for the importance of a careful autopsy examination in order to clarify the exact mechanism of the death.

Penetrating head injuries can be the result of numerous intentional or unintentional events, including missile wounds, stab wounds, and motor vehicle or occupational accidents (nails, screwdrivers). The most common wound is a knife injury, although bizarre craniocerebral-perforating injuries have been reported that were caused by nails, metal poles, ice picks, keys, pencils, chopsticks, and power drills. Here is presented a case where a farmer was wounded with a pitchfork.

In the rural area in southern Italy, a 56-year-old Caucasian farmer was found unresponsive by his father-in-law a few meters from their farmland, with a tine of the pitchfork penetrating the right eye. He was quickly taken by helicopter to the nearest hospital in serious clinical condition and immediately accepted in the Intensive Care Unit. Glasgow Coma Scale score was three. A penetrating circular wound in the right eye was detected. The cranium CT showed a large hemorrhagic area in the right frontal-temporal-parietal lobe, hemoventricle and right to left brain shift. Subarachnoid hemorrhage and fractures of the lateral wall of

the orbital bone in the right occipital region was present. Neurosurgical treatment was performed for subarachnoid hemorrhage, but the man was pronounced dead four days after the penetrating stab trauma.

Prosecutor arranged the autopsy on the body because the circumstances of the wounding suggested that the death could have been a murder in connection with the father-in-law.

A complete autopsy was performed 24 hours after death. The external examination revealed a laceration in the external part of the upper eyelid measuring approximately 0.5 cm x 0.4 cm and surrounded by traces of reddish color, a wide subconjunctival hemorrhage and in the upper lateral quadrant of cornea a 0.5 cm in diameter circular tear. This corneal lesion penetrated in the eyeball that was removed and revealed on the lateral wall of the orbital bone a round bone defect measuring 0.5 cm in diameter that went through the orbit in the cranial cavity and exited in the anterior cranial fossa with a circular tear of dura mater measuring 0.5 cm in diameter. The brain was oedematous and was fixed for three weeks in 10% buffered formalin prior to being sectioned with coronal cuts. Dissection revealed right to left shift of the midlines structure. A circular injury measuring 0.5 cm was present in the right frontal region. This injury penetrated into the parenchyma from the base in the frontal region upwards and maintained the same diameter through the frontal end of the parietal lobes. The entire distance from the anterior cranial fossa bone defect to the parietal lobe measured 7 cm.

Wide foci of hemorrhages were present in the right hemisphere and characteristic petechial hemorrhages continuing throughout coronal cuts. Examination of the other organs was unremarkable. Routine histological investigation applying haematoxylin and eosin staining was performed on various organs and revealed a detachment of the upper epidermal areas mainly extends through the basal-cell layers with flattened and stretched epidermis on the eyelid skin. The deeper parts of stratum papillare and underlying upper layers of the corium were characterized for wide erythrocytes accumulation. The eye samples collected on the round laceration were stained with trichromic dye and presented the discontinuation of corneoscleral coat, choroids, until posterior camera and vitreous space with wide spread erythrocytes infiltration. Brain sections showed intraparenchymal diffuse hemorrhages.

The examination of the pitchfork showed a perfect compatibility with eye and intracranial lesions. No fingerprints from the father-in-law were collected on the pitchfork.

According to the autopsy findings and histological data, death was attributed to brain hemorrhages. The tool that caused the death was the pitchfork, and the mechanisms of trauma were consistent with an accidental trauma.

Furthermore, the circumstantial data confirmed the hypothesized death scene: it was an accidentally self-inflicted stab penetrating injury due to pitchfork.

Pitchfork, Self-inflicted Stab Lesions, Penetrating Head Injuries

G81 Head Injury Associated With Posterior Distraction of the Spine in a 4.5 Months Old Baby: Analysis of the Lesional Mechanisms

Audrey Farrugia, MD, Annie Geraut, MD, Bertrand Ludes, MD, PhD, and Jean Sébastien Raul, MD, PhD, Medico-Legal Institute, 11 Rue Humann, Strasbourg, 67065, FRANCE*

After attending this presentation, attendees will understand the analysis of lesional mechanisms in association with lesions of head and spine in a young baby.

This case report concerns a 4.5-month-old boy measuring 62.5 cm and weighing 5.5 kg who was treated by an emergency team for a cardio-respiratory arrest at the parent's house. He was declared dead upon arrival at the hospital. The first explanation by the mother was that the child had been dropped and it suffered an accidental fall down the stairs. Quickly, the theory of an accident fall was denied by the two parents.

The postmortem CT scan of the entire body showed a right parietooccipital fracture with cerebral lesions. The medicolegal autopsy found a contusion with abrasion of parietooccipital region with a bending of head, a huge hematoma associated with bone defect, diastatic fracture and extradural and subdural hemorrhage, cerebral contusions and oedema. Skin ecchymosis (three ecchymosis in right temporal region and one ecchymosis in left frontal region) was also noted. The dissection of the spine by posterior incision showed a fracture of the right part of the neural arch of T12 with extra and subdural hemorrhage of the medullar cord associated with haematic infiltration of the posterior part of the intersomatic spaces extensive on 7 cm and a small ecchymosis of the anterior part of T12 body. Because of the initial story indicating the child fell, an opening of the joints of the four limbs was performed and no macroscopic lesion were noted. The knee and wrist joints were removed for anatomopathological analysis. There was no congestion of the internal organs.

The anatomopathological findings confirm the macroscopical description consistent with premortem lesions. They pointed out an infra-clinical fracture of the right knee and a haematic infiltration of the left radio-ulnar membranous.

The spine lesions were consistent with impact of the parieto-occipital region associated with a violent anterior flexion of the spine leading to posterior distraction lesion of the spine. The infra-clinic lesion of the right knee and the left wrist suggest a violent projection of the baby against a hard surface (like a wall) followed by a fall.

This case report shows the significance of carrying out a complete dissection of the spine and the spinal cord and performing an opening of the limb joints and a removal for anatomopathological analysis in cases of suspected of non accidental injury in a baby.

Child Abuse, Lesional Mechanisms, Head and Spine Injury

G82 Genetic Testing of Sudden Cardiac Death Victims: From a Forensic to a Multidisciplinary Approach

Katarzyna Michaud, MD*, Centre Universitaire Romand de Médecine Légale, Rue du Bugnon 21, Lausanne, 1005, SWITZERLAND; and Bernice Elger, PhD, Centre Universitaire Romand de Médecine Légale, 1211 Genève, Rue Michel-Servet 1, Genève, SWITZERLAND

After attending this presentation, attendees will learn a practical, ethically, and legally acceptable approach to cases of sudden cardiac death thought to be of genetic etiology.

This presentation will impact the forensic community by demonstrating an interdisciplinary approach in cases of sudden cardiac death believed to be related to channelopathies.

Sudden cardiac death is considered as the most important cause of death in western countries. In cases of sudden, unexpected deaths and especially in young people, a forensic autopsy is required, frequently followed by complementary investigations, in order to determine the cause of death. However, it happens that even after an autopsy is performed in accordance with international recommendations, the cause of death remains unexplained. Such cases, called also autopsy negative sudden deaths, are not rare (6% to 40%) and are often considered to be due to a sudden cardiac arrhythmia.

Thanks to the progress made in molecular biology, it is admitted that most cases of sudden cardiac death of children and young adults are

related to genetically determined cardiac diseases. Some of them have a morphological substrate at autopsy as hypertrophic cardiomyopathy. But those related to channelopathies are impossible to detect without genetic analysis. Postmortem genetic testing referred to as molecular autopsy was recently carried out by many authors in cases without morphological explanation of the sudden death and allowed to identify pathogenic mutations described already in clinically known arrhythmic syndromes. However, it is also possible to perform genetic testing to refine the diagnosis of a hypertrophic cardiomyopathy in cases without evident morphological substrate. The genetic cardiac disease may explain the death, but it may also be at the origin of a traffic accident with a loss of car control or drowning. The channelopathies may also be involved in cases supposed to be related to intoxications. Therefore, it is important to consider the genetic screening in forensic investigations.

The legal and ethical aspects of genetic testing in forensic investigation are complex. In Switzerland, the investigating magistrate may mandate genetic testing in the forensic context in order to determine the cause of death. In fact, the particularity of medicolegal autopsy is that during the investigation procedure and in contrast to a clinical context the genetic tests can be carried out without the consent of the dead person or proxy consent. The consent is however necessary for any research activity. Genetic screening is important to establish the cause but also to detect the asymptomatic carriers in order to prevent sudden death in other family members. This prevention involves a multidisciplinary collaboration. In Lausanne, such collaboration was established between services of cardiology, medical genetic, toxicology, and forensic medicine.

This presentation will be illustrated by autopsy cases for which the interpretation of the results of the genetic screening is explained in the light of other autopsy findings. The interdisciplinary collaboration as well as the juridical and ethical aspects of genetic analyses in cases of sudden cardiac death will also be briefly discussed.

Sudden Cardiac Death, Channelopathies, Molecular Autopsy

G83 Unexpected Death of 24-Year-Old Male With a Phenotype Strongly Suggestive of Lujan-Fryns Syndrome

Stojan Petkovic, PhD*, Department of Forensic Medicine, Clinical Center of Vojvodina, Hajduk Veljkova 5-7, Novi Sad, 21000, SERBIA AND MONTENEGRO; Branislav Budakov, MD PhD, Hajduk Veljkova 3, Novi Sad, 21000 SERBIA AND MONTENEGRO; Slobodan Savic, PhD, School of Medicine, University of Belgrade, Institute of Forensic Medicine, Deligradska 31a, Belgrade, 11000, SERBIA AND MONTENEGRO; and Isidora Samoilik, MD, Department of Pharmacology and Toxicology, Faculty of Medicine, Hajduk Veljkova 3, Novi Sad, 21000, SERBIA AND MONTENEGRO

After attending this presentation, attendees will be acquainted with features of a rare genetic disorder which may be of great interest in common forensic practice, but at the same time is very difficult to be recognized.

This presentation will impact the forensic community demonstrating that in certain cases sudden and unexpected death could be attributed to peculiar genetic disorder which has not been described until now in forensic literature.

The presented case concerns unexpected death of a 24-year-old male shortly after his discharge from the hospital where he was admitted due to severe psychiatric behavioral disorder. He had been treated in the course of three months with the following final diagnoses: moderate mental retardation, non-organic non-specified psychosis, and significant behavioral disorder which needs special care and treatment. He was sent home in the phase of psychiatric symptoms' remission. Heteroanamnestic data obtained from the family members revealed his

cognitive and behavioral impairment many years before hospitalization; in addition, they described the physical status of the young man two days after his hospital discharge-frequent vomiting, severe abdominal pain, fever and exhaustion. Thus, he refused to eat and *ante finem* he even couldn't open his mouth. Together with other family members, his mother tried to help him by giving food and water, but all the efforts were in vain – he died in his bed. The police report confirmed all statements given by the deceased's family.

The external examination showed distinct facial dysmorphism (elongated narrow face, prominent forehead, long nose, maxillary hypoplasia, and small mandible), as well as marfanoid stature with long slender extremities. The internal examination disclosed aortic narrowing (circumference of 4.5 cm at the valves level), right aortic arch, low heart weight (240 g) with normal thickness of the left and right ventricle wall. The large intestine was widened, tensed, and full of gases and liquefied feces. No other pathological abnormalities were noticed in all other examined organs. Microscopically, slight congestion and edema of all tissues were found; specific staining for elastic fibers (Verhoeff method) showed rupture of elastic lamina and scarcity of elastic fibers with cystic degeneration of aortic media.

The postmortem toxicological screening detected the presence of clozapine and fluphenazine (neuroleptics) in the blood and bile, as well as clozapine and midazolam (benzodiazepine) in the stomach content. These findings fitted well the data in the medical records informing that the man received depot intramuscular injection of fluphenazine decanoate (25 mg) three days before his release and was instructed to continue with his therapy at home by taking clozapine (50 mg three times a day), lorazepam (2.5 mg three times a day) and midazolam (15 mg when needed at night). In the conclusion of the autopsy protocol, the cause of death was attributed to paralytic ileus due to antipsychotic therapy applied.

On the basis of the case circumstances, collected medical records, heteroanamnestic data and the autopsy findings - including peculiar facial appearance along with both macroscopical and microscopical cardiovascular features (narrowing of aortic root and ascending aorta and mediocystic degeneration of aortic wall), there was a strong suspicion on the Lujan-Fryns syndrome. In the available forensic literature the case of the Lujan-Fryns syndrome with fatal outcome is not found.

The Lujan-Fryns syndrome is defined by X chromosome-linked mild to moderate mental retardation, distinct facial dysmorphism (long narrow face, prominent forehead, long nose, maxillary hypoplasia, and small mandible), marfanoid stature with long slender extremities and behavioral problems. The genetic defect is not known; therefore the diagnosis is based on the presence of the clinical manifestations.

Lujan-Fryns Syndrome, Paralytic Ileus, Antipsychotics

G84 Fatal Air Embolism During Hemodialysis

B.G. Brogdon, MD*, University of South Alabama Medical Center, Department of Radiology, 2451 Fillingim Street, Mobile, AL 36617; and LeRoy Riddick, MD*, University of South Alabama Medical Center, Department of Pathology, 2451 Fillingim Street, Mobile, AL 36609

By attending this presentation, attendees will learn of this extremely rare complication of dialysis, understand the most likely cause, and the difficulties in verifying the diagnosis.

This presentation will impact the forensic science community by reminding them of this rare complication (almost exclusively related to human frailty thwarting an otherwise foolproof system), its presentation and diagnosis.

Systemic air embolization during renal dialysis is so rare it is not referenced in any major neurology text since 1976. The most recent

articles found by computer search even mentioning this complication are from 1985 and 1989.^[1,2] This reflects the effectiveness of safety devices built into hemodialysis systems in recent decades. Air embolism can occur, however, in dialysis setting through improper use or technique with venous access outside the monitored system.

A 53-year-old man had undergone renal dialysis thrice weekly for three years because of end-stage renal disease. While on dialysis his general health otherwise was good. He was normotensive, without evidence of cardiac disease, and with normal blood glucose determinations. He had been evaluated and approved as a candidate for renal transplantation and was awaiting a donor organ.

Early on a Saturday morning he reported to the dialysis facility for his final session of the week, along with eleven other patients. This Saturday the facility was understaffed with one of two nurses (RNs) missing and one patient care technician (PCT) absent. Nevertheless, the preparation and dialysis proceeded normally for the patient through the rinse-back phase. Disconnected from the dialysis machine, he had a routine sitting blood pressure check recorded as 169/86. He then positioned himself for the routine standing blood pressure check but complained of lower extremity cramping (a common complaint in dialysis patients) and sat back down on the dialysis chair. The PCT hurriedly plugged in the line of a half-filled saline bag hanging on the machine. This is a routine treatment for post-dialysis cramps or hypertension (a BP of 86/47 was recorded).

It is important to note here that the patient is disconnected from the machine and its safeguards against air in the system. The saline bag (which should have been full) and its line are outside the machine and have no air alarm. The line from the bag is connected to an existing venous access in the forearm. The bag ran empty or nearly so and was hand pumped by the PCT to get every bit of saline out of it, while calling for help. A full saline bag was quickly obtained and replaced the empty one, but no one recalled having cleared the air from the new bag and its line.

The patient fell back in the chair, unconscious and unresponsive. He could not be revived. An ambulance was called and transported the patient to a hospital. There was no venous access during transport. On admission, he remained unconscious and unresponsive. A non-contrast CT of the head showed scattered small round low-density areas on the convexity of the cerebral hemispheres suggesting air embolism. On two subsequent daily CT studies, the air shadows were gone but massive swelling of the right cerebellum with subtentorial herniation consistent with acute infarction.

Electrocardiography suggested an anterior myocardial infarction. A cardiac catheterization showed ventricular changes consistent with infarction, but coronary arteriography showed a remarkably clean coronary arborization, given his history, with only minimal to mild atherosclerosis and no occlusive disease through five and six bifurcations. Patent coronary arteries and a subendocardial infarct were confirmed at autopsy.

The mechanism and route of systemic air embolism via venous access will be discussed.

Renal Dialysis, Fatal Complication, Air Embolism

G85 Traffic Accident Deaths? The Importance of Autopsy

Duarte N.P. Vieira, PhD*, Instituto Nacional de Medicina Legal, Coimbra, 3000-213, PORTUGAL; Cristina Cordeiro, MSci, Instituto Nacional de Medicina Legal, Largo da Sé Nova, Coimbra, FL, PORTUGAL; and Helena Garcia, MD, CEDAP, Av. Calouste Gulbenkian, Coimbra, 3000, PORTUGAL

After attending this presentation, attendees will understand Portuguese law which determines that a forensic autopsy in victims of traffic accidents must always be performed in cases of immediate death or death without medical assistance. The importance of the autopsy in these situations is obvious, since the accident is not always the cause of death. Situations of apparent victims of traffic accidents that were suicides or homicides have been described as well as natural deaths.

This presentation will impact the forensic science community by presenting several practical cases of apparent traffic accident victims in which the autopsy presented some surprises and totally different situations from those initially expected.

The need of a full autopsy and the demanding of complementary exams in these cases, namely histological, must be emphasized, reminding the fact that several judicial errors can occur in countries where a forensic autopsy is not routinely performed. Insurance rewards can be incorrectly taken into account, homicides cannot be detected, an accidental aetiology can be given to a suicide situation.

Traffic Accidents, Autopsy, Natural Death

G86 Undiagnosed Preeclampsia-Eclampsia Leading to Maternal Death

William J. Bonner, BA*, 1100 South Broad Street, Unit 402B, Philadelphia, PA 19146; John E. Tomaszewski, MD, Department of Pathology and Laboratory Medicine, Hospital of the University of Pennsylvania, 3400 Spruce Street, Philadelphia, PA 19104; and Fredric N. Hellman, MD, Office of the Medical Examiner, Fair Acres, Rte 352, Lima, PA 19037

After viewing this presentation, attendees will appreciate how common preeclampsia-eclampsia is, the necessity for early diagnosis of the disorder, and the dangers encountered when it goes undiagnosed.

This presentation will impact the forensic community by bringing attention to a frequent complication of pregnancy that can be deadly if overlooked by healthcare providers. With more attention and continuing research, this disorder will be better understood, and future mothers who suffer from the disorder will potentially be saved.

Preeclampsia-eclampsia is a common hypertensive disorder of pregnancy with significant global morbidity and mortality. This disorder can be effectively treated with early recognition, but imposes serious risks for both the mother and the fetus when left untreated. Physicians sometimes fail to realize developing preeclampsia and, as a result, place both the mother and fetus in grave danger. The cause of this disorder is currently unknown, but many different ideas have been considered. Perhaps with a better understanding of the etiology of preeclampsia-eclampsia, physicians will less frequently overlook its warning signs.

The case of an 18-year-old pregnant black female found unresponsive on a pullout sofa in her apartment is reported. The decedent had received regular prenatal care at a local hospital. Medical records disclosed that she exhibited significant proteinuria of 8.8 g/24 hr five days prior to her death, with relatively normal blood pressure measurements. Instead of being admitted to the hospital, her physician elected to send her home on bed rest. Autopsy records revealed that the decedent was 38 weeks pregnant at the time of death, with autopsy

examination revealing some well-known sequelae of preeclampsia-eclampsia, including intracerebral hemorrhage and platelet and fibrin microthrombi of the kidneys that indicated a thrombotic microangiopathy. Hepatocellular necrosis was also observed. The singleton pregnancy revealed an unresponsive male fetus with no evident developmental abnormalities. The cause of death was listed as complications of preeclampsia, with extensive intracerebral hemorrhage. **Preeclampsia-Eclampsia, Maternal, Death**

G87 Rupture of the Left Ventricle Due to Blunt Trauma - A Pediatric Case Study

Francois Paysant, MD*, Chu, Hopital Michallon, BP 217, 38043 Grenoble Cedex 9, Grenoble, FRANCE

The goal of this presentation is to describe cardiac rupture following thoracic or abdominal trauma, which is relatively unknown, particularly in the pediatric traumatology.

Cardiac tamponade due to traumatic rupture of the chambers of the heart, in particular the left ventricle, after blunt thoracic trauma is described only sparsely in the literature. Most cases involve multiple thoracic trauma following motor vehicle accidents. To the best of knowledge, blunt traumatic injury following a household accident has not been described.

The case study will be presented of a five-year-old victim of a household accident, in which two concrete basins apparently fell on him. He died quickly despite attempted resuscitation.

The autopsy showed an ecchymotic scrape in the lumbar region as the only external lesion, with no bone injuries, bilateral pulmonary contusions at the base of both lungs, hemorrhagic extravasation of the diaphragm and mediastinum, hemopericardium, and massive damage to the apex of the left ventricle. Pathological exam confirmed the traumatic origin of the cardiac rupture, with no underlying pathology.

The mechanisms described in the literature that result in such lesions, the mechanism which the authors believe most probable in this case, and the importance of background information will be discussed. In this case study, lack of specific information concerning the accident prevents a definitive conclusion of the exact mechanism that caused this massive trauma particularly due to the fact that the external examination couldn't find any lesion in favor of a thoracic or abdominal traumatism. It is unknown if such an isolated case of a lesion causing almost immediate death has previously been described in the literature.

Blunt Thoracic Trauma, Left Ventricular Rupture, Autopsy

G88 Postmortem Examination of Coronary Artery Stents Using a Hand-Held Rotary Tool

Christopher Tape, MD*, and Patrick E. Lantz, MD, Department of Pathology, Wake Forest University, SOM, Medical Center Boulevard, Winston-Salem, NC 27157-1072

The goal of this presentation is to describe a practical technique for postmortem evaluation of coronary artery stents.

This presentation will impact the forensic community by permitting evaluation of intra-luminal patency, thrombosis, and restenosis of coronary artery stents and assist in determination in assigning cause and manner of death.

Since the development of the intra-luminal coronary artery stent in the late 1980's the use of coronary stents has increased dramatically worldwide. In 2005 one or more stents were placed within coronary

arteries of 620,000 patients in the United States. Numerous clinical studies have shown the benefits of coronary artery stents in the treatment of coronary artery disease; however, the main early complication with an intra-luminal coronary artery stent is thrombosis, while the primary long-term complication is in-stent restenosis. Today, stent surfaces and coatings are designed to prevent thrombogenesis and many elute drugs that inhibit neointimal proliferation to reduce in-stent restenosis. Despite advances in stent technology, stent thrombosis and in-stent restenosis remain common complications that can lead to myocardial ischemia, infarction and possible death. Discovery of clinically significant stent complications at autopsy can be crucial for the pathologist trying to determine the cause or manner of death. However, evaluation of coronary artery stents at autopsy is challenging and has been limited to postmortem angiography, serially sectioning the stent with a low-speed diamond saw or simply by visual examination of the stent lumen and estimating any luminal narrowing. Most medical examiner offices cannot afford the expense, space, or training required for postmortem angiography or a low-speed diamond saw to examine coronary artery stents.

A hand-held rotary tool can serially section coronary artery stents with minimal deformation of the stent, distortion of the luminal space or disruption of intra-luminal contents. The excised coronary artery stent is serially sectioned in 2 -3 mm increments. When laid out in cross-section from proximal to distal, the sections of the stent and surrounding coronary artery can be assessed and photographed. Luminal contents can be removed by careful dissection using 20-gauge needles. Subsequent histological evaluation can determine if the intra-luminal material is postmortem clot or premortem thrombus. Sectioning of coronary stents with a hand-held rotary tool is affordable, easy to master, and permits objective assessment of intra-luminal coronary artery stent patency, thrombosis or restenosis.

Forensic Science, Coronary Artery Stent, Hand-Held Rotary Tool

G89 Detection of Wild Game DNA in Maggot Tissue

Jill C. Ross, BS, and John R. Wallace, PhD, Department of Biology, Millersville University, Millersville, PA 17551; and Jane E. Huffman, PhD, Northeast Wildlife DNA Laboratory, East Stroudsburg University, East Stroudsburg, PA 18301*

After attending this presentation, attendees will learn a new technique to assist conservation or game officers in the identification of illegally harvested wild game through the detection of DNA specific to several game species in maggot tissue. The attendee will learn how to rear, collect and preserve maggots, identify insect developmental stages as well as perform molecular analyses to identify non-human DNA.

This presentation will impact the forensic community as well as game law enforcement by demonstrating that entomological evidence can be useful in criminal investigations other than determining a minimum postmortem interval. To date, molecular analyses are useful to identify game species through their DNA; however, analyzing insect tissue for the presence of animal/bird DNA may provide another technique useful in wild game management and conservation.

Poaching wildlife is a problem faced by many conservation and game officers and many people are caught and convicted each year, but it is a crime that even more offenders get away with. Annually, there are approximately 1,000 big game poaching cases prosecuted. Unfortunately, many cases do not reach the court of law due to either the lack of personnel required to patrol over 26,000 square miles of forested game lands or lack of evidence required to identify the game species in question. The use of entomological evidence in human death-scene investigations in terms of estimating the minimum postmortem interval has been well documented as well as to some degree with wildlife. In

addition, insect evidence can be used to differentiate between human and animal DNA through molecular analyses of the food stuffs in maggot crops. The purpose of this study was to examine maggot tissue (crop or entire body) and determine if wild game DNA could be detected using PCR analysis. The objectives for this study were to develop protocols using current PCR technology to identify and compare wild game DNA isolated from Dipteron larvae, and determine if larval developmental stage influenced the isolation and identification of wild game DNA.

Three species of forensically important flies were reared in the laboratory (Calliphoridae: *Calliphora vicina* and *Lucilia cuprina*; Sarcophagidae: *Sarcophaga haemorrhoalis*) on approximately 350 g of deer, bear, coyote, bobcat livers. Bear, deer, coyote, fox, and bobcat livers were obtained from either euthanized animals or vehicle strikes. They were frozen immediately after removal. Fly larvae were collected at mid-molt from each larval instar, preserved in 95% ethanol and identified for species and age confirmation. After identification, maggots were individually preserved in 1.5mL of 95% ethanol and shipped in centrifuge tubes to the Wildlife Forensics Laboratory in East Stroudsburg University for PCR analysis.

Before DNA extraction, maggots were washed to remove potential external contaminants. Each maggot was individually soaked for 2 min a 1.5mL tube containing 1mL of 20% bleach. The bleach was removed and each maggot was rinsed twice with 1 mL of sterile distilled water. Each clean maggot was with iris scissors, then a ventral incision was made from the posterior to anterior end of the maggot. If possible, the crop was removed with forceps. In some circumstances, either the entire anterior inside of the maggot was removed or the entire maggot was extracted.

Amplifications were performed using Promega PCR Master Mix.

Each reaction included 1 μ L of each primer (5 pmol/ μ L) and 5 μ L of DNA extract. The PCR program consisted of an initial denaturation cycle of 95°C for 3 minutes, 45°C for 1 min and 72°C for 1 minute-30 seconds, then continued with 33 cycles of 94°C for 1 minute, 45°C for 1 minute and 72°C for 1 minute-30 seconds, with a final extension at 72°C for 3 min 30 s. The success of PCR reactions was determined using an agarose yield gel stained with ethidium bromide. Sequences were aligned and edited using Sequence Navigator software (Applied Biosystems). Quantitation of crop extractions showed the amount of DNA recovered varied with the species analyzed. The extractions produced at least 1.0 ng/ μ L. The samples analyzed produced the correct mtDNA haplotype for deer.

Maggot Tissue, Wild Game, DNA

G90 Conversion of the Wyoming State Crime Laboratory From FM-BIO Slab Gel Technology to the AB 3130 Genetic Analyzer for CODIS and Casework Sample Analysis

Timmy L. Neece, BS, BA, 1239 9th Street, Apartment 1, Huntington, WV 25701*

After attending this presentation, attendees will have gained an understanding of the work involving validation of the forensic methodology used with an Applied Biosystems 3130 Genetic Analyzer for genotyping CODIS. This validation includes the study of precision, reproducibility, concordance, sensitivity and the ability to resolved mixtures of biological samples.

This presentation will impact the forensic community due to its validation of methodology for use on an instrument and associated kit technologies is vital to obtaining precise and accurate profiles of genetic samples for case work or the CODIS database.

For a method to be validated for forensic analysis it must meet several guidelines put in place by the Scientific Working Group on DNA

Analysis Methods. The data must show a degree of precision and reproducibility based on known laboratory controls. To validate such a system it must be shown that there is no contamination between samples run on the instrument. A series of non-probative samples must be run to verify that the protocols are suitable for samples that could be encountered during forensic casework.

The validation was performed with the Profiler Plus™ and the COfiler™ allelic kits and all the samples were analyzed using the Genemapper ID™ software. To ensure the reproducibility and precision of the instrument a series of allelic ladders were injected. The allele calls and the peak heights were analyzed and confirmed that the protocols performed by the Wyoming State Crime Laboratory (WSCL) were conservative enough to meet the stringent standards necessary for forensic investigation. A series of fifteen samples were amplified, run and analyzed with the standard WSCL protocols. These samples had been analyzed before on the WSCL's AB 310 genetic analyzer and had known profiles. The experimentation with the 310 concluded that the instrument was capable of producing profiles that matched the known profile. These studies demonstrated that no contamination between samples injected on the instrument occurred. With each study, negative controls were performed across the board with each sample showing no contamination.

The data obtained from the validation of the Applied Biosystems 3130 at the WSCL. It is important for those using the AB 3130 genetic analyzer to be familiar with how the instrument and associated kit technologies were validated and the experimentation that was performed.

3130, Validation, CODIS

G91 A Rapid Penta STR Screening Method by Microchip Capillary Electrophoresis

Maurice J. Aboud, BSc, 10720 North West 66th Street, Apartment #113, Miami, FL 33178*

After attending this presentation, attendees will understand the development of a fast and portable DNA screening method that uses microchip electrophoresis for forensic DNA applications. Attendees will gain an understanding for how this system operates, the limitations of the system, and how these limitations were surmounted to achieve the desired resolution on the microchip.

This presentation will impact the forensic community by development of a multi-loci penta DNA system in combination with an STR micro-chip electrophoresis system that provides a new tool for quick and portable screening in forensic DNA analysis.

Due to the ever-increasing forensic DNA caseloads and the potential need for remote forensic DNA analysis, DNA analysis systems that are both quick and portable are needed. While short tandem repeat (STR) DNA analysis by capillary electrophoresis is capable of high resolution and has a large power of discrimination in forensic identification, these instruments are not portable and require a relatively long sample run time. It is on this basis that this study aims to develop a rapid and portable DNA screening method using a commercially available microchip electrophoretic system. Generally speaking microfluidic systems require fairly long channels and complex detection systems for proper resolution and identification of forensic DNA. However there currently exists commercially available systems, such as the Agilent 2100 Bioanalyzer, which have a small footprint and utilize chips with short channels and reduced resolution. Such portable systems might be valuable in situations where evidence screening is necessary in remote locations. However due to its lower resolution, most STRs will not properly separate on such a system. In this project the development of mini-Penta STRs as potential tools for microfluidic analysis was investigated. These five base STRs should produce more consistent results in such circumstances.

The design and development of such a portable system capable for forensic DNA screening with high enough resolution for single allele separation required that the following issues be investigated in order to increase the resolution. First the analysis of the current Penta STR markers available from Promega Corporation and redesign of these primer sets to reduce amplicon size and improve the mobility and separation within the micro-channel. Secondly, the development of a denaturing polymer for single stranded DNA separation to be used on the microchip that would take advantage of the improved resolution in single stranded DNA assays. Finally, the development of a Penta multiplex STR kit that would increase the power of discrimination for forensic samples and become a more powerful forensic tool.

These studies were designed to overcome the limitations of current microchip systems for portable forensic applications by trying to increase the resolution of the short micro-channels. It is with these changes that the resolution of the system should be capable of separating between five base pair repeats accurately and robustly.

This research will address the problems and limitations encountered with the current systems such as poor resolution, large amplified DNA fragments, and the ability to only detect double stranded DNA on the currently commercial available microchip systems such as the Agilent 2100 Bioanalyzer. As a result of this research the development of a multi loci penta DNA system in combination with an STR microchip electrophoresis system should provide a new tool for quick and portable screening in forensic DNA analysis.

DNA, Penta STR, Microchip

G92 How Does Season Affect the Release of Ninhhydrin - Reactive Nitrogen Into Grave Soil?

Jessica D. Wilkerson, and Brianna F. Anderson, University of Nebraska-Lincoln, 202 Entomology Hall, PO Box 830816, Lincoln, NE 68583-0816; and David O. Carter, PhD, University of Nebraska, Lincoln, Department of Entomology, 202 Plant Industry Building, Lincoln, NE 68583-0816*

After attending this presentation, attendees will understand that seasonality can significantly affect the rate at which ninhydrin - reactive nitrogen (NRN) enters grave soil and that the dynamics of grave soil NRN can contribute to the estimation of postmortem interval (PMI).

This presentation will impact the forensic community by serving as a fundamental investigation into the estimation of extended PMI. Accurate estimates of extended PMI are currently difficult to achieve.

During the summer months, when temperatures are warm, bodies tend to decompose at a more rapid rate. Recent research has shown that a body releases NRN into grave soil during decomposition. At present, few studies have investigated NRN in grave soil when decomposition begins during colder months. The release of NRN has primarily been used to locate graves, but more recently, has been investigated for its use in estimating PMI. To investigate this use, researchers decomposed carcasses in winter and summer to compare the release of NRN into grave soil.

The experimental site was located at the University of Nebraska Agricultural Research Development Center located approximately 48 km north of Lincoln, Nebraska, USA. The site is a pasture that is intermittently grazed by cattle and horses. The soil at the site is a deep silty clay loam of the Yutan series (Mollie Hapludalf). The climate is temperate midcontinental characterized by hot summers, cold winters, and moderately strong surface winds. Average annual precipitation is 695 mm. Approximately 75 percent of the precipitation occurs between April and September. Mean annual temperature is 9.8°C with mean minimum and maximum temperatures ranging from 0 C (January) to 31°C (July). The vegetation at site is dominated by non-native grass

(smooth brougham) and forb (white clover) with some native vegetation, including daisy fleabane, yellowwood sorrel nut sedge, and pasture rose.

Swine (*Sus scrofa*) carcasses (~40 kg) plus a control (no cadaver) were used. Swine were killed with blunt force trauma to the cranium and placed on their right side on the soil surface facing west. Swine were killed and placed on the soil surface during February 2008 (winter) and June 2008 (summer). Soil samples were collected (0-5 cm depth) from adjacent to the cadaver at intervals of 15 days for the initial 30 days. This experiment was replicated three times, which resulted in a total of six cadavers.

The concentration of NRN during the summer months was greater than during the winter months. Elevated levels of NRN were observed during the summer months after 15 and 30 days postmortem. In contrast, a significant increase in NRN was not observed during the initial 15 days of decomposition during the winter months. These results demonstrate that NRN would not be an accurate method to test for the presence of grave soil during the initial 15 days of death. As decomposition in terrestrial ecosystems is primarily biologically mediated, this influx was likely more rapid during the summer months because of greater insect and microbial activity. A more accurate way to measure postmortem interval during the winter months would be to use degree days, which will be presented along with measurements of NRN after 60 and 90 days.

Forensic Taphonomy, Postmortem Interval, Temperature

G93 Consumption of Fly Artifacts After Deposition and Translocation of Bloodstains by *Calliphora vicina* (Diptera: Calliphoridae)

*Becca Striman**, 1347 North 37th Street, Lincoln, NE 68503; *Amanda Fujikawa, BS*, 202 Entomology Hall, University of Nebraska-Lincoln, Lincoln, NE 68583-0816; *Larry Barksdale, MA*, Lincoln Police Department, 575 South 10th Street, Lincoln, NE 68508; and *David O. Carter, PhD*, University of Nebraska, Lincoln, Department of Entomology, 202 Plant Industry Building, Lincoln, NE 68583-0816

By attending this presentation, attendees will learn of two newly observed behaviors through which *Calliphora vicina* can alter bloodstain patterns.

This presentation will impact the forensic community by contributing information to the current literature regarding the behavior of *Calliphora vicina* when exposed to blood. Blow fly behavior can alter bloodstain patterns at crime scenes, which can lead to inaccurate crime scene reconstruction.

The purpose of this study was to observe the behavior of *C. vicina* when exposed to an expired bloodstain pattern and their effect on bloodstains on wallpaper, white textured wall, and white laminate floor.

The experiment was conducted using eight microscenes (0.46 m³ wooden boxes) that had two glass walls and a plexiglass ceiling to enable easy observation and documentation. The other surfaces consisted of a textured, white painted wall, a wallpapered wall, and a white laminate floor. A holding cage was attached to each microscene, in which ten flies were placed. Four of the microscenes were control scenes and no flies were placed in their holding cages. The holding cages were designed to allow the flies access to the microscene without human intervention.

Fresh human blood was used within ten minutes of being drawn. In each microscene, approximately three milliliters of blood were poured into a pool in a corner of the microscene. The donor then put three milliliters of blood in his mouth and expired blood into the microscene. The blood was directed towards the interface between the wallpaper and white painted wall. The flies were allowed entry to the microscene for 72 hours and had access to sugar and water.

Flies moved from the holding cage into the microscene within 10 minutes and began feeding on the blood within five hours. All deposited

artifacts that were observed were produced from defecation. No artifacts with long tails were made while the flies were exposed to light. Blow flies were observed feeding on fly artifacts, sometimes within seconds of the deposition of the artifact. Some of the artifacts were completely consumed by the flies. During the last half of the experiment, the flies fed on artifacts in equal or greater proportion to the bloodstain pattern. A small drop of blood was translocated by the mouthparts of the flies. The mouthparts were swept across the wall in an arc, beginning at the original source and ending at the new droplet, without leaving a trail of blood. The flies were observed feeding on the bloodstain pattern until the experiment ended.

The consumption of fly artifacts may occur because the artifacts could be easier to digest than pure blood, in the same way that regurgitated blood is easier to digest. However, defecated artifacts are unlikely to be as nutritious as pure blood. Translocated blood droplets may cause additional confusion when analyzing bloodstain patterns, especially if a reliable method is developed to distinguish fly artifacts from human blood. It is unknown how common this behavior is or whether it could significantly alter the overall bloodstain pattern. It is important for crime scene investigators to consider the behavior of blow flies when attempting to reconstruct a crime scene based on bloodstain pattern analysis. However, many more experiments are needed before this subject is thoroughly understood.

Forensic Entomology, Expirated Blood, Blow Fly

G94 Decomposition of Child-Sized Remains in Dumpsters

*Kevin M. Willis, BS**, Washington County Sheriff's Office, 1535 Colfax Street, Blair, NE 68008

After attending this presentation, attendees will have an increased understanding of the decomposition of child-sized remains placed in a dumpster.

This presentation will benefit the forensic community, as well as those in the fields of the postmortem interval estimation and rate of decomposition research. It may benefit investigations of children killed and placed in dumpsters. The research demonstrates that a child-sized carcass placed in a black plastic bag and in a closed dumpster will decompose at a slower rate than one placed in a dumpster unbagged. Both pigs in dumpsters decompose more slowly than a control pig outside the dumpster.

The results of this research will benefit forensic science in the fields of postmortem interval estimation and rate of decomposition research. It may benefit investigations of children killed and placed in dumpsters. The research demonstrates that a child-sized carcass placed in a black plastic bag and in a closed dumpster will decompose at a slower rate than one placed in a dumpster unbagged. Both pigs in dumpsters decompose more slowly than a control pig outside the dumpster.

Research on child-sized remains has been done by depositing pigs in a variety of ways including surface deposit, shallow grave, covered by branches and debris, suspended by a rope, and rolled in carpet (Morton and Lord, 2002). However, there is not much study, if any, on the decomposition of child-sized remains in a dumpster, despite the forensic cases where children's bodies have been disposed of in this fashion. The aim of the research is to understand the environmental and taphonomic factors that affect the postmortem interval (PMI) on child-sized remains in a dumpster.

This thirty-day project began on June 15, 2008 and ended July 15, 2008. Three small pigs, which were humanely dispatched, were used as child-sized remains. Pigs were chosen because their internal structures and progression of decomposition are similar to humans. Two pigs were placed on plywood in individual dumpsters and the third was placed on plywood on the ground as a control. The control pig was not covered but protected on all sides by a chain-link fence.

A four-lead temperature coupler was placed with each pig and programmed to take hourly temperature readings for the duration of the project. Each pig was weighed daily using a digital scale and their girths measured. An incised wound was also placed behind the right shoulder of each pig.

Each board was weighed without a pig and then with a pig subtracting the difference for obtaining the weight of each pig. The two dumpsters were each two cubic yards in size with two plastic lids. The lids were kept closed except for collecting data.

The pigs in the dumpsters had temperature leads placed in the following locations: in the mouth, underneath the pig (between the pig and the plywood), hanging loose inside the dumpster and hanging outside the dumpster. The control pig had a temperature lead in the ground approximately two inches in front of the pig in lieu of the temperature lead hanging loose inside the dumpster; other temperature leads were placed in the same positions as with the pigs inside the dumpsters. Data collection was performed each day. Information recorded included weather conditions, body temperature, container temperature, and carcass weight loss. Photographs were also taken of each carcass.

General decomposition patterns were observed on each of the specimens. Fly succession following the usual pattern for the region was noted on all three specimens. As measured by weight loss, the control pig decomposed at a faster rate than either pig in a dumpster. The pig in a bag in the dumpster decomposed more slowly than the pig not in a bag in the dumpster. The initial data suggests that the decomposition rate of remains placed in a dumpster is noticeably inhibited.

Decomposition, Dumpsters, Taphonomy

G95 Inadvertent Administration of Lidocaine: Illustration of Two Cases

Cettina Sortino, Via del Vespro 129, Palermo, ITALY; Fleres Pierangela, Institute of Legal Medicine, Via del Vespro, n. 127, Palermo, Italia 90100, ITALY; Paola Pugnetti, Department of Biotechnology and Legal Medicine, Section of Legal Medicine, Via del Vespro, n. 129, Palermo, 90127, ITALY; Antonino Bonifacio, MD, Institute of Legal Medicine, Via del Vespro, n. 127, Palermo, 90100, ITALY; Massimo Grillo, and Valentina Triolo, Department of Biotechnology and Legal Medicine, Section of Legal Medicine, Via del Vespro, n. 129, Palermo, 90127, ITALY; and Paolo Procaccianti, PhD, Palermo University, Via del Vespro, n. 127, Palermo, 90100, ITALY*

After attending this presentation, attendees will have viewed two cases showing that the inadvertent administration of lidocaine can lead respectively to death and to serious tetraparesis linked to loss of the cognitive functions.

This presentation will impact the forensic community by describing two cases that show how the inadvertent administration of lidocaine can lead respectively to death and to serious tetraparesis linked to loss of the cognitive functions.

Case 1: In the first case, a 35-year-old man who for many years has been affected by protruded disk between L4-L5 causing right lumbosciatic neuritis, during an orthopedic examination, was administered lidocaine and Thiocolchicoside injection in right paravertebral lumbar area.

Soon after the man started to feel worse, and over an hour, showed sudden loss of consciousness, seizures, acute respiratory insufficiency, arterial hypertension, and severe tachycardia. The man was transported to the local emergency room where he arrived comatose. The cerebral CAT showed small gas bubbles in the cornua of the lateral ventricles and suprasella cistern.

Despite the pharmacological treatment, the man suffered serious seizures with heart attack and subsequent death. After the family's

complaint, by an order of the legal authorities, the external examination and the autopsy were performed two days later.

External examination: The man was 175 cm tall and his weight was 76 kg. No injuries were found in his body; the external examination showed only some puncture marks on the right wrist, on the antecubital fossae and on the back of the left hand, and subcutaneous tumefaction in right paravertebral lumbar region, on which there was a puncture mark 4 cm from the spinous apophysis of L5.

Autopsy findings: The forensic autopsy revealed brain edema and congestion of cerebral veins. There was no lesion in the scalp and in the galea capitis and no intracerebral hemorrhage was found. Pulmonary edema, pancreas and kidney congestion were found. The heart showed hypertrophic left ventricular and septal wall and left ventricular chamber dilatation. The section of subcutaneous tumefaction in right paravertebral lumbar region, saw in the external examination, showed a rounded formation, circumscribed by a fine membrane, of soft and elastic consistency, dark red complexion, contains a blood clot. The section of lumbar vertebrae and the following extraction of the conus medullaris allowed to find, at the level of the L5, a blood infiltration in the posterior dural sac and underlying arachnoid.

Histological Findings: The microscopic examination showed multivisceral congestion. Myocyte cellular hypertrophy and contraction-band necrosis of left ventricular and septal wall were observed. Severe left anterior descending coronary artery stenosis, softening of temporal cortex, white substance edema and neuronal cerebral and bulbar cytotoxic edema, spinal cervical cord edema were also noted. The terminal conus medullaris at the level of the L5 showed blood infiltration in the posterior dural sac and underlying arachnoid, soft and adipose tissue hemorrhagic extravasation.

Case 2: In the second case, a 58-year-old woman who for ten years had cervical pain due to protruding disk between C5-C6 was submitted to lidocaine infiltration made laterally to the cervical spinous apophysis.

Soon after, the doctor noticed the progressive decrease of the radial pulse, the loss of consciousness and the cardiac activity, so he started the external cardiac massage. After 15 minutes, the emergency medical doctor made an intracardiac injection adrenaline, after which there was a restarting of the cardiac activity. The woman was transferred to a hospital where she fell into coma.

The cerebral CAT showed many gas bubbles in the suprasellar, perisellar, and temporal periencephalic space, left sylvian valley and cornua of the lateral ventricles.

Currently the woman shows a serious situation of rigid-spastic tetraparesis and loss of cognitive functions.

Discussion: In the first case, vascular-peridural iatrogenic inoculation and the consequent sistematical diffusion permitted the neurotoxic damage lidocaine and epileptogenic action thiocolchicoside. The toxic cerebral effects destabilized the pre-existing ischemic cardiopathia, serious but clinically asymptomatic, causing the death of the man.

In the second case, at first the anaesthetic damaged the cervical orthosympathetic chains nerve ending, leading to a reflex inhibition of spinal cardiac-vasomotor centers and consequently to a hypovolemic shock, an then produced a direct neurotoxic damage of the S.N.C., both responsible of the quadriplegia.

Lidocaine, Coma, Tetraparesis

G96 Asphyxia by Confinement: The Death of a Man Kidnapped and Segregated in a Small Underground Cistern

Cettina Sortino*, Antonino Bonifacio, MD, Sergio Cinque, MD, Stefania Zerbo, MD, Livio Milone, PhD, and Paolo Proccianti, PhD, Department of Biotechnology and Legal Medicine, Section of Legal Medicine, Via del Vespro, n. 129, Palermo, 90127, ITALY

The goal of this presentation is to illustrate a particular case of homicide of a 68-year-old Caucasian man who was found dead inside an underground cistern, tied with ropes and chains.

This presentation will impact the forensic community by presenting the unpredictability of death by asphyxiation from confinement of a man unlawfully restrained for the purpose of extortion.

The air of confined environments can be subject to alteration by shares of various causes. Those persons who stay indoors need to have available a sufficient volume of air appropriately refreshed.

The sensitivity of the subject varies in relation with the temperature of moving air (compared to room temperature), the direction of air current, and conditions of the subject.

In February 2007 a male corpse of the apparent age of 65-70 years was found inside a cistern built underground, three meters deep, and used to conduct the passage of water (size of 3x3x3 meters, closed tightly with a metal lid of 63x63 cm).

The analysis of clothing made it possible to identify the victim; it was a Caucasian 68-year-old man who had disappeared a month before the discovery.

From data carried out during inspection, the victim was lying on the ground and immobilized by the presence of several girdles consisting of a rope and a chain.

The rope, surrounding the sides, kept him in contact with water and blocked any possibility of his movements. The chain consisted of steel mesh fixed at both of wrists and left ankle, as follows: the right wrist was linked to the left ankle at a distance of ten mesh chain links. This position forced the bending of the left knee over 90° and the extension of the right arm, not allowing any movement of the arm or the leg.

The left wrist was also linked to the left ankle by a chain at a distance of 22 cm, allowing the bending of forearm and arm; this chain also passed below the rope tied to waist passing on the left side.

The external examination of the corpse showed chromatic-emphysematous state of putrefaction; negroid face, with disjunction of hair in large areas of the scalp, eyeballs completely concave for colliquation and evaporation, easy detaching of skin grafts; massive destruction of nasal cartilage and perioral soft tissues, with exposure of dental arches and jawbone.

There were also larvae in various stages of maturation (pupae of 1 and 2 stage) and skin erosions caused by their destructive action. Several skin areas were affected by the presence of fungal growth on the right side, in particular: the neck, the chin, the right auricle, the upper right region of chest, the stump of right shoulder, and the periumbilical region.

Some skin areas were blackish and partially wrinkled (head, neck, upper region of chest, and upper limbs), while others were affected by phenomena of maceration with detachment of skin (hands, feet, right thigh, and both legs).

There were no signs of constriction on the neck. Under the hypogastric area, umbilical region, right wrist and left wrist, there were impressions caused by the rope and the chain. The autopsy showed advanced putrefaction in all organs, in particular in the brain, pancreas, and adrenal glands.

The histological examinations made it possible to detect signs of vitality on the skin of wrists and, in particular, there was oedema and intralveolare hemorrhage swelling and bleeding intralveolare and, inside the blood vessels, the red blood cells seemed conglutinate with focal

fibrin blood clots. Histological examination of the heart showed only a moderate atherosclerosis in coronary vessels.

The toxicological tests carried out on tissues and fluids have ruled out the presence of drugs and/or psychotropic substances, and showed the presence of 7% of carboxyhemoglobin.

On the basis of putrefaction, the presence larval and the conditions under which he was forced, it is estimated that the death could be traced back presumably, in a variable range of about 20 days before its discovery. The increase in CO₂ in the blood was responsible for a respiratory acidosis with consequent iperpnea-vasodilation, sweating, dehydration, peripheral venous stasis, ispisatio sanguinis, red cell lung clots, and cardiorespiratory failure that led to the death the subject.

Asphyxia, Confinement, Kidnapping

G97 50 Years Later: How Insect Evidence is Key in Turning Over a Wrongful Conviction in Canada's Most Notorious Case – *Regina v. Steven Truscott*

Sherah L. Van Laerhoven, PhD*, University of Windsor, Department of Biology, 401 Sunset Avenue, Room 119 Bio, Windsor, ON N9B 3P4, CANADA; and Richard W. Merritt, PhD, and Ryan K. Kimbirauskas, MS, Department of Entomology, 243 Natural Science Building, Michigan State University, East Lansing, MI 48824

After attending this presentation, attendees will understand the history and cultural impact of R. v. Truscott, and the evidence that lead to overturning this miscarriage of justice.

This presentation will impact the forensic community by illustrating the use of modern evidence in reanalysis of older cases, the importance of having forensic analyses based on scientific evidence and value of recreation experiments.

The body of 12-year-old Lynne Harper was discovered at 1:50 p.m. on June 11, 1959 in a woodlot northeast of Clinton, Ontario. She had been raped and strangled using her blouse. Insect evidence was photographed and collected both at the scene and autopsy, and the insects were reared to adult for identification. However, the insect evidence was not used in the 1959 trial or 1960 appeal. Stomach content analysis was used to pinpoint a 45 minute period for the time of death, two days prior (7:00 – 7:45 p.m., June 9, 1959). Based predominantly on this time frame and some circumstantial evidence, Lynne's classmate, 14-year-old Steven Truscott was convicted of her murder and scheduled to be hanged on December, 1959. A temporary reprieve on November 20, 1959 postponed his execution and on January 22, 1960, his death sentence was commuted to life imprisonment. Truscott was the youngest person to be sentenced to death in Canada, and his case provided the major impetus toward abolition of the death penalty in Canada. Truscott always maintained his innocence. After serving his sentence, Truscott was released and in 2001, he filed for review of his 1959 murder conviction. Fresh evidence was presented at hearings held at the Ontario Court of Appeal in 2006-2007. This new evidence included testimony of three forensic entomologists, with three other forensic entomologists filing reports (but not called to testify) on the insect evidence. Based on the analysis of the insect evidence, a recreation experiment of insect evidence and a reanalysis of the pathology evidence on stomach content analysis, the original estimate of time of death was considered to be unreliable. Truscott was with numerous witnesses prior to 1900 h and after 8:00 p.m. on June 9, 1959, thus the estimate of time of death was the most critical evidence in the original 1959 trial and the 2006-2007 appeal. In 2007, his conviction was declared a miscarriage of justice and Truscott was acquitted of the murder.

Forensic Entomology, Wrongful Conviction, Historical Cases

G98 First Insect Succession Study on a Human Cadaver in Texas

Jennifer L. Pechal, MS*, Texas A&M University, 2475 TAMU, College Station, TX 77843-2475; Adrienne L. Brundage, MS, 2001 Cobblestone Ln, Bryan, TX 77807; Elizabeth T. Brandt, BA, 232 Evans Liberal Arts, Anthropology Dept, 601 University Drive, San Marcos, TX 78666; Connie L. Parks, BS, 8802 Featherhill Road, Austin, TX 78737; Jeffery K. Tomberlin, PhD, Department of Entomology, TAMU 2475, College Station, TX 77843-2475; and Jerry Melby, PhD, Department of Anthropology, 601 University Drive, ELA 273, Texas State University-San Marcos, San Marcos, TX 78666-4616

After attending this presentation, participants will be introduced to the first succession of insects observed on a human cadaver in Texas.

This presentation will impact the forensic community by providing information on the succession patterns and abundances of forensically important insect species attracted to a human cadaver.

These data can potentially be used to determine a more refined estimate of the period of insect activity (PIA) on human remains discovered in the southwestern United States. Correctly identifying arthropod species found associated with a body allows for time approximations to be made based on development data and behaviors. The PIA is divided into two ecological phases termed the pre-colonization (pre-CI) and post-colonization (post-CI) intervals. Insects arrive at bodies in waves or series. The pre-colonization interval (pre-CI) is defined by insects being initially attracted to remains without colonizing the resource. Various species arrive at different times based on seasonality and abiotic factors. Insects are attracted to a body in a predictable pattern based on its stage of decomposition. Many of these insects will colonize (post-CI) the resource once the remains are discovered. Succession patterns may be influenced by the condition of the body and the area in which it is located. The following factors about the condition of the body may influence the rate of colonization, species richness, and abundance: direct sunlight, partially shaded, indoors, urban, rural, buried, or submerged. Applying the knowledge of arrival time (pre-CI), colonization patterns (post-CI), and associated behaviors allows for a better assessment to be made concerning approximations in the length of time a body may have been at a specific location.

Blow flies (Diptera: Calliphoridae) were initial colonizers of the human remains in this study. Over the duration of this study three blow fly species were regularly collected in the vicinity of the body: *Cochliomyia macellaria*, *Chrysomya rufifacies*, and *Phormia regina*. There were also *Piophilidae casei*, as well as Muscidae and Sarcophagidae species collected from the body. Coleoptera species also will colonize a body because of the readily available food resource of dipteran larvae as well as decomposing materials. Five beetle families were collected near or around the body: Cleridae, Histeridae, Silphidae, Staphylinidae, and Dermestidae.

C. macellaria is one of the initial colonizers in warmer temperatures while *P. regina* is more active during cooler weather. The diversity of flies collected may be an indicator of the range of temperatures experienced during the study. The hairy blow fly larva, *C. rufifacies*, is a facultative predator and will feed on larvae of previous colonizers such as *C. macellaria*. The hairy maggot blow fly can be distinguished from other maggots on a resource by the spine-like projects on each segment. It was interesting to note that there was a delayed colonization of Calliphoridae. Abiotic factors such as temperature may have influenced the colonization times or other unaccounted factors may have influenced the delay of oviposition but it is important to note that the body was not immediately colonized. Various ants from the family Formicidae and fleas, *Xenopsylla cheopis*, were also collected during this study. Postmortem ant bites on a body have been previously documented in other studies. Fleas collected near the body do not imply that the subject was infested; rather it may represent the environmental fauna and the

potential pests they carry. This study appears to have followed known succession patterns expected for the arthropod species collected; however, this is the first study in the state of Texas to examine insect succession patterns using a human cadaver.

This study is also important because it allows forensic entomologists to better assess delay in colonization estimations of insect activity on remains as it relates to the pre-CI. The specific time when a body is placed out into the field can be compared to estimations based on entomological development data. Establishing the accuracy of time estimations using development data for those insects collected from the remains may lead to more refined methods for calculating how long a body has been in a particular area prior to colonization. It is noted that this is a primary study with many more conditions to be replicated as potential body recovery sites and thoroughly analyzed to gain a better understanding of attraction, colonization time, development, and interactions among insect species on a human resource.

Insect Succession, Human Cadaver, Texas

G99 Comparison of Biological Sensors to Detect Human Remains: Canine Versus Hymenopteran

Glen C. Rains, PhD*, University of Georgia, PO Box 748, Tifton, GA 31793; Ben Alexander, MS, Texas A&M University, TAMU 2475, College Station, TX 77843; Jeffery K. Tomberlin, PhD, Department of Entomology, TAMU 2475, College Station, TX 77843-2475; and Jerry Melby, PhD, Department of Anthropology, 601 University Drive, ELA 273, Texas State University-San Marcos, San Marcos, TX 78666-4616

After attending this presentation, attendees will have a greater understanding of principle of associative learning and its use to train vertebrate and invertebrate species to detect human remains in unknown samples.

This presentation will impact the forensic community by providing information on the use of canines and conditioned insects to screen soil samples for the presence of human remains.

A tremendous amount of effort in the scientific community has focused on deciphering how animals, as well as plants, receive and interpret environmental stimuli. In regards to forensics, these efforts have primarily targeted the development of biological sensors, such as canines, for tracking missing individuals or escapees from custody. Other efforts have evaluated the use of canines to detect explosives or narcotics in places frequented by people.

In recent years the U.S. Department of Defense has initiated research examining the ability of arthropods to detect and locate compounds of human importance. *Microplitis croceipes* has served as a model for a number of studies to detect plant pathogens, explosives, and human remains (Lewis & Martin, 1990; Takasu & Lewis, 1993, 1995, 1996; Rains 2004, 2006). These efforts have translated into the development of a biological sensor that is capable of detection at the nanogram level.

While the use of cadaver dogs in detecting human remains is widely accepted, there is little research that scientifically validates the capabilities or mechanisms by which the dogs function. This study compared cadaver dog performance to that of the trained wasps in terms of threshold and accuracy. Five nationally certified and experienced cadaver dogs with "real world finds" were tested in two types of evaluation paradigms. The cadaver dogs varied in age from three to nine years and consisted of two Border Collies, one Rottweiler, one Labrador Retriever, and one Doberman Pinscher. Cadaver dog threshold was equal to *M. croceipes* as the dogs were able to detect and alert to the presence of human remains using 0.02 grams of soil from beneath a human cadaver mixed with 20 grams of background soil.

Two types of presentation trials were utilized. The first trial set consisted of singular jar presentation in a room. This matched the presentation to the conditioned wasps but was not a traditional method of training or evaluation for testing detector dogs. The second trial, which was conducted upon the end of the first trial, consisted of a scent line-up with all four targets present. Targets were placed approximately three feet apart in a single row line. This is a traditional presentation utilized in research and training of scent dogs.

No type one errors were seen with the dogs; however, there were type II errors. Training biases may account for some of the error margin. Target odors are most often placed into containers for preserving and storing the target for continued use. Preservation of training aids necessitates the use of containers, cages, and other devices which can subsequently become a visual cue for the dog. Most research performed on scent detection dogs involve line ups or concealed target odors to avoid visual cueing. Placing containers in plain sight may have lead to a bias based on expectations by the dog's previous experience. Cadaver dog training scenarios typically include at least one target odor within a designated search area; therefore the dog is expecting to find something. This defines a need for cadaver handlers to continue to train their canine partners on scenarios involving visual negative targets to reduce association between a visual target and alerting, thereby increasing their efficiency on real world searches.

Cross contamination, residual scent, indoor ventilation systems, and container placement may have also contributed to the type II errors. Cross contamination can also occur due to residual scent. A recent study indicated that dogs can detect human remains odors of human corpses on carpet squares even though the squares did not come into direct contact with the corpse (Oesterhelweg, 2008). Since so little is still known about detector dogs, research that help define thresholds and other factors is essential in increasing the effectiveness of these dogs.

Canine, *Micropititis Croceipes*, Biological Sensor

G100 Generating Development Data for Forensically Important Flies That Are Difficult to Rear in the Laboratory

*Anne E. Nichols, BS**, West Virginia University, 1367 Stewartstown Road, Apartment W-7, Morgantown, WV 26505; *Neal H. Haskell, PhD, 425 Kannal Avenue, Rensselaer, IN 47978*; and *Jeffrey D. Wells, PhD, West Virginia University, Department of Biology, Life Sciences Building, Room 3135, 53 Campus Drive, PO Box 6057, Morgantown, WV 26506-6057*

After attending this presentation, attendees will learn how carrion fly development data can be obtained for species that are not suitable for rearing under common laboratory methods.

This presentation will impact the forensic community by providing rearing techniques for blow flies that have minimal development data due to their difficulty to rear in a laboratory setting. With these data forensic entomologist can generate more accurate development data for commonly encountered forensically important blow flies leading to increased accuracy and precision in postmortem interval estimations.

Forensic entomologists have so far been unsuccessful in their attempts to establish laboratory colonies of some of the more commonly encountered carrion insect species. Therefore, it has been difficult to produce the growth models often used to estimate a minimum postmortem interval based on specimen age of these species. Notable examples of this technical problem in North America are the green bottle flies *Lucilia illustris* and *Lucilia coeruleiviridis*. It has been found that a wild-caught *L. illustris* female will lay eggs in a laboratory cage, but the resulting f1 generation will not mate under these standard rearing

conditions. *Lucilia coeruleiviridis* presents an even more difficult problem, in that post-feeding *L. coeruleiviridis* larvae, either collected from a corpse or obtained from a wild adult female, will not pupate under laboratory conditions. The larvae have been observed to go into an extended wandering stage lasting several days only to eventually shrivel and die.

It was hypothesized that post-feeding *L. coeruleiviridis* larvae require a larger pupation medium volume than is typically used for laboratory culture. The hypothesis that rearing *L. coeruleiviridis* eggs obtained from wild females in containers much larger than those used in this research would have an effect on their development was tested. *Lucilia illustris* was similarly investigated because of the lack of developmental data currently available for this species as well.

During midsummer at the study site in northwest Indiana, 11 piglet carcasses were exposed to short duration (max 2.5hrs) fly activity and inspected for eggs every half hour. Once eggs were observed, the piglets were individually placed on (approximately 0.11 m³) leaf litter, collected on site, in large plastic storage tubs (approximately .16 m³). Breathable cloth-like material was immediately secured over the plastic tubs to exclude further oviposition. Ambient (outside) and interior container temperatures were monitored. Adult flies that emerged from a container were collected daily and identified.

Aspects of development will be discussed for three of the blow flies that were successfully reared to adulthood in this experiment; *L. illustris*, *Lucilia sericata*, and *L. coeruleiviridis*. Physiological time calculations for *L. illustris* were compared to those reported by other authors. Both *L. coeruleiviridis* and *L. illustris* developmental data were contrasted to the extensively studied *L. sericata*, because some investigators have used *L. sericata* growth models to estimate *L. coeruleiviridis* age. Under these conditions *L. coeruleiviridis* total development time was numerically longer than that of *L. sericata*. Total development time of *L. illustris* was comparable but slightly more accelerated than that of *L. sericata*.

The procedure used in this experiment provides forensic entomologists with a means of obtaining growth rate data for flies that were previously difficult to rear. Having data on these forensically important flies can be used to increase precision and accuracy of estimations of the postmortem interval.

***Lucilia*, Postmortem Interval, Forensic Entomology**

G101 Insect Pupal Cases as Decay-Resistant Reservoirs of Human Soft Tissue Radiocarbon Content

*Gregory W. Hodgins, DPhil**, University of Arizona, Department of Physics, 1118 East Fourth Street, Tucson, AZ 85721

After attending this presentation, attendees will understand how above-ground nuclear testing in the 1950s and early 1960s dramatically increased environmental levels of radiocarbon. These elevated levels have been incorporated into all organisms living since that time and thus can serve as temporal markers. Potentially, radiocarbon measurements of postmortem human tissues can be used forensically to establish year-of-birth and/or year-of-death. One advantage of this approach is that it functions independently of chemical or biological methods for the determination of postmortem interval or age-at-death and thus might augment current methods for establishing these parameters.

This presentation will impact the forensic community by outlining the possibility of determining year-of-death of human remains in advanced stages of decay based on the radiocarbon content of insect pupal cases obtained from the surrounding soil. Remains in advanced stages of decay pose particular challenges for determining postmortem

interval, and other temporal parameters. The presentation has two objectives: (1) to outline a hypothesis and an experimental design, and (2) to canvas the forensic science community for suitable samples.

Over the past sixty years, environmental levels of radiocarbon have been rapidly changing. Previous work in this laboratory has established that radiocarbon levels in human soft tissues essentially reflect levels in the contemporary environment. Therefore measuring radiocarbon levels in postmortem tissues and correlating these with known levels in the past environment can indicate Year-of-Death. Direct measurements on tissues from known age/known year-of-death donors have shown promise and quantified the potential precision of this approach to approximately ± 2.5 years.

The paradox of suggesting such an approach is that in many environments, soft tissues disappear within short spans of time due to natural process of decay. What are required are decay-resistant proxies of soft tissue radiocarbon content. The hypothesis of this study is insect pupal cases might fit the bill. Just as humans take on the radiocarbon content of ingested foods, insect larvae feeding on decaying human remains take on the remains' radiocarbon content. Although emergent adult insects leave, pupal cases are left behind. Large numbers are often encountered in the soil surrounding decayed remains long after soft tissues have disappeared.

Preliminary measurements on samples generated from field tests will be presented as well as measurements on paired samples of soft tissues and pupal cases obtained from a Medical Examiner's Office archives. The design of future experiments will be discussed.

Admittedly, the approach is potentially complex. For example, direct measurements of radiocarbon levels in different human tissues show tissue-specific variation. These differences are the consequence of rapidly changing environmental levels and differences in metabolic turnover rates. Consequently, one might expect that insect larvae feeding on different tissues of the same individual might be differentially labeled. On the one hand, this might reduce the precision of Year-of-Death estimations. However, if species-specific differences in larvae feeding behaviors exist among the succession of insects that infest decaying remains, this might result in species-specific differences in pupae radiocarbon levels. Such differences might be exploited to advantage. Clearly experimental data is required.

The approach is intriguing. It would require a trivial modification of existing sample collection practice: merely collecting a larger than normal number of pupae. It is potentially a new avenue for the forensic estimation of Year-of-Death.

Radiocarbon, Year-of-Death, Pupal Cases

G102 Reconstruction of Decay Processes of a Dead Child's Body in a Plastic Garbage Bag

Heike Klotzbach, PhD*, Institute of Legal Medicine, Fürstengraben 23, D-07743 Jena, GERMANY

After attending this presentation, attendees will know how important questions concerning a homicide case were answered by step-by-step reconstruction using pig cadavers and special knowledge of various disciplines.

This presentation will impact the forensic community by underlining the statement that "extraordinary" methods are sometimes helpful in forensic taphonomy and moreover emphasize the cooperation of scientists from different disciplines.

The remains of a 10-year-old girl hidden in a plastic garbage bag in a wooded area in Northern Germany were recovered. The girl had been reported missing three months earlier. Her body was in a stage of advanced decay, the soft tissue had been entirely liquefied, colored

grayish pink and foamy in sections, whereas the bare skeleton was visible. The bones were complete and the arrangement of the skeleton indicated that the body had originally been left in *anteflexion* with bent knees. The foot bones were still inside the shoes and the underpants were positioned around both ankles indicating preceding sexual abuse. No evidence as to mammalian-feeding defects neither to preceding blow fly (Diptera: Calliphoridae) activity was observed. Only some skipper flies (Diptera: *Piophilidae*, "Cheese Skippers"), well known as late colonizers, were detected. Considering the climate of northern Germany the question had to be answered. Could a dead body get into that advanced state of decay within three months time without addition of any chemical substances? Extensive toxicological investigations merely resulted in high concentrations of calcium (1120 mg/kg) in the liquefied tissue. The influence of hydrogen peroxide was considered but excluded because large quantities of the long scalp hair were found still in its original brown color.

Experiments with pig cadavers (n=14; 20-30 kg) in plastic bags under equivalent environmental conditions revealed that soft tissue was liquefied equally with the skeleton left in anatomical position in those cases without addition of any chemical substances (e.g., quick lime). The pig cadavers where quick lime was added (1:3, 1:10, 1:30) were found with rather dry and hard soft tissue, aridity was increasing with the concentration of quick lime. By following investigations in a specialized microbiological laboratory *Clostridia* species (*C. limosum*, *C. novyi*, *C. sordellii*, *C. sporogenes*) were detected in the remains of the child as well in the liquefied porcine tissue. These *Clostridia* species are reported to produce both histolytic and cytolytic enzymes. Also the foamy consistency of the soft tissue could be explained due to the well documented gas producing activity of *Clostridia* species. Furthermore high calcium levels equivalent to these in the original specimens were determined in the liquefied porcine tissue.

In summary it was concluded, that the body of the child inside the plastic bag reached the state of liquefaction without addition of any chemical substances. The environment inside the closed plastic bag without oxygen supply promoted a shift to benefit the development of the anaerobic bacteria like *Clostridia* species. Hence high concentrations of histolytic and cytolytic enzymes secreted by these microorganisms resulted in a relatively fast liquefaction of the soft tissue. These conclusions were also in accordance with the crime scene analysis (closed plastic bag above ground, underpants around ankles of the corpse) indicating a fast disposal of the dead body after sexual abuse.

Decay Processes, Plastic Bag, Taphonomy

G103 Unusual Methods of Suicide in Chicago, Illinois, Cook County

Michelle A. Jorden, MD*, James A. Filkins, MD, JD, PhD, and Tera A. Jones, MD, Cook County Medical Examiner Office, 2121 West Harrison Street, Chicago, IL 60612

After attending this presentation, attendees will learn about some unusual methods of suicide recently observed in Chicago, IL during the first half of 2008. This paper is being introduced during a time of economic strain within the United States.

This presentation will impact the forensic community by making attendees aware of the unusual methods of suicide are being observed in Chicago, IL.

In 2004, according to the National Institutes of Health (NIH), suicide was the eleventh (11th) leading cause of death in the United States, accounting for 32,439 deaths. The major risk factors for the commission of suicide are well known and include a history of depression, substance abuse, stressful life events, family history of suicide, and prior suicide attempt. Males are four times (4X) more likely to commit suicide compared to females. Recent research has suggested

the risk of suicide may be the result of an imbalance of neurotransmitters in the brain, thus emphasizing the importance of diagnosis and the role of antidepressants in the treatment of depression.

Firearms, suffocation, and poisoning were the most common methods chosen by individuals to commit suicide, although the methods differed between the sexes. Males tend to commit suicide using firearms, whereas females commit suicide by poisons. Non-Hispanic whites commit suicide at the highest rate. Although some data is similar to that published by the NIH, the authors will introduce a total of eight individuals who committed suicide by unusual methods rarely seen in a major metropolitan area.

One case involves a white male with multiple shotgun wounds who was found in his secure residence. The second case involves a white male inflicting sharp force injury to his dialysis catheter causing exsanguination and air embolism. Two cases, a white male and white female, involved the “death by Hibachi” method, which is accomplished by carbon monoxide intoxication from burning charcoal in an enclosed environment. At autopsy, both cases revealed bright cherry-red lividity and the carbon monoxide level ranged from 54%-80% saturation. One case involved a white female chemistry student who ingested acetylferrocene, an orange crystalline powder that is extremely toxic once ingested, and who died of liver failure. One case involved a white male hanged with simultaneous electrocution from a manmade apparatus. One case involved a white male who used ligature strangulation as a means of suicide. Finally, the last case involving a white male is noteworthy and unusual in the sense that the commission of suicide was performed with the production of hydrogen sulfide gas. This is a most unusual case of suicide from medical examiners office but deserves mention as this method is becoming increasingly popular overseas.

Suicide notes were left at the scene in only three cases, a similar frequency seen in prior reports. Two detailed suicide notes were recovered from individuals performing the “death by Hibachi” method. The third suicide note was recovered from the male inflicting sharp force injury to his dialysis catheter.

With the introduction of the internet, old as well as new and more unusual methods of committing suicide are available to the population. As seen in this research, the “death by Hibachi” method would take time to plan and execute (i.e., spending time on the internet, buying and burning the charcoal, taping the doors in the room and writing detailed suicide notes).

All cases involved non-Hispanic white individuals, similar to that seen in the NIH data. In this study, there was a preponderance of males committing suicide (6:2). In each of the cases, the reasons for committing suicide coincide with the NIH data (i.e. depression, stressful life events). Although one of the cases involved a male using a firearm as a means of suicide and one case involved a female using a poison to commit suicide, these were not common means of suicide as people seldom kill themselves by inflicting multiple shotgun wounds and ingesting acetylferrocene. Additionally, people seldom commit suicide via means of ligature strangulation. The remaining cases also illustrate uncommon and unusual methods of suicide. In this small study, six of the eight individuals had a prior documented suicide attempt.

Suicide is one of the most preventable deaths in the society and the recognition and treatment of depression is underscored. However, the medical examiner/coroner will continue to examine suicide deaths especially in economic hardship as recently experienced in the United States. This paper serves to introduce some uncommon methods of suicide recently observed during the 2008 year.

Suicide, Unusual Methods, Chicago, IL

G104 Mass Fatality Investigation Due to Combustible Dust Related Industrial Explosion and Fire

J.C. Upshaw Downs, MD, and Edmund R. Donoghue, MD, Regional Medical Examiner, Georgia Bureau Investigation, 925 A Mohawk Street, Savannah, GA 31419-1796*

After attending this presentation, the attendee will recognize the dangers of combustible dusts and their relation to industrial deaths, and better understand unique features of mass fatality investigation in an industrial setting and an active fire scene.

This presentation will impact the forensic community by exposing practitioners to the under-recognized dangers of combustible dusts and the complexities involved in mass fatality in an industrial/fire setting.

Combustible dust is an under-recognized industrial hazard. The United States Chemical Safety Board identified over 280 events with 837 casualties (including 119 deaths) in the period 1980 to 2005. The industries involved are varied and include organic dusts (wood, sugar, grains, etc.), metal powders (magnesium, aluminum), chemical manufacturing, plastic production, pharmaceutical production, and coal handling/processing. In fact, “any industrial process that reduces a combustible material and some normally noncombustible materials to a finely divided state presents a potential for a serious fire or explosion” (NFPA’s Industrial Fire Hazards Handbook). In fact, sugar may seem harmless but is recognized as a strong explosion hazard (Bureau of Mines – “The Explosibility of Agricultural Dust”). In addition to the usual fire-triangle components (fuel, fire, and oxygen), a combustible dust explosion requires sufficient quantity and concentration of dust in a confined space. A major risk in such settings is the rapid dispersion of previously quiescent depots of dust particles follows a lesser primary explosion. With a significant fuel reservoir abruptly literally shaken loose and into the ambient air, a more devastating secondary explosion can be anticipated if the reservoir ignites. Safety procedures can reduce the risks associated with combustible dusts, especially related to the fuel, dispersion, and ignition but are less effective in controlling the confinement and ambient oxygen.

Shortly after 9 p.m., a series of explosions rocked the second largest cane sugar refineries in the United States (responsible for ~15% of total national production). The fires took days to extinguish due to the nature of the incident – a large depot of molten sugar remained ablaze in one of three storage silos despite significant efforts to put it out. Up to an estimated 100 personnel (of 472 total) were reported working in the affected plant area at the time of the blast. Of these, upwards of 40 individuals were seriously injured and a total of eight individuals were eventually reported missing and presumed dead. Recovery efforts, including law enforcement and medical examiner staff, to locate the presumed deceased proceeded while the silo fire was actively burning and scene stability was questionable. Over the ensuing days and weeks, the bodies of the dead were recovered and identified. The extensive thermal damage to those who remained in the burning plant longest posed identification challenges due to fragmentation and calcination. At the conclusion of the medicolegal investigation, all eight dead on scene were identified and the remains were re-associated with the appropriate individual. An additional five fatalities occurred related to extensive burn injuries, for a total 13 deaths. The case resulted in extensive media scrutiny and eventually the third-largest fines in OSHA history.

This presentation reviews the nature and dangers of combustible dust related fires. Specific issues related to the death investigation process and body recovery are addressed. The investigative outcomes, including recognized risks and identified cause are presented.

Combustible dust, Explosion, Sugar

G105 Worker Fatalities by Hydrogen Sulfide Poisoning: Autopsy and Toxicological Findings

Biagio Solarino, PhD, Sezione di Medicina Legale, Università Degli Studi di Bari, P.zza Giulio Cesare, 11, Bari, 70125, ITALY; Giancarlo Di Vella, PhD, Sezione di Medicina Legale, DIMIMP, University of Bari, Policlinico, Piazza G. Cesare, Bari, 70121, ITALY; Lucia Tattoli, MD, Sezione di Medicina Legale, University of Bari, Bari, , ITALY; Claudia Liuzzi, MD, Sezione di Medicina Legale, Università Degli Studi di Bari, Bari, 70100, ITALY; Giuseppe Strisciullo, BES, University of Bari, Policlinico, Piazza G. Cesare, 11, Bari, 70124, ITALY; and Roberto Gagliano-Candela, PhD, University of Bari, Cattedra Tossicologia Forense, Policlinico, Piazza G. Cesare 11, Bari, 70124, ITALY*

After attending this presentation, attendees will have an understanding of some particular aspects of Hydrogen Sulfide poisoning which is an important cause of work-related death.

This presentation will impact the forensic community by emphasizing the fact that Hydrogen Sulfide (H_2S) is a harmful and lethal chemical, and accidents may occur upon exposure to it in its natural gaseous state in various work environments.

The goal of this presentation is to recount the story of the deaths of five men who, while working in a truck tank which transported liquid sulfur, were poisoned by Hydrogen Sulfide. Variations in pathological and histological findings, coupled with toxicological results, and crime scene investigations will be illustrated.

Hydrogen Sulfide is a powerful, rapidly acting, colorless, poisonous gas. H_2S has a specific gravity (1.19) higher than air, and its presence can be detected by its characteristic odor of rotten eggs. Acute occupational poisoning and fatalities have been reported from exposure to H_2S in industrial settings, sewage disposal facilities, and septic tanks. This gas is very unstable and thiosulfate is its major metabolized substance. For this reason, the presence of thiosulfate is known to be a useful indicator of Hydrogen Sulfide poisoning in forensic analysis.

Case History: Five workers were found motionless in an empty truck tank which had previously contained liquid sulfur. They were soon removed from the tanker; four of the five men had already died. The fifth man, who was also the youngest, died at the hospital the following day. Crime scene investigation revealed that the first of the victims began the cleaning operation of the truck tank when he became unconscious. One by one, fellow colleagues attempted to rescue their co-workers, each succumbing to the toxic gas, and each falling into unconsciousness, ultimately followed by death.

Autopsy Findings: The workers had a mean age of 37.6 years (range 20-64). External examination of the bodies revealed congestion of the head, neck, and shoulders with cyanosis of lips and fingernails in all cases. The ocular conjunctiva showed marked hyperemia and a few petechiae. Two workers displayed traces of solid yellow sulfur on their faces and on the soles of their shoes. One of the workers, who was 23-years-old, displayed a very characteristic greenish discoloration of his eyes, anterior cervical region, and precordia. Only one worker showed signs of putrefaction. Two of the men presented with blunt force injuries on the occipital areas with subgaleal contusions which resulted from falling.

Upon internal examination, it was noted that the lungs of all the workers were heavy with edema and congestion which was also present in the kidneys and spleen. The 23-year-old worker displayed a greenish discoloration both in the thorax muscles, as well as on the surface of the stomach. There were no remarkable findings related to the other organs except for slight cerebral edema which was present in all five victims. In addition, an aortocoronary bypass graft was present in the oldest victim. Microscopic examination revealed passive congestion which was evident in the lungs, spleen, kidneys, and adrenal glands. Massive

hemorrhagic edemas were found in all the workers, most notably in the youngest victim who died 12 hours after the tragic event.

Toxicological results: Toxicological analyses of peripheral blood vessels (femoral) were negative for alcohol and illicit drugs in all of the workers. Thiosulfate in the heart blood was quantified using a gas chromatography-mass spectrometry (GC/MS) technique after derivatization with pentafluorobenzyl bromide. Each of the victims had a blood thiosulfate level that, according to other international reports, was enough to determine that the cause of death was due to fatal hydrogen sulfide poisoning: thiosulfate levels ranged from 2.6 mg/l (first worker in who entered into the tank) to 183 mg/l.

The analyses performed on air samples collected from inside the truck tank, as well as analogous trunk tanks used for liquid sulfur transport revealed that H_2S air concentration levels were high to have caused these occupational fatalities.

Hydrogen Sulfide, Worker Fatalities, Thiosulfate

G106 Suicide by Hanging in Harris County, Texas

Sara Nunez-Doyle, MD, and Sharon M. Derrick, PhD, Harris County Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054*

After attending this presentation, attendees will have comprehensively reviewed the features of suicidal hangings, including demographic characteristics of the decedents, frequency and types of injuries identified at autopsy, ligature characteristics, and scene investigation information. This review will provide the attendee with a reference base for common and uncommon findings in suicidal hangings.

This presentation will impact the forensic community by providing insight into the case findings and epidemiological characteristics of suicidal hangings presenting to the Harris County Medical Examiner's Office from the large diverse population of Harris County, Texas.

Suicidal hangings comprise 19% (320) of the 1676 suicides that occurred in Harris County, Texas from January 1, 2004, through June 30, 2008. Hanging was the second most common method of suicide after firearm wounds. An upward trend in the total number of hangings was recorded over this four and one-half year period, with 51 hangings occurring in 2004, 73 in 2005, 71 in 2006, 81 in 2007, and 43 in the first half of 2008. Although the total number of suicides in Harris County also increased over this period (from 298 in 2004 to 424 in 2007), the percentage of hangings compared to total suicides increased, with hangings comprising 17.1% of the total suicides in 2004 and 21.8% of the total suicides in the first half of 2008. Accounting for the approximated 7% population increase in Harris County from 2004 through 2007, the actual rate of suicidal hangings increased slightly over this period, from 1.3 per 100,000 people in 2004 to 2.1 per 100,000 in 2007, as did the rate of total suicides, from 8.1 per 100,000 in 2004 to 10.8 per 100,000 in 2007.

The majority of the decedents who hanged themselves (81%) were male, a trend that is common for other methods of suicide. Female decedents comprised 19% of the suicidal hangings and 24% of the total number of suicides in the period examined. The ages of decedents hanging themselves over the period studied ranged from 10 to 80. Children were over-represented in the hanging category when compared to total suicides. Ten percent of the decedents hanging themselves were under the age of 18, compared to 3.8% of the decedents committing suicide by all methods. Senior citizens were under-represented. Decedents over the age of 65 comprised 2.5% of suicidal hangings compared to 11.5% of all suicides in the time period studied.

The majority of decedents who hanged themselves were Caucasian (54.4%), followed by Hispanic persons (31%), African-American persons (10.1%), and persons of other race/ethnicity (4.5%). The breakdown of ethnicity for people dying by suicide by all methods was

similar, with 68% white, 18% Hispanic, 11% black, and 3% other race/ethnicity. In suicidal hangings as well as suicide by all methods, white persons appear to be over-represented when compared with the population breakdown of Harris County, in which approximately 37% of the population is white.

Of the 320 suicidal hangings examined, 260 (81%) took place in the decedent's residence or property immediately surrounding the residence (yards, garages, utility sheds, and other outbuildings). Of the remaining 19% of cases, the more common locations of the hangings included parks, fields, or wooded areas (15 cases), jails or other correctional facilities (13 cases), places of business (11 cases), and motels or hotels (8 cases). Hanging was the only method of suicide used by incarcerated persons over the four and one-half year period studied. Approximately one-fifth of the decedents (62 cases) were transported from the scene of the hanging and received medical care prior to being pronounced dead. The remaining four-fifths of the decedents were pronounced dead at the scene of the hanging.

The types and frequency of injuries of the internal neck structures identified at autopsy such as hemorrhage of the neck musculature, fractures of the hyoid bone, and fractures of the tracheal and laryngeal cartilages as well as injuries of the spine will be reviewed in detail. In addition, the various types of ligatures recovered, ligature positioning, and positions in which the decedents hanged themselves will be discussed. The prevalence of factors such as previously diagnosed mental illness, physical illness, and prior suicide attempts in decedents who hanged themselves will also be examined.

Hanging, Suicide, Epidemiology

G107 Death in a Tanker Truck

Christopher B. Rogers, MD, Los Angeles County, Medical Examiner's Office, 1104 North Mission Road, Los Angeles, CA 90033; John Kades, BA, Los Angeles County, Department of Coroner, 1104 North Mission Road, Los Angeles, CA 90033; and Lakshmanan Sathyavagiswaran, MD, Los Angeles County, Medical Examiner's Office, 1104 North Mission Road, Los Angeles, CA 90033*

After attending this presentation, attendees will understand the need for thorough investigation of work-related fatalities and will be familiar with the autopsy presentation of death by inhalation of caustic substances.

This presentation will impact the forensic community by suggesting strategies for investigating occupational deaths by using interagency communication and cooperation.

In this case, a 23-year-old man was cleaning the inside of a tanker truck which had been used to carry 50% potassium hydroxide. The procedure for cleaning the tank included a confined space entry procedure, consisting of 21 pages of instructions.

The cleaner used spray head to flush the tank with water at least four times, then used a fan to dry the tank. The tank would be checked for adequate oxygen concentration using a digital meter. A worker would then go into the tank, using a safety harness, mask, ladder, personal air monitor, personal motion detector, and protective equipment. A second worker, acting as the safety attendant, remained outside the tank. Ventilation was introduced by using an air hose inserted into a small hatch in the tank. The worker would remove any remaining chemical using a high-pressure water hose, hand dry the tank, and inspect it for corrosion. During the cleaning procedure, the truck engine was off.

On the day this case occurred, the decedent was working alone. Fifteen minutes after he entered the tank, another worker checked on him and found him unresponsive at the bottom of the tank. He was removed from the tank using his safety harness, and taken to a hospital, where he was pronounced dead.

Autopsy showed pulmonary edema, and pulmonary and gastric hemorrhage. Toxicology was negative except for vitreous urea nitrogen of 30 mg/dL.

The supervising Coroner's investigator and Chief Medical Examiner-Coroner visited the scene and discussed the procedures used for cleaning the tank with employees of the transportation company. In addition, Coroner's staff met with the involved police agency and representatives of California Department of Industrial Relations, Division of Occupational Safety and Health. The Material Safety Data Sheet for potassium hydroxide and the medical literature provided additional information.

The cause of death was determined to be pulmonary edema due to potassium hydroxide exposure and other undetermined factors. Dehydration was given as a contributing condition.

The medical literature contains reports of chronic obstructive lung disease following sodium hydroxide inhalation. However, rapid death after potassium hydroxide inhalation has not been reported. The mechanism of death proposed for this case is that the caustic potassium hydroxide produced widespread pulmonary edema, with rapid degradation of respiratory function. The exothermic reaction of potassium hydroxide and water may have contributed to death by heating the inside of the tank.

Given the non-specific autopsy and toxicology findings, additional investigation was essential in determining the cause of death for this decedent. Through cooperation between the Coroner, law enforcement, and occupational health agencies, the cause of death could be established in this case.

Occupational Health, Potassium Hydroxide, Inhalation

G108 Agonal Sequences in Eight Filmed Hangings: Analysis of Respiratory and Movement Responses to Asphyxia by Hanging

Anny Sauvageau, MD, Lab de Sciences Judiciaires, et de Medecine Legale, 1701, Parthenais St, 12th Fl, Montreal, QP H2K 3S7, CANADA; Romano La Harpe, MD, Institut de Medecine Legale, 9 Av de Champel (CMU), Geneva, 1206, SWITZERLAND; and Vernon J. Geberth, MS, MPS, P.H.I. Investigative Consultant Inc., PO Box 197, Garnerville, NY 10923*

After attending this presentation, attendees will have a better understanding of the pathophysiology of human asphyxia by hanging.

This presentation will impact the forensic community by providing new insights into the body responses to asphyxia by hanging, based on results from the Working Group on Human Asphyxia.

Introduction: In the conducting of investigations and trials, forensic pathologists are often asked questions related to body responses in human asphyxia. Those questions are very difficult to answer considering the paucity of literature. Animal studies have been conducted, but the extent to which those results can be applied to human is doubtful. As for direct human experimentation, it is of course out of question for obvious ethical concerns. To palliate these limitations, the Working Group on Human Asphyxia was formed in 2006 at the 58th Meeting of the AAHS in Seattle. This working group has for main objective to regroup filmed hangings in order to give new insights into the pathophysiology of human hanging.

Methods: A total of eight filmed hangings from three different countries (Canada, Switzerland, and United-States) were analyzed: two filmed suicides and six autoerotic deaths. Hangings were of different types: free hanging, hangings with feet on the ground, hanging kneeling and hanging almost lying face-down. The hanging ligatures also varied widely, from cloth band to ropes with or without padding and electric

cords. All victims were adult males. Those filmed hangings were compared in terms of loss of consciousness, convulsions, decortication and decerebration rigidities, loss of muscle tone, last muscle movement, and respiratory responses. The time frame at which each of these responses occurred was taken by two judges.

Results: With the time 0 representing the onset of hanging, rapid loss of consciousness was observed (at 8 – 18 seconds), closely followed by appearance of convulsions (at 10 – 19 seconds) in all cases. A complex pattern of decerebration and decortication rigidity was then observed in all cases. Last isolated muscle movement occurred between 1 minute-2 seconds and 7 minutes-31 seconds. High similitude was observed for respiratory responses: onset of very deep respiratory attempts between 13 and 24 seconds, last attempt between 1 minute-02 seconds and 2 minutes-05 seconds.

nd : no data/– not observed

	Case #1	Case #2	Case #3	Case #4	Case #5	Case #6	Case #7	Case #8
Movement Responses								
Loss of consciousness	13s	nd	18s	nd	10s	8s	10s	12s
Convulsions	15s	14s	19s	18s	13s	11s	10s	14s
Decerebration	46s	19s	21s	nd	1min19s	31s	11s	26s
Decortication #1	21s	1min08s	1min00s	nd	59s	33s	26s	31s
Decortication #2	1min11s	1min32s	1min04s	nd	–	–	34s	–
Loss of muscle tone	1min38s	2min43s	2min04s	nd	1min52s	–	–	–
Last muscle movement	4min10s	3min01s	3min01s	nd	7min31s	1min02s	nd	nd
Respiratory Responses – Very Deep Respiratory Attempts								
Start	20s	21s	22s	24s	13s	19s	13s	16s
End	2min00s	2min47s	2min04s	nd	2min5s	1min02s	nd	nd

Conclusion: Despite differences in the types of hanging, similarities could be revealed regarding rapid loss of consciousness and onset of convulsions, pattern of decortication rigidity and respiratory responses. To date, this is a unique study of agonal movements in asphyxia by hanging. The importance of inter-laboratory collaboration in extending this project by adding other available filmed hangings is discussed and the importance of the Working Group of Human Asphyxia (WGHA) is further emphasized.

Asphyxia, Hanging, Physiopathology

G109 Dead Victim Identification: Age Determination by Analysis of Bomb-Pulse Radiocarbon in Tooth Enamel

Henrik Druid, PhD, Department of Forensic Medicine, Karolinska Institutet, Retzius v. 3, Stockholm, SE-171 77, SWEDEN; Kanar Alkass, BSc, Department of Forensic Medicine, Retzius v 3, 171 77, Stockholm, SWEDEN; Kirsty Spalding, PhD, Department of Cell and Molecular Biology, Medical Nobel Institute, Karolinska Institutet, Stockholm, SWEDEN; and Bruce Buchholz, PhD, Lawrence Livermore National Laboratory, 7000 East Avenue, Livermore, CA 94550*

After attending this presentation, attendees will understand how biological samples produced in the past 60 years can be dated using the radiocarbon bomb-pulse. Specifically, they will learn how the 14C content of dental enamel can be used to determine year of birth of persons born after 1945.

This presentation will impact the forensic community by providing a technique that improves the accuracy in age determination of dead victims, such as suspected homicides and victims of mass disasters.

Background: Determining the age of an individual is an important step in dead victim identification, particularly in suspected homicide cases and in mass disaster work. Age determination can be performed with high precision up to adolescence by analysis of dentition, but establishing the age of adults has remained difficult. The enamel of individual permanent teeth is formed at distinct, well-characterized time points during childhood. After being laid down, there is no turnover of

enamel, so its ¹⁴C concentration reflects the level in the biosphere at the time of enamel formation. Atmospheric testing of nuclear weapons doubled the global ¹⁴CO₂ level between 1955 and 1963. After adoption of the Partial Test Ban Treaty in 1963, the level of atmospheric ¹⁴CO₂ started to decrease exponentially with a mean life of about 16 years due to transport into large carbon reservoirs such as the oceans and losses to space. The enhanced level of ¹⁴C worked its way up the food chain from CO₂ so that all living things are labeled with the pulse.

Material and Methods: The concentration of ¹⁴C in tooth enamel from individual teeth and related it to the known concentration in the atmosphere over time (1950 – present) to establish the time of tooth formation was measured. The dates were then used to estimate the year of birth of the person. To this end, the crown of the tooth was cut away from the root at the level of the cervical line. The crown was then immersed in 10N NaOH, before being placed in a water-bath sonicator. The enamel was then washed with DDH₂O and re-submersed in 10N NaOH during approximately four days to remove all dentin until pre-treated for accelerator mass spectrometry (AMS) analysis.

Results: The technique matched ¹⁴C content in enamel to known age very well along the bomb spike curve. The absolute difference between estimated age and true age was 1.1 ± 0.9 years for teeth from Scandinavian subjects, implying a much higher precision than any previous method. Analysis of teeth from deceased subjects from other continents showed similar accuracy, suggesting that the geographical variation of the bomb-pulse radiocarbon does not significantly influence the readings. For teeth formed before 1955, the ¹⁴C analysis can only tell that the person was born before the nuclear tests (birth year of person before 1945 - 1952, depending on type of tooth analyzed), but with absolute certainty.

Conclusion: AMS analysis of teeth offers a precise age determination that can be applied in forensic casework, particularly to assist in investigations of unidentified human cadavers. If radiocarbon determination and aspartic acid racemization analysis of teeth are combined, information of both the year of birth and the year of death can be established.

This work was supported by the Human Frontiers Science Program and Wenner-Gren Foundation.

Age Determination, Radiocarbon, Tooth

G110 Postmortem Injury Detection in an Aviation Mishap: Computed Tomography Imaging Versus Autopsy

David M. DeLonga, PhD, Naval Medical Center Portsmouth, 6513 Harbour Pointe Drive, Suffolk, VA 23435; Angela D. Levy, MD, United States Army, Department of Radiology and Radiological Sciences, Uniform Services University of the Health Sciences, 4301 Jones Bridge Road, Bethesda, MD 20814; and Howard T. Harcke, MD, Department of Radiologic Pathology, Armed Forces Institute of Pathology, 3205 Coachman Road, Wilmington, DE 19803*

After attending this presentation, attendees will understand the utility and limitations of postmortem computed tomography (CT) analysis of traumatic injury victims compared with standard autopsy.

This presentation will impact the forensic community by demonstrating how CT imaging can complement the conventional autopsy in the injury detection of aviation mishap victims.

Purpose: This study compared and contrasted the sensitivity of CT imaging versus autopsy in the postmortem detection of injuries sustained in an aviation mishap.

Methods and Materials: Four male victims from an aviation mishap were studied with whole-body CT examinations prior to conventional autopsy. Autopsies were conducted by forensic pathologists and autopsy reports created without reference to the CT

imaging studies. Blinded to autopsy reports, two radiologists then retrospectively interpreted each study in a consensus fashion. Images were evaluated for fractures, dislocations, and soft tissue abnormalities resulting from traumatic injury. Radiology interpretation was compared to autopsy reports to determine the sensitivity of each method in detecting these injuries. CT studies were then re-examined to review missed or discordant findings in order to determine if a successful imaging correlate with the autopsy results could be obtained.

Results: Autopsy and CT imaging detected a total of 236 fractures and dislocations. Autopsy detected 139 (59%) and CT imaging detected 231 (98%) of these findings. In regions of the body that were not fully explored during the autopsy procedure (e.g., posterior vertebral body elements, scapula, and ribs), the CT images frequently revealed fractures not recorded on the autopsy reports. Autopsy and CT imaging detected a total of 56 soft tissue abnormalities. Autopsy detected 55 (98%) and CT imaging detected 14 (25%) of these findings. The detailed description of soft tissue abnormalities found in the autopsy reports was frequently not appreciated with CT imaging. Some of these soft tissue abnormalities were apparent in retrospect after being un-blinded to the autopsy reports.

Conclusion: The use of CT imaging is a useful adjunct to autopsy in the postmortem detection of injuries following an aviation mishap. CT imaging demonstrates high sensitivity for the detection of fractures and dislocations but is currently limited in the detection of soft tissue injuries.

Computed Tomography, Traumatic Injury, Aviation Mishap

G111 Usefulness of Systematic Histological Examination in Routine Forensic Autopsy

Geoffroy Lorin de la Grandmaison, PhD, AP-HP, Philippe Charlier, PhD, AP-HP, and Michel Durigon, PhD, AP-HP, 104 Boulevard Raymond Poincaré, Raymond Poincaré Hospital, Garches, F-92380, FRANCE*

After attending this presentation, attendees will be aware of the considerable discrepancy rate between macroscopic and microscopic findings provided by standard histology in forensic autopsy.

This presentation will impact the forensic community by showing that histology is an important feature regarding forensic autopsy quality and is still essential to confirm, refine, or refute macroscopic findings.

Material and Methods: A prospective study was carried out on 1,786 autopsies performed in the department of pathology and forensic medicine at the Raymond Poincaré hospital from 2003 to 2007, for which standard histological examination was systematic according to autopsy protocol (including microscopic sections of the heart, lungs, liver, kidneys, pancreas, spleen, thyroid, adrenal glands, prostate and neuropathological study after brain formalin fixation). Histological sections were stained with haematoxylin and eosin. From all these autopsy cases were randomly selected 428 cases for which microscopic sections were reviewed by two forensic pathologists. SIDS cases and skeleton cases were excluded from the study. For each case, information provided by histology regarding respectively cause and manner of death, death mechanism, prior medical condition of the deceased, and documentation of eventual traumatic lesions were analyzed. Discrepancies between gross anatomic and microscopic findings were also studied.

Results: The mean age of the population was 46.2 years (range 5-91 years). The sex ratio (H/F) was equal to 2.46. Bodies showed respectively putrefaction in 92 cases, mummification in one case and diffuse carbonization in 15 cases. Concerning manner of death, the

majority of the cases were natural deaths (n=130, including 63 cases of sudden death), followed by suicide (n=113), accident (n=104). Homicide and undetermined manner of death were respectively found in 40 and 41 cases. The most frequent causes of death were blunt force injuries (n=73), cardio-vascular diseases (n=90), mechanical asphyxia including drowning (n=62), acute intoxication (n=59) and gunshot wounds (n=47). No cause of death was found in 32 cases. Mechanism of death not shown by gross anatomic findings was discovered by histology in about 40% of the cases (n=173). The main mechanisms of death found were respectively cardiac arrhythmogenic substrate (n=98), acute myocardial ischaemia (n=17), pulmonary infection (n=17), vital alimentary aspiration (n=14), fat embolism (n=13), pulmonary thromboembolism (n=5), diffuse axonal injury (n=3), disseminated intra-vascular coagulation (n=2) and sickle cell crisis (n=2). Cause of death was established only by histology in 8.4 % of the cases (n=36). In the 32 cases for which no cause of death was found, histology showed possible mechanism of death in 11 cases corresponding to a cardiac arrhythmogenic substrate. Microscopic findings affected the manner of death in 13% of the cases (n=56). Histology provided complementary information about prior medical condition of the deceased in about 49% of the cases (n=211). Traumatic lesions were better documented by histology in about 22% of the cases (n=94). The majority of discrepancies between microscopic and gross autopsy findings involved the liver, the heart, and the lungs. According to these results, microscopic findings are relevant if adequate sampling for histology is performed during autopsy. In most of the studied cases, histology can be considered contributory regarding respectively mechanism, cause and manner of death, prior medical condition of the deceased and traumatic lesions documentation.

Conclusions: According to the results of this study, systematic standard histology for the main organs should be used in routine forensic autopsies.

Forensic Autopsy, Histology, Cause of Death

G112 Radiology Students and Morgues: A Mutually Beneficial Relationship

Nancy S. Adams, BS, 202 Milford Street, #155, Tupelo, MS 38801*

After attending this presentation, attendees will be better informed of the benefits that may be realized by affiliating with a radiologic technology program to provide radiology students with clinical morgue experience.

This presentation will impact the forensic community by making people aware of the improvements to radiographic image quality that may be accomplished when radiology students are allowed to observe autopsies and assist with forensic radiographs. A secondary benefit is recognized in preparing the radiologic technologist to assist with other skills such as evidence collection and preservation.

Interest in the forensic sciences has grown significantly in recent years as events and the media have focused attention on forensic investigations, and the radiologic sciences are no exception. Due to most morgues and medical examiner facilities being totally separate from hospitals today, the radiology student and radiology practitioner do not have adequate experience in forensic imaging. As radiology equipment becomes more and more sophisticated, and imaging techniques such as virtual autopsies and 3D CT reconstruction are utilized more frequently, the skills of the board-certified technologist will be in greater demand. Due to the nature of the work, it is important for the student to have some knowledge of the expectations and working conditions to aid in determining if this is a field they may wish to pursue. Just as the student obtains knowledge and experience in a broad range of imaging modalities to decide on a career path after graduation, an introduction to the morgue and forensic imaging should be available as well. Many times the radiologic technologist must image living and deceased

subjects in the emergency department, and if that technologist has some forensic training and background, preservation of evidence would be complied with, observation and interview skills would be enhanced, and the images obtained would provide proper legal documentation.

The morgue or medical examiner's facility can benefit by having students and instructors available who are well-versed in recognizing imaging artifacts, equipment and image processing malfunctions, and are able to troubleshoot and correct or at least identify the problem. They can develop proper exposure techniques and set up guidelines; train morgue assistants in obtaining better images; recognize foreign objects and implants; position to overcome superimposition of structures or demonstrate an anatomical part more accurately. In addition, the instructors work with the students to compare ante-and postmortem images and reproduce an antemortem position if necessary for comparison. An additional benefit includes access to board-certified instructors who are available to the facility for consultation, physically or electronically. A financial benefit to the facility may also be considered, as the students and instructors are not paid employees, and may assist in reducing overhead by maintaining the x-ray and image processing equipment in proper working order. And as a final benefit, the facility may be able to recruit exceptional candidates for employment, many of whom will have a bachelor's degree and may seek additional training as a multi-skilled individual.

This presentation describes an arrangement between a radiologic technology program and a medical examiner's facility and the mutual benefits both groups have enjoyed to date, including the development of a forensic radiography handbook suitable for both the novice radiographer and the morgue assistant involved in taking forensic x-rays.
Radiology, Student, Education

G113 CT Autopsy Imaging in the State Medical Examiner Setting: Logistic Issues, Techniques, and Findings

Kyle Shaw, MBBS, David R. Fowler, MD, Zabiullah Ali, MD, and Jack M. Titus, MD, Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201; Mary G. Ripple, MD, 68 Bluebird Road, Port Deposit, MD 21904; Barry Daly, MD, Radiology Department, University of Maryland Medical Center, 22 South Greene Street, Baltimore, MD 21201; and Clint W. Sliker, MD, University of Maryland Medical Center, Diagnostic Imaging Department, 22 South Greene Street, Baltimore, MD 21201*

The goals of this presentation are to describe this research experience with logistic and technical aspects of the development of a CT autopsy imaging service for the state medical examiner's (ME) investigation of traumatic death, describe and compare CT imaging autopsy appearances with the ME's autopsy findings, and consider the future potential of CT imaging autopsy.

The logistic and technical challenges to the development of a CT autopsy imaging service require educational efforts and infrastructure development. Imaging autopsy is an accurate tool for the detection of most major injuries and causes of death resulting from blunt trauma or drowning. This presentation will impact the forensic science community by demonstrating how CT imaging autopsy has the potential to replace conventional medical examiner autopsy in some deaths resulting from accidental blunt trauma and may facilitate rapid retrieval of ballistic fragments in cases where forensic autopsy is required.

The medical examiner community has shown interest in the use of CT autopsy imaging, but faces problems of access due to financial, technical, transportation, interpretation, and related difficulties in incorporating this tool into regular practice as compared to CT imaging

in the clinical care of the living. Sharing collective experience, both positive and negative, in addressing these issues is important in identifying its long-term role in the medical examiner setting.

The logistic and technical challenges to the development of a CT autopsy imaging service require educational efforts and infrastructure development. Imaging autopsy is an accurate tool for the detection of most major injuries and causes of death resulting from blunt trauma or drowning. CT imaging autopsy has the potential to replace conventional ME autopsy in some deaths resulting from accidental blunt trauma and may facilitate rapid retrieval of ballistic fragments in cases where forensic autopsy is required.

CT Imaging, Autopsy, Logistics

G114 Intersecting Fractures of the Skull and Gunshot Wounds: Case Report and Literature Review

Guido Viel, MD, University of Padua, Via Falloppio 50, Padova, 35121, ITALY; Axel Gehl, MD, Department of Forensic Pathology - Institute of Le, Hamburg, GERMANY; Giovanni Cecchetto, MD, University of Padua, Via Falloppio 50, Padova, 35121, ITALY; Massimo Montisci, PhD, University of Padua, Via Falloppio 50, Padova, 35121, ITALY; and Jan P. Sperhake, MD, Department of Forensic Pathology - Institute of Le, Hamburg, GERMANY*

After attending this presentation, attendees will have a clear example of Puppe's rule utility in gunshot wounds analysis and will learn the advantages of a Multi-Slice Computed Tomography approach in such cases.

This presentation will impact the forensic community by demonstrating the ability of CT scanning to show gunshot wounds to the skull vault including entrance wound, exit wound with beveling, direction of the bullet path as well as differentiation between entrance and exit wounds using intersecting fractures (Puppe's rule).

This paper highlights the ability of CT scanning to show gunshot wounds to the skull vault including entrance wound, exit wound with beveling, direction of the bullet path as well as differentiation between entrance and exit wounds using Puppe's rule.

This rule, established by the German forensic pathologist Puppe in 1903, states that when two or more fracture lines of the skull produced by different blunt forces intersect, it is possible to reconstruct the sequence of injuries.

The intact skull allows fracture lines to develop normally while the presence of bone damages causes the subsequent injuries to stop in the point of intersection with the previous wounds. In other words this means that fracture lines produced by subsequent impacts are arrested at pre-existing fractures of the skull.

No exceptions to this rule have been found in systematic investigations on skulls, glass, and eggs stricken with subsequent blows.

Although multiple gunshots cause an extensive and sometimes very complex pattern of fractures due to the hydrodynamic effect produced by the bullet traversing the temporal cavity of the brain, in the majority of cases, Puppe's rule can be usefully applied.

This principle gains interest in sequencing multiple gunshot injuries and in determining the direction of fire. However, it may be useful also in differentiating entrance from exit wounds, especially if specific distinguishing features are absent (i.e., internal/ external beveling of the skull).

Herein a case of a 76-year-old man who shot himself in the mouth with a Walther PPK 7.65 handgun (caliber 9x17 mm) is reported.

Prior to autopsy a total body multislice computed tomography scan (MSCT) was performed. MSCT scanning was executed on a MX 8000

Quad Diamond select unit (Philips Medical Systems, Andover, MA). In areas of forensic importance, axial MSCT was performed with 4 x 1, 25 mm collimation. The duration of MSCT scanning was approximately 15 min. Using an open-source workstation (OsiriX version 3.1) it was possible to calculate two-dimensional sagittal and coronal reformations and three-dimensional reconstructions.

Major radiological findings were: a bone defect of the hard palate, a complex pattern of fractures of the ethmoid bone with hemorrhagic filling of the ethmoid sinus, an anterior pneumoencephalus, a fracture of the anterior cranial fossa and a bone defect of the vault with external beveling of the outer table.

The abrupt termination of a fracture line belonging to the exit wound pattern (parietal bone) at a pre-existing damage caused by the entering bullet (temporal fracture originating from the entrance wound), well documented by the 3D-CT reconstruction, was used as an adjunctive tool to better distinguish the entrance from the exit wound.

This paper describes a clear visual example of Puppe's rule utility in the analysis of gunshot injuries of the skull and highlights the importance of postmortem forensic radiology.

In fact, MSCT allowed the investigation of the anatomical sites that are hardly accessible at autopsy (such as paranasal sinuses, temporal and ethmoid bones, etc.) and offers different views and angles of imaging improving the quality of the investigation.

Gunshot Wounds of the Skull, Intersecting Fractures, Puppe's Rule

G115 Sudden Cardiac Death Due to Atrophy and Fibrous and/or Fatty Substitution of Right Ventricle: Pathologic Substrates and Postmortem High Resolution MRI

Massimo Grillo, Department of Biotechnology and Legal Medicine – Section of Legal Medicine, Via del Vespro, n. 129, Palermo, 90127, ITALY; Pierangela Fleres, MD, and Cettina Sortino, Via del Vespro, n. 129, Palermo, , ITALY; Antonino Bonifacio, MD, Institute of Legal Medicine, Via del Vespro, n. 129, Palermo, 90127, ITALY; Livio Milone, PhD, Via del Vespro, n. 129, Palermo, 90127, ITALY; Paolo Procaccianti, PhD, Palermo University, Via del Vespro, n. 129, Palermo, 90100, ITALY; and Emilio Maresi, PhD, Via del Vespro, n. 129, Palermo, 90127, ITALY*

After attending this presentation, attendees will be introduced to some cases arrived to observation of Section of Legal Medicine of Palermo about sudden cardiac arrhythmogenic death, in order to show the possible disease that can cause death. This presentation emphasizes the difficulty of making diagnosis of Arrhythmogenic right ventricular cardiomyopathy (ARVC) without genetic analysis: myocardial atrophy and fatty/fibro-fatty substitution is diagnostic of ARVC at autopsy only in absence of any other cardiac and extracardiac remarkable injuries.

This presentation will impact the forensic community by demonstrating how data showed highly frequent association between ARVC and the fatty variant with cardiomyopathic pattern. MRI is more sensitive to detect the fatty variant with the cardiomypathic pattern rather than fibro-fatty and/or infiltrative substrate. With this presentation authors will show cases reached to their attention in the last years, characterized by atrophy and fibrous and/or fatty substitution of right ventricle's muscle, with consequent sudden cardiac arrhythmogenic death. Besides, authors will try to make differential diagnosis between different nosologic entities compatible with histological findings, in order to reach the most probable diagnostic hypothesis.

ARVC is a primitive disease of myocardium with not-well-known aetiology, characterized by structural and functional abnormalities of right ventricle, that consist in an hemodynamic, rhythmic and electric disarrayes, due to progressive myocardial atrophy with fatty or fibro-fatty substitution.

Sectorial or widespread atrophy of the myocardium of free wall of right ventricle is the typical morphologic case, with normal characteristics of left ventricle and interventricular sept. Loss of myocardium set the trans-lightning of the wall, that appears to be yellowish for the fatty substitution and/or whitish for the fibrous substitution. Another constant find is the right ventricular dilatation, from mild to severe, with hypokinesia or akinesia of the muscle.

Less frequent are noticed single or multiple right parietal aneurysms, more often at the back side, infundibulous or apex. Besides, frequently there's mural thrombosis of right ventricle and septal fibrosis. This can cause a consequent bilateral atrial dilatation with the high risk of auricular thrombosis with possible systemic and pulmonary embolism.

From 1990 to 2006 474 autopsies of sudden cardiac death (SCD) were performed. In this series, ARVC accounted for 27 cases (16.4%), including 21 males and 6 females (16 to 43 years old; median 26 years). Circumstances of death were during physical exercise in 20 cases, and at rest in seven cases. The family history of ARVC and/or SCD was negative.

The transmural loss of the myocardium in the right ventricular free wall was diffuse in 11 cases and segmental in 16 cases. External bulging of right ventricular free wall and left ventricular was present in four and six cases respectively. The myocardial atrophy was replaced by fatty tissue in 20 cases and by fibro-fatty tissue in seven cases. The interface between residual cardiomyocytes and tissue replacing the myocardium (fatty or fibro-fatty), was wave front (cardiomyopathic pattern) in 21 cases, and lacelike (infiltrative pattern) in six cases. Active myocarditis was detectable in the fibro-fatty variant only. MRI describe the fatty replacement on T1-weighted images with moderate inter-intra observer variability, thus sequende like "fat suppression" or "triple inversion recovery" to evaluate fatty replacement might provide a significant improvement in the diagnosis of ARVC.

The data showed highly frequent association between ARVC and the fatty variant with cardiomyopathic pattern. MRI is more sensitive to detect the fatty variant with the cardiomypathic pattern rather than fibro-fatty and/or infiltrative substrate.

With this presentation cases reached to their attention in the last years, characterized by atrophy and fibrous and/or fatty substitution of right ventricle's muscle, with consequent sudden cardiac arrhythmogenic death will be discussed. Besides, authors will try to make differential diagnosis between different nosologic entities compatible with histological findings, in order to reach the most probable diagnostic hypothesis.

Sudden Cardiac Death, Arrhythmogenic Right Ventricular Cardiomyopathy, Magnetic Resonance Imaging

G116 Autopulse® Associated Injuries

Kathryn H. Haden-Pinneri, MD, Harris County Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054; Dwayne A. Wolf, MD, PhD, Harris County Medical Examiner's Office, JAJ Forensic Center, 1885 Old Spanish Trail, Houston, TX 77054; and Jennifer C. Love, PhD, and Roger A. Mitchell, Jr., MD, Harris County Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054*

By attending this presentation, attendees will become familiar with the Autopulse® resuscitation device and the variety of internal injuries that can be associated with its use.

This presentation will impact the forensic community by educating forensic pathologists about the visceral and skeletal injuries associated with the use of automated chest compression devices so that they are not misinterpreted as perimortem trauma.

Automated devices have been utilized to assist with cardiopulmonary resuscitation (CPR) for many years. The most commonly encountered device is an Automated External Defibrillator

(AED) which provides rapid defibrillation for those patients with shockable rhythms. The newest device is a portable automatic external chest compression device. The Autopulse® Non-Invasive Cardiac Support Pump is one of these devices. Originally developed by the Revivant Corporation and subsequently purchased by Zoll Medical Corporation, the Autopulse® provides consistent, uninterrupted chest compressions through a load distributing band which squeezes the entire chest. Utilizing the device frees the emergency medical technician normally assigned to do chest compressions to perform other life saving activities while transporting the patient.

This FDA-approved device consists of a short backboard and a load distributing disposable compression band, called a LifeBand®. The patient is placed on the board and the band is secured around his or her chest. The band automatically sizes the patient, calculating the size, shape and compliance needed without requiring any patient information to be entered. Once started, the Autopulse® rhythmically constricts the entire rib cage, compressing at a rate of approximately 80 beats per minute. The LifeBand® can be placed over AED pads, but must be removed for standard paddle defibrillators. Compressions continue for as long as necessary or until the device is stopped. Standard protocol is for patients to receive manual chest compressions before the device is started.

Houston, Texas became a test center for the use of the Autopulse® with devices installed in all Houston Fire Department first responder vehicles. During a two month period, the Autopulse® was utilized on 264 patients, 156 (59%) of whom died and met criteria for medical examiner jurisdiction. Of these cases, 54 (35%) were autopsied. Nearly all patients had the external stigmata associated with Autopulse® use, a finding previously reported in the literature. More importantly, though, a significant number had internal injuries. The most common finding, after the external abrasions, is posterior rib fractures associated with posterior intercostal muscle hemorrhage, an injury previously not associated with manual chest compressions. Other injuries include liver and spleen lacerations, hemoperitoneum, vertebral body fractures, and mesenteric lacerations.

A subsequent study at the Harris County Medical Examiner's Office of patients who were resuscitated utilizing the Autopulse® was undertaken to determine if body habitus or bone strength played a role in occurrence of injuries. A total of 58 cases were reviewed and 36 (62%) were found to have posterior rib fractures. Rib fractures occurred fairly equally amongst younger individuals with robust bone as well as older individuals with osteoporosis. Furthermore, the overall size of the chest did not appear to be associated with an increase or decrease in rib fractures or visceral injuries. However, band placement, evidenced by the characteristic skin abrasions, and body habitus were associated with bone and visceral injuries.

Data is still being analyzed in the utility of the Autopulse® in mainstream resuscitation. Some studies have shown improvement in survival over manual compressions, while others did not. Over 4300 units have been installed and approximately 24000 LifeBands™ have been used clinically, and these numbers are likely to increase. A comprehensive understanding of biomechanics and resultant bone and visceral injuries is crucial for forensic pathologists charged with the responsibility to differentiate between Autopulse® and traumatic injuries. It would be prudent to have a policy in place with the EMS responders in your area such that they are not used on patients with traumatic injuries and they should never be utilized on children.

Autopulse®, Autopsy, Posterior Rib Fractures

G117 Migration of a Bullet in the Lumbosacral Spinal Canal: A Case Report and Review of the Literature

Audrey Farrugia, MD, Bertrand Ludes, PhD, Annie Geraut, MD, and Jean Sébastien Raul, PhD, Medicolegal Institute, 11 Rue Humann, Strasbourg, 67065, FRANCE*

After attending this presentation, attendees will understand rare cases in common medicolegal autopsy practice, descriptions of different types of spinal canal migration reported in the literature, and mechanisms and conditions that could induce a bullet migration.

This presentation will impact the forensic community by explaining a well known but relatively rare phenomenon in common medicolegal autopsy practice.

Reported here is a case of a 22-year-old man who was hit by a gunshot on the left part of the chest in the sixth intercostal space. The bullet had a previous course in a first victim.

The X-Ray examination of the body of the 22-year-old man showed a metallic object projected at the level of L1. At autopsy, examiners described that the bullet during its trajectory induced a pulmonary lesion, gastric perforation, pancreas, and hepatic lesion and left renal vein and artery perforation. The bullet then entered the spinal canal through the L1-L2 intervertebral foramen. Classical laminectomy at the lumbar level was performed, the dura was opened, and the bullet was found at the L5-S1 level. This case illustrates a bullet migration due to gravitational forces as its kinetic energy decreased after an intermediary target (the first victim) and collision with body structures.

The different cases reported in the literature, particularly the different types of migration will be discussed. If migration of T10-S1 seems to be more frequent, some authors reported a C1 to S2 or cranium to L4 migration. In one case, a migration from S1 to L4 level in the cranial direction, because of the patient's position, was also described. The different mechanism of migration and the symptomatic effect of this phenomenon will also be discussed.

Bullet, Migration, Spinal Canal

G118 Homicide-Suicide in Tours France: 2000-2007

Pauline Saint-Martin, MD, and Patrick O. Byrne, MD, Service de Médecine Legale, Hôpital Trousseau, Centre Hospitalier Régional Universitaire de Tours, Tours, 37000, FRANCE*

After attending this presentation, attendees will learn about the characteristics of homicide-suicide in a French rural area in an eight-year period, as only one study on these events has been conducted in France.

This presentation will impact the forensic science community by expanding knowledge of homicide-suicide in France. An important stage could be the creation of a national surveillance network, so that studies could be conducted over the whole country and over a long time span, allowing the possibility of preventive intervention.

Introduction: Homicide-suicide (HS) has been defined by a homicide committed by a person who subsequently commits suicide within one week of the homicide. These events are relatively uncommon but they have often drawn the media's attention. HS occupies a distinct epidemiological domain that overlaps with suicide and domestic homicide. Two major classifications have been proposed. Both are based on victim-offender relationship and motive. Few statewide studies of HS events have been conducted, but no data from France are available, except one Parisian study. This study of the characteristics of

all HS in Tours, France during an eight-year period was compared with results obtained in other international studies.

Material and Methods: Case records of the Institute of Forensic Science of Tours were reviewed for 2000-2007. The age and sex of the perpetrator and victim, the relationship between them, the method of death, and the circumstances were noted.

Results: Sixteen HS involving a total of 33 decedents occurred during the 8-year period. It represents 11% of the total case of homicides within this period, for a population of 871,000 persons. All offenders were male, with a mean age of 68 years. In 11 events (68%), the offender used a rifle for both the homicide and suicide. Most victims were female (14/17), with a mean age of 64 years. Fourteen events occurred at home. Five were suicide pacts, during which one person killed the other before committing suicide. In these cases, a suicide note was always found.

Discussion: Data were similar to those obtained in other studies. The victim was often a female who was younger than the offender and her intimate partner. The most frequent apparent motive was the breakdown of the relationship. Suicide pacts were also frequent. Shooting was the most frequent used method of both homicide and suicide. Availability of firearms in this rural area of France can be explained by an important activity of hunting. The percentage of HS related to the total number of homicides was important and this result confirmed one epidemiological law of HS: the lower the homicide rate, the higher the percentage of HS. One limitation of study was the limited number of cases. However, a research strategy should be developed in France to expand knowledge of these events. A phase of this strategy could be the creation of a national surveillance network, as well as preventive interventions.

Homicide-Suicide, Suicide Pact, Amorous Jealousy

G119 Sudden Deaths Associated With Sexual Activity

Albert Y. Chu, MD, Sharon M. Derrick, PhD, and Luis A. Sanchez, MD, Harris County Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054*

Attendees will review of non-homicidal sudden deaths associated with sexual activity that occurred in Harris County, Texas, from January 2004 until the present. The goal of this presentation is to describe the epidemiological characteristics, autopsy findings, and toxicology results in this group of decedents.

This presentation will impact the forensic community by describing a population of decedents that commonly present to medical examiner and coroner's offices, including a description of the relatively high prevalence of substance abuse in this population.

Because deaths associated with sexual activity often occur suddenly and outside of the care of a physician, they are frequently reported to the local medical examiner or coroner's office. The extent of the resulting death investigation may range from no additional investigation to a full autopsy with histologic and toxicologic evaluation, depending on the circumstances of the particular case, office-specific guidelines, and the judgment of the individual pathologist/investigator. To further characterize this group of decedents and thereby aid in the investigation of similar deaths in the future, a review of sudden deaths associated with sexual activity was performed.

A review of cases from the Harris County Medical Examiner's Office from January 2004 until the present identified 35 cases of sudden death associated with sexual activity (excluding homicides). These cases fell into three broad categories: (1) collapse occurring either during or immediately around the time of sexual intercourse (22, 62.9 percent), (2) individuals found unresponsive in adult-oriented establishments (theaters, video booths, etc) (11, 31.4 percent), and (3) cases of autoerotic asphyxiation (2, 5.7%).

Autopsies were performed in 29 of 35 (89.7%) of all cases and toxicology testing (including at least a screen for stimulants) was performed in 25 of 35 (71.4%) of all cases. The population was overwhelmingly male, with a male to female ratio of 10.7 to 1. The mean age was 57.6 years. Atherosclerotic and/or hypertensive cardiovascular disease represented the most common natural cause of death, and was identified in 29 of 35 (82.9%) of all cases. The mean heart weight was 543.9 grams among natural deaths and 490.0 grams among deaths attributed to substance abuse.

Deaths were attributed to substance abuse in nine of 35 (25.7%) of all cases and nine of 25 (36.0%) of cases in which toxicology testing was performed. Of these, only five of nine (55.6%) had a known history of substance abuse. Among cases in which toxicology testing was performed, substance abuse-related deaths occurred in five of 14 (35.7%) of individuals having sexual intercourse and four of nine (44.4%) of individuals found in adult-oriented establishments. Cocaine was the most commonly identified drug of abuse, followed by methamphetamine and methylenedioxymethamphetamine. One case of inhalant abuse (ethyl chloride) was identified. Atherosclerotic and/or hypertensive cardiovascular disease was identified in six of nine (66.7%) of deaths attributed to substance abuse.

The high prevalence of cardiovascular disease that researchers observed is consistent with previous studies of myocardial infarction and/or sudden death associated with sexual activity. Less recognized by the existing medical literature is the significant prevalence of substance abuse in this population, including those decedents with no known history of drug use. The results of this review suggest that a history of sudden death in association with sexual activity warrants at least a toxicologic analysis for stimulants in order to classify accurately the cause and manner of death, even in the absence of a known history of substance abuse.

Sudden death, Sexual, Toxicology

G120 Sex Killer: Sexually Related Trauma and Deaths - Forensic Aspects

Gilles Tournel, PhD, IML de Lille, 1, Place de Verdun, Faculté de Médecine, Lille, 59045, FRANCE; and Valery Hedouin, PhD, Cédric Houssaye, MD, Frédéric Grimopont, Antoine Stelandre, Anne Becart, PhD, Viviane Gnemmi, Sandrine Depret, MD, IML de Lille, Lille, 59045, FRANCE; and Didier Gosset, PhD, IML de Lille, Faculte de Medecine, Lille, 59045, FRANCE*

After attending this presentation, attendees will know the description of potentially dangerous sexual practices and their consequences involving death.

This presentation will impact the forensic science community by the knowledge and the awareness of these particular sexual practices and their consequences involving death.

Introduction: Many men and women practice a broad range of voluntary sexual activities, most of which are harmless. Many minor injuries of the genital, oral, and anal areas do occur but most of them only require symptomatic therapy. The only erotic activities with an unacceptable risk for injury are vaginal insufflations during pregnancy, and fist fornication. Some forensic deaths are indirectly linked to sexual activity. Three cases of deaths with unusual fatal mechanisms during sexual activities are reported.

Materials and Methods: Forensic investigations of the crime scene and the autopsy findings of three cases: two women and one man will be presented. Another living woman with important genital lesions provoked by sexual activity was examined by a forensic pathologist and gynecologic doctor. The pelvic and abdominal lesions are described.

Results: In Case 1, a 35-year-old woman was found dead in her bed. The death was attributed to asphyxia by strangulation. At autopsy,

anal and sphincter injuries and massive rectal hemorrhage were seen, due to rectal fist insertion (fisting). Her husband was sentenced for murder by strangulation and sexual assault. Case 2 presents a 42-year-old man was found dead in his car in the driver's seat, his clothes (trousers and underpants) pulled down around his ankles. Police and forensic investigations supposed voluntary sexual practices with a prostitute, such as oral sex. At autopsy, investigators observed an internal thoracic hemorrhage linked to a ruptured aortic aneurysm. The sexual activity brought about the tearing of aortic tissue. Case 3 presents a 48-year-old woman performed voluntary sexual activities such as vaginal and rectal fist and foreign body insertion (alcohol bottle into the base) during heterosexual activity. The surgeons observed haematomas of the vulva, major labia, minor labia, and anal area. A colostomy was performed for the anal sphincter injuries and a surgical act to drain off the haematomas. In Case 4, a 37-year-old woman was found dead in her bed. A large quantity of blood was observed between and over the thighs. Her husband specified that the blood resulted from menstruation. At autopsy, vaginal injuries and massive hemorrhage were observed, due to vaginal fist insertion (fisting). The cause of death was vaginal hemorrhage due to the fisting. Toxicological analysis showed she was drunk. Her husband pretended that she consented to this sexual activity. He was sentenced for sexual assault leading to the death by hemorrhage.

Discussion: Anal and/or vaginal fist or foreign bodies being inserted are uncommon and potentially dangerous sexual practices. Forensic investigations, the autopsy, toxicological and histopathological findings, and the manner and the mechanism of death for three persons will be discussed. The insertion of a clenched hand and forearm into the vagina or rectum during heterosexual activity and indirect performing aortic rupture on pre-existing lesions during oral sex are linked to the cause of death. The frequency of such fatal outcomes or sexual activity of anal and vaginal penetration, the injuries observed, the cause of death due to these acts (exsanguinations by traumatic damage to the canal anal and to the vagina or/and air embolism), the consequences of these practices, the relationship between the perpetrator and the victim and the special features at the scene, are discussed and compared to the literature. Indeed, foreign bodies, arm, and forearm inserted into the rectum and the vagina with associated hemorrhage and perforation have been well documented in medical literature. However, death following these acts has very rarely been reported. Such cases remain rare but have to be reported to alert the forensic pathologists, investigators, and coroners. In a larger range, the public must be aware of the role of such sexual activity and their consequences involving death.

Fisting, Hemorrhage, Erotic Death

G121 Conducted Electrical Weapons — A Review of the Medical Literature

Donald M. Dawes, MD, Lompoc Valley Medical Center, 518 East Hickory Avenue Lompoc, CA 93436; and Jeffrey D. Ho, MD*, Hennepin County Medical Center, 701 Park Avenue South, Department of Emergency Medicine, Minneapolis, MN 55415*

After attending this presentation, attendees will have gained a working knowledge of the existing medical literature on conducted electrical weapons such as the TASER X26.

The presentation will impact the forensics community by improving knowledge of the existing medical research on conducted electrical weapons which may be important especially for those who make determination of death decisions.

Conducted electrical weapons are used to control violently resistive subjects. The devices discharge a small electric current that stimulates both afferent sensory neurons causing pain and efferent motor neurons causing involuntary sub-tetanic muscle contraction. The use of these devices is growing in the United States since it fills a large void in the

use-of-force continuum. There is controversy in the lay press and medical literature regarding the use of these weapons and the sudden, in-custody death phenomenon. Some groups have claimed that these devices have caused several hundreds of deaths. This presentation is a review of the existing medical literature on these devices. By attending this presentation, attendees will develop a comprehensive understanding of the existing medical literature on conducted electrical weapons and will develop and understanding of questions that remain to be answered. The existing animal studies, case reports, and human prospective studies will be examined. The focus will be particularly on the existing prospective human research.

The presentation will examine issues such as cardiac safety, respiratory effects, and the impact of the devices on other physiologic parameters such as blood chemistries, pH, stress markers, and temperature. The presentation will examine the use of these devices in the presence of cocaine, and in the presence of cardiac pacemakers and internal defibrillators. The difference between animal data and human data will be discussed.

It is important for the forensic community to be knowledgeable about the existing research and the questions that are still not answered, particularly those individuals who make determinations of cause of death.

Conducted Electrical Weapon, TASER, In-Custody Death

PATHOLOGY/BIOLOGY

G1 Decapitation Due to Car Accident: Description of a Case and Review of the Literature

Francesco Ausania, MD, Antonio Oliva, MD, PhD*, Fidelia Cascini, MD, Massimo Senati, MD, Vincenzo L. Pascali, MD, PhD, and Francesca Cittadini, PhD, Catholic University, School of Medicine, Institute of Forensic Medicine, Largo Francesco Vito 1, Rome, ITALY

The occurrence of complete decapitation as consequence of car accident is an extremely rare event, while suicidal decapitation by hanging has been reported sporadically in forensic literature. The goal of this presentation is to describe a case of decapitation with complete degloving injury of the neck in a man involved in a traffic accident and we review other similar cases reported in literature.

This presentation will impact the forensic community by demonstrating how in such deaths, the concordance of crime scene investigations, autopsy findings and the presence of eyewitnesses if any, should be the ideal situation to achieve a reliable medico-legal analysis.

The occurrence of complete decapitation as consequence of car accident is an extremely rare event, while suicidal decapitation by hanging has been reported sporadically in forensic literature. Decapitation is usually seen in pedestrians run over by trains, and also in motorcyclists who impact against the tail board of trucks. Complete transection of pedestrians and occupants of cars is seen in road accidents with vehicles traveling at a high speed. In a recent report, Kibayashi has described a case of decapitation of a front seat passenger in a single vehicle accident. Another report described the vertical iron bar of a grill fence penetrating the neck and decapitating the driver of a two-wheeler scooter. Here we describe a case of decapitation with complete degloving injury to the neck, of a man involved in a traffic accident, and we review other similar cases reported in the literature.

A 55-year-old Caucasian man was driving his car at a speed of about 120 km/h near the city of Rome when the vehicle skidded off the road, hit another vehicle coming from the opposite direction, and finally impacted the road barriers. The decapitated body of the victim was extracted from the driver's seat, and the head was recovered outside. The immediate police report found that the victim was not wearing a seatbelt. At the autopsy, the body was that of a Caucasian man, decapitated at the first cervical vertebrae. The decapitation site had irregular, ragged and contused margins. Multiple abrasions on the face along with closed fractures of the facial bones and mandible were present. Internal examination of the head revealed diffuse subscalpular hemorrhages, and multiple fractures of the skull bones. The brain was edematous and slight subarachnoid hemorrhage was of the left temporal lobe. There were compound fractures of both humeri, multiple fractures of the ribs on both sides, and closed injuries of the shaft of left femur. Toxicological analysis revealed the presence of alcohol at the following blood concentration 2g/L. No other drugs were detected. Death was instantaneous owing to complete severing of vital neck structures.

Topography, morphologic nature of the wounds, and severity of the injuries of car occupants depend on several factors such as speed at the moment of impact, nature of the collision, active, and passive protection of the occupants, and sitting position. Several efforts and experimental studies have been made to explain the possible mechanisms provoking decapitation following vehicle accident. This injury, in the majority of cases, has been associated with failure to use seat belts, fast driving speed, and road barriers. In this case, it is plausible that because of the high-speed crash, the decapitation was provoked by an external object, such as road-barriers or structural elements of the vehicle being pushed back into the cabin and acting as a sharp-force to the neck. It is believed that in such deaths, the concordance of crime scene investigations, autopsy findings, and the presence of eyewit-

nesses, if any, should be the ideal situation to achieve a reliable medico-legal analysis.

Road Accident, Decapitation, Neck Injuries

G2 Unusual Gunshot Wound Death of a Sex Offender on the Way to Jail in the World of CSI

Karen B. Looman, DO*, Tidewater Office of the Chief Medical Examiner, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510

After attending this presentation, attendees will learn to assess an unusual case where the evidence at the scene makes it difficult for the medical examiner to decide homicide, suicide or accident and to evaluate peculiar scene circumstances involving ballistic evidence.

The presentation will impact the forensic community by showing how important it is to look at all the evidence at a scene and at an autopsy before making a decision about the manner of death.

A 36-year-old man was dropped off by his wife at a bus stop. He was taking the bus to jail for a nine year sentence in a juvenile sex offender case. He was found two days later on the back road of a rural area. He was sitting in the driver seat of the family car that had been in storage, suffering from a gunshot wound to the leg. He had a tourniquet tied around the injured leg. He had been dead for an unknown period of time and had started to decompose in the summer heat.

Crime technicians noted an unusual finding. Although there were no bullet holes through the car, there was a handgun on the ground outside the driver's door. There was a wooden dowel taped to the barrel of the gun, and a nylon string was tied to the trigger guard of the gun with the other end tied to the steering wheel. Lastly, there was an athletic sock covering the handle of the gun.

The autopsy was routine. The deceased was a healthy man, in the early stages of decomposition. There was a gunshot wound to the right thigh that entered the anterior medial thigh and exited the posterior medial thigh. Dissection revealed that the bullet transected both the femoral artery and vein. The cause of death was exsanguination from a gunshot wound to the leg.

The manner of death was less clear. What was the reason for the wooden dowel and the gun with the sock over the grip? There are several scenarios possible. The first scenario is that the man was attempting suicide because of his conviction and because his relationship with his wife was troubled, but did not want his death to look like a suicide. He used the sock to hide fingerprints and had the dowel taped to the gun so that he could hold the gun far enough away to look like a distant shot. Since he was holding the gun by the taped dowel he needed the string to pull the trigger and then he may have intended to jettison the gun, string, and dowel before dying. He successfully shot himself in the leg, but died in the driver seat of the car before he could get rid of the evidence.

The second scenario is an attempt to look like a holdup or an assault. The individual again knows about fingerprints, gunshot residue and range of fire determination. He rigged the gun to pull the trigger and shoot himself in an attempt to look like someone else shot him. Perhaps he wanted to go to the hospital and delay the start of his jail sentence or obtain sympathy from his wife. But he shot himself in the wrong area of the thigh and although he put a tourniquet on the leg, he bled to death before he could get help.

The third scenario is an accident. Perhaps he was doing something with the string and the dowel that could never be understood, unless the victim himself explained it, and he was accidentally shot. He lost too much blood to drive himself to get help, and he died at the scene.

Questions remain unanswered as to what his motive was. Also, why was the string tied to the steering wheel? Did he use some of the string to make a tourniquet and tie the end of the string to the steering wheel just to prevent the string from blowing away? Why wasn't he able to get help in time? Why was he in this rural area? It is also unclear where he acquired his knowledge of ballistics, but the complex scenario suggests familiarity with the world of CSI.

These are questions that may never have a final answer. But this is a good example of the need for thorough scene examination, background investigation, and straightforward autopsy technique. This presentation will discuss the evidence for each manner of death in this unusual gunshot wound case.

Range of Fire, Ballistics, Unusual Death Scene

G3 The Effect of Clothing on Decomposition Rate: A Teaching Model

Phillip L. Watson, PhD, Ferris State University, 808 Campus Drive, 2004 ASC, Big Rapids, MI 49307*

The goal of this presentation is to illustrate the difference in decomposition rates and insect colonization under identical environmental conditions.

The presence or absence of clothing can alter the decomposition rate. This is a difficult concept to teach unless there is a method that can be duplicated to show both conditions under identical conditions. This study will impact the forensic science community by determining the rate of decomposition of a clothed and unclothed pig as a function of summer environmental conditions.

The presence or absence of clothing can alter the decomposition rate (Anderson 2001, Kelly 2006). This is a difficult concept to teach unless there is a method that can be duplicated to study both scenarios under identical conditions. This study was conducted to determine the rate of decomposition of a clothed and unclothed pig as a function of summer environmental conditions. Insects were collected twice a day until the dry-remains stage occurred, and climate consisting of temperature, relative humidity, rainfall, and wind speed data was collected on an hourly basis. The data show increased activity of forensically important insects to be a function of both temperature and clothing. The delay of the clothed victim to reach the dry-remains stage was significantly different than the victim without clothing. The stages of larvae collected from the clothed victim were also significantly smaller than the larvae collected from the unclothed victim at all collection dates until the unclothed victim was no longer attractive to forensically important flies.

Data collection to be demonstrated will be larva size and species composition on each pig over time. Comparisons were done as an ANOVA test and a species-diversity comparison for all days. Results will be used to set up teaching mock crime scenes to illustrate the effects of clothing on PMI calculations.

Clothing, Decomposition, Flies

G4 Improved Estimation of Time Since Death With Multiple Protein Markers and Automated Analytical Methods

Behnoush Memari, MS, Kenneth G. Furton, PhD, and Alberto Sabucedo, Florida International University, 11200 South West 8th Street, Miami, FL 33199*

After attending this presentation the attendee will learn how degradation of cardiac Troponin I (cTnI) and Troponin T (cTnT) analysis can help forensic scientists narrow their estimate of postmortem interval.

This presentation will impact the forensic community by improving the precision and rate of postmortem interval (PMI) estimates using an automated analytical method to better assist law enforcement in many criminal, civil, and forensic investigations.

Knowledge of the time since death (PMI) has enormous legal, criminological, and psychological impact; but currently suffers from uncertainties on the order of days to weeks without mathematically defined confidence information and a lack of technological advances. The main principle of the determination of the time since death is the calculation of a measurable date along a time-dependent curve back to the start point. Characteristics of the curve slope and the start point are influenced by internal and external, antemortem and postmortem conditions which need to be taken into consideration. Current methods utilize temperature-based algorithms intended to model the cooling of the body after death in order to estimate the postmortem interval which introduces considerable inaccuracy due to influencing factors. Livor mortis, rigor mortis, and to a lesser degree, algor mortis also have been used to estimate the postmortem interval. Forensic pathologists agree that these characteristics only provide "postmortem windows." Quantitation of the vitreous fluid potassium level has been of some value in evaluating the early postmortem interval, but the accuracy of this method is dependent on external conditions, the availability of vitreous fluid and the purity of the sample. For practical purposes, a simple, relatively inexpensive assay performed on readily available cardiac tissues, less dependent upon external factors, and providing data that could be plotted on a reproducible control curve would be of value in determining the postmortem interval accurately.

Cardiac Troponin I (cTnI) and cardiac Troponin T (cTnT) are proteins found in heart tissue as selective markers of cardiac muscle damage, and investigation of these proteins for determining time since death shows great promise in mammalian heart tissue. These proteins are good substrates for several enzymes released in cardiac tissue upon death (necrosis); the proteolytic breakdown of these proteins in postmortem cardiac tissue can be exploited to determine the PMI. This technique takes a small sample of cardiac tissue that is homogenized and the proteins are then extracted with magnetic microparticles, separated by SDS-PAGE and visualized by Western blot, which is probed with mouse monoclonal antibodies against cardiac TnI and TnT. This step is followed by labeling and precipitation with a colored substrate to monitor degradation patterns. The area of the bands within a lane is quantitated by scanning and digitizing the image using commonly available scanners. This methodology is also migrated to more automated capillary electrophoresis.

The results show a linear relationship between the percent protein degraded and the log of the postmortem time. A fresh "reference" human heart tissue obtained at time T_0 was incubated to obtain a temporal degradation profile. Comparison of human cardiac tissue samples with unknown time of death can be evaluated qualitatively against the "reference" human heart tissue. The time of death can be estimated by matching the "degradation fingerprint". Similarly, a calibration curve ($r > 0.95$) can be obtained with the percent cTnI degraded plotted against the log of the time postmortem using the reference human heart tissue. This curve can be used to estimate the time of death relative to the "reference" tissue based on the percent degradation. The data indicate that the degradation of cTnI in heart tissue shows very spe-

cific bands during a postmortem interval of a week. The Troponin T is a more stable protein in comparison to Troponin I, so the degradation of cTnT takes longer. Combining the data obtained from the cTnI and cTnT can then be used for extended PMI estimates. Frozen human cardiac tissue samples at known times of death were analyzed by both the semi-quantitative and the qualitative techniques and both show similar agreement with the known time of death. Overall, the data demonstrates that this technique represents a major advance in time of death determination providing a fast and reliable semi-quantitative biochemical marker from a protected organ versus other measurements. Tissue cardiac Troponin I and Troponin T shows excellent characteristics as a time of death marker in the extended postmortem interval which is difficult to estimate with current methods.

TnI (Troponin I), TnT (TroponinT), Postmortem Interval (PMI)

examine the relative levels of DNA degradation and these results were compared with profiles of the extracted samples generated from an ABI Prism® 310 Genetic Analyzer. Comparisons made between bone, blood and tissue samples and corresponding non-degraded blood samples were used to estimate relative rates of degradation. Studies on the effects of inhibitors on these samples will also be discussed.

The results of this study indicate that there is a timeline that degradation follows as samples that were 8 weeks or older have, when compared to more recent remains, a substantial reduction in the amount of extractable DNA. This study also indicates relative rates of decompositions based on sample conditions and helps provide a comparison of different extraction and amplification procedures using real samples with known history.

DNA, Degradation, Environmental

G5 The Effect of Environmental Degradation on DNA With Respect to Time and Conditions

Matt Buettner, BS, Kerry Opel, BS, Bruce R. McCord, PhD, International Forensic Research Institute, Department of Chemistry, Florida International University 11200 SW 8th St, Miami, FL 33199; and Lee Jantz, PhD, 250 South Stadium Hall, Knoxville, TN 37996*

The goals of this presentation are to show the effects of environmental degradation of DNA due to environmental conditions and exposure over time and to show the development of degradation curves and a degradation timeline based on type of burial.

This presentation will impact the forensic community by providing an estimation of decomposition of rates of nuclear DNA and provide information concerning the best method for recovery of information from degraded samples.

The goal of this presentation is to show the effects of environmental degradation on DNA with respect to time and environmental conditions in order to develop a better understanding of these effects on the analysis of tissue and bone samples. Ultimately these studies will assist an analyst in determining the relative age of an individual sample, whether a lack of PCR activity is due to degradation or PCR inhibition, and what quantity of DNA must be recovered from the sample in order to generate an optimal genetic profile.

This study will examine the rate of decomposition of human remains under a variety of conditions, focusing on the quality and quantity of DNA that can be recovered over time. Control blood samples will be utilized to provide a clear estimate of initial quality of the DNA. The effect of different types of burial environments on DNA will then be investigated. Three types of samples will be obtained: above ground, in water, and underground burials. The focus of this study will be to determine the rate of degradation of DNA between samples based on the type of burial and the environmental conditions. Both real time PCR and STR amplification will be used to estimate these effects. Due to the advances in rtPCR techniques and the development of mini STR kits, current capabilities for the analysis of such samples have greatly improved. However, laboratories need guidance on when to use specialized analytical systems for degraded samples and when more traditional large multiplex kits can be used. Ultimately it is expected that these experiments will provide guidelines on how such samples should be prepared and analyzed.

Tissue, blood, bone, and nail samples have been obtained from the University of Tennessee Anthropological Center and extracted using QIAGEN Blood and Tissue kits and amplified using an Alu based Real-Time PCR method. The 25mg Lfor samples tissue samples typically yielded concentrations of well over 1ng/ μ L less than 4 weeks old. For samples 4 to 6 weeks old, a yield of between 1.0ng/ μ L and 0.1ng/ μ L was observed. More highly degraded samples obtained after 8 weeks yielded even lower concentrations of DNA. A variety of amplicon sizes were used with real time PCR to next

G6 The Role of Scene Investigation in Uncovering Staged Suicides

Jerri McLemore, MD, and Steven Tyrdik, BS, Iowa Office of the State Medical Examiner, 2250 South Ankeny Boulevard, Ankeny, IA 50023*

After review of this presentation, the audience will understand the need for careful documentation of a death scene and retaining a healthy dose of skepticism when investigating apparent suicides. The audience will also understand the need for good communication between agencies in relaying discrepant findings and their potential significance in these investigations.

This presentation will impact the forensic community especially death scene investigators by emphasizing the need to adhere to standard guidelines when investigating all death scenes and to treat each scene as a potential homicide. This presentation will also impact the medical examiners' offices that must provide justification for performing autopsies on suicides.

Scene investigation is a vital component along with findings from a postmortem examination in ascertaining the cause and manner of death. Failure to approach a scene with an open mind where the cause and manner of death seem obvious results in an inability to recognize subtle discrepant clues or leads to irrevocable loss of valuable information. Careful investigations of death scenes where homicide is obvious are almost second nature for law enforcement officials and medical death investigators. Similar careful investigations may be lacking where the manner of death looks like suicide, natural or accident especially when investigators have determined the manner of death before analyzing the scene. Such an approach to scene investigation may lead to erroneous conclusions in homicides that have been staged to look like suicides. Although these staged deaths have been discussed in the forensic literature, most of these cases involved the perpetrator staging the scene to look like a hanging.

Two case studies of homicides that appeared to be suicides will be presented. One death involved a woman who had recently been diagnosed and surgically treated for cancer who was found dead in bed with a gunshot wound to her head. The other case involved a woman who was having marital difficulties and was found in her vehicle while the engine was running in her closed garage. In both cases, the investigators recognized inconsistencies and processed each scene as if they were dealing with a potential homicide. In the case of an apparent self-inflicted gunshot wound to the head, the investigator's concern over blood stain patterns that were inconsistent with the information that this investigator was obtaining from the home-health nurse and decedent's grandson led to the appropriate work-up of the scene and, eventually, to the prosecution of the grandson for homicide. An investigator's observation that a woman's blouse was on backwards in the apparent carbon monoxide poisoning, aided in the correct determination of manner of death due to a more thorough examination of the vehicle, remainder of the house, and decedent at the scene. Communication of the investigators' suspicions to the forensic pathologist in both cases enabled an even more careful examination and documentation of injuries.

Death Investigation, Suicide, Blood Stains

G7 Intrauterine Sudden Death: Study of the Fetal Morphological Substrates

Emiliano Maresi*, Antonina Argo, Pierangela Fleres, Paolo Procaccianti, and Michele Spicola, Palermo University, Via del Vespro, n. 127, Palermo, 90100, ITALY

After attending this presentation, attendees will understand the risk factors, causes, and prevention of many fetal deaths as well as ancillary studies utilized for proper diagnoses.

This presentation will impact the forensic community by serving as an educational resource through discussing sudden fetal death in such cases as funicular thrombosis due to anticardiolipin antibodies, chorioamnionitis, deciduitis, cervicitis, and intrauterine Botallo's duct closure due to aspirin

Healthy pregnancy derives from the anatomic and functional relationship between all the components of the pregnancy including, the fetus, placenta, and the mother. If the normal relationship between these elements fails because of intrinsic or extrinsic factors, a pathological pregnancy leading to fetal death may occur. To evaluate the morphological substrates leading to sudden death, an accurate evaluation of the fetal autopsy and examination of the placenta, together with the determination of chromosomal pattern, serological and microbiological evaluation, and total body X-rays are mandatory for a correct diagnosis of the death. An exact diagnosis of fetal sudden death may help prevent the event from recurring in future pregnancies.

For a pregnancy, to be normal, it needs a complex anatomical-functional cooperation between three different biological systems: fetus, placenta, and pregnant mother. The interruption of this kind of connection, due to intrinsic or extrinsic causes, produces a pathological pregnancy that can result in fetal death. In olden times, fetal deaths were not considered a competence of obstetricians, pediatricians, or pathologists, so it was not possible to establish the cause of death and identify the death-risks for subsequent pregnancies. On February 2, 2006, the Italian government issued a law establishing the role of pathologists in the sudden fetal death after 25th week. According to this rule, the pathologist must identify all the anomalous morphologic substrates, by performing a careful autopsy examination, with total body X-rays of the fetus, serological/ microbiological tests, and placental screening tests, in doing so to promote primary and secondary prevention. An essential role is obtaining an accurate medical history.

This retrospective study describes the causes of 1836 fetal deaths occurring after the 25th week, from January 1987 through December 2006. 314 sudden fetal deaths (38.8%) were observed. In this group there were 176 males (56%) and 138 females (44%), ranging in age from 26 weeks to 42 weeks of pregnancy; 127 (40.5%) fetal deaths occurred before the 37th week of pregnancy. 258 of 314 fetuses showed maceration due to intrauterine death. Some fetuses of this group showed signs of distress. Maternal risk factors were identified in 251 (80%) of the fetal deaths including hypertension (35%), diabetes (20%), bigeminal pregnancy (18%), and central placenta previa (7%).

The fetal sudden deaths were due to placental causes in 283 (90%) cases, fetal causes in 16 (5.1%) cases, maternal causes in 10 (3.4%) cases and unknown causes in 5 (1.5%) cases.

The placental causes were: 130 (46%) funicular disorders; 54 (19.2%) amniotic membrane disorders; 99 (35%) chorionic villi disorders.

The fetal causes were: 12 cardiomyopathies; 4 intrauterine Botallo's duct closure.

Maternal causes were: 7 mother's sudden deaths due to amniotic and thrombotic pulmonary embolism; 3 uterus ruptures.

Most of sudden intrauterine fetal deaths are caused by funicular and chorionic villi disorders. It is possible to prevent sudden fetal death in cases of funicular thrombosis due to anticardiolipin antibodies, chorioamnionitis, deciduitis, cervicitis, and intrauterine Botallo's duct closure due to aspirin. Genetic tests are important in the deaths due to cardiomyopathies. The sudden fetal deaths, occurring after 40° week, are related to maternal risk factors so it's important advance the delivery.

Fetal Sudden Death, Autopsy Guidelines, Prevention

G8 Fatty Acid Methyl Ester Profiling of Bacterial Spores for Microbial Forensics

Christopher Ehrhardt, PhD*, Counterterrorism and Forensic Science Research Unit, Federal Bureau of Investigation Academy, Building 12, Quantico, VA 22135; Mark Reimers, PhD, Alcon Laboratories, Inc., 6201 South Freeway, Fort Worth, TX 76134; Mathew Ducote, PhD, Midwest Research Institute, 1470 Treeland Boulevard South East, Palm Bay, FL 32909; James Robertson, PhD, Counterterrorism and Forensic Science Research Unit, Federal Bureau of Investigation Academy, Building 12, Quantico, VA 22135; and Jason Bannan, PhD, Federal Bureau of Investigation, Laboratory Division, 2501 Investigation Parkway, Quantico, VA 22135

After attending this presentation, attendees will be familiar with the use of fatty acid profiling to determine the source of bacterial spores grown on several different culture media and the forensic applications of gas chromatographic (GC) techniques for examining the fatty acid composition of the membranes of organisms isolated from biological evidence.

This presentation will impact the forensic community by introducing a technique that may assist investigators in determining the culture methods employed to produce a microbial agent used in a biocrimes or act of bioterrorism.

Fatty acids are components of bacterial membranes that can be regulated by the cell in response to the types of available nutrients present in the culturing media. Therefore, genetically identical bacteria that are grown on different media substrates can vary in their fatty acid composition. Previously, fatty acid methyl ester (FAME) profiling has been used in clinical settings for bacterial strain identification, but has not yet been applied for forensic applications.

In this research, three hypotheses were tested. First, whether a clinical method for FAME profiling of bacterial cells can be adapted for use with bacterial spores. Second, can reproducible FAME profiles be produced from minimal amounts of evidence (<3mg spores). Third, can a database of FAME profiles of spores grown under a variety of well-established conditions be used to reliably identify the medium used to grow the spores of an unknown sample.

For this work, 22 different culture formulations were used to prepare and process *Bacillus cereus* T-strain (BcT) cultures. Fatty acid extraction and GC profiling were performed on spores from each media preparation using two different analytical techniques: (1) the clinical FAME method ("Rapid Method") which requires approximately 30 mg of biological material and two hours to process, and (2) the more forensically relevant method ("Instant Method") which requires only 1 mg of biomaterial and approximately 15 minutes of processing time. The effect of media substrate on spore fatty acid composition was examined using Cluster Analysis (CA) and Principal Component Analysis (PCA) of all generated profiles.

FAME profiles from both methods and each media substrate were used to construct two BcT strain spore databases. Similarity indices calculated between FAME profiles with the Sherlock Microbial Identification System (MIDI) software were used to evaluate the variability and reproducibility of the spore database data.

The results of this research suggest that FAME profiles from spores grown on most of the surveyed media substrates can be statistically distinguished using CA and PCA. Oleic Acid appears to be specific for Columbia Blood Agar and Tryptic Soy Agar with Blood indicating that certain fatty acids may be diagnostic for specific media types. In addition, reproducible fatty acid profiles were generated from less than 1mg of dry spores using the "Instant Method." Results will be presented for comparison of 'blind' spore profiles against the profiles in the BcT spore-media databases. These studies will demonstrate the potential usefulness of FAME profiles for forensic microbiology.

Fatty Acid, *Bacillus*, Bioterrorism

G9 Suicidal Intoxication by Copper Sulphate

Jerónimo Fonte Santa Silva*, Bairro de Santa Justa, 10, Coimbra,
3000-356, PORTUGAL

The goal of this presentation is to present a case of suicidal intoxication by an unusual chemical compound.

This presentation will impact the forensic community by demonstrating how Intoxications (accidental, suicidal or homicidal) with copper sulphate are rare, as can be seen in the few cases described in forensic literature.

Introduction: Portugal is traditionally an agricultural country; therefore intoxications by pesticides are very common, especially with paraquat and organophosphorous. Copper sulphate is a fungicide used to control bacterial and fungal diseases of fruit, vegetables, nut, and field crops. It can also be applied in water treatment systems to control algae. This pesticide is available as dust, wettable powder, and liquid concentrate. In Portugal its major application is in vine plantation.

Copper sulfate solutions may irritate eyes, skin, respiratory and mucous membranes. Poisoning by this compound may affect the central nervous system, liver, kidneys, and capillaries, frequently causing renal failure and haemolytic anaemia.

Despite Portugal's major wine production, intoxications (accidental, suicidal, or homicidal) with this compound are relatively rare, as can be seen in the few cases described in forensic literature.

An 81-year-old male, diabetic with chronic renal insufficiency was admitted at the hospital with suspicion of voluntary ingestion of copper sulphate. Four days later he died. He was admitted in the Nephrology unit with acute renal failure and anaemia, and was treated with intensive hemodialysis and blood transfusions. Later on, he developed metabolic acidosis and there was a worsening of his anaemia. During admittance a 1.5 mg/L copper concentration was detected in his blood.

At the autopsy, it was possible to see a green coloration of the nails, ascitis, and pleural effusion on the right side. Samples from heart, kidneys, lungs and liver were taken for histopathological examination. The major microscopic changes were bilateral severe lesions of chronic pyelonephritis, renal arterioarteriolosclerosis, epithelial cytoplasmic vacuolization, and basophilic discolouration of the renal proximal convoluted tubules, perivenular hepatotoxic lesions with necrosis, and mainly mononuclear sinusoidal and portal inflammatory cell infiltration.

Clinical features indicative of acute intoxication by copper sulphate were renal failure, anaemia, and high copper concentration in blood (the normal concentration being 1 mg/L). Nevertheless, autopsy findings weren't significant; the most common features like gastric and esophageal erythema or ulceration were absent. The diagnosis was based on the microscopic alterations. In fact, not only was there evidence of renal histologic changes related with diabetes and chronic renal insufficiency (arterioarteriolosclerosis, chronic pyelonephritis), but also lesions suggesting copper sulfate poisoning: epithelial cytoplasmic vacuolization and basophilic discolouration of the renal proximal convoluted tubules. Furthermore, the histopathologic lesions observed in the liver were another clue to determining the diagnosis.

Copper Sulphate, Intoxication, Suicide

G10 Visceral Leishmaniasis in Turkey: Sociocultural Issues in Forensic Epidemiology

Hüseyin Cakan, PhD*, and Veçdet Oz, PhD, Istanbul University, Institute of Forensic Sciences, Adli Tip Enstitusu, Cerrahpasa Kampusu, PK10, Istanbul, 34303, TURKEY; Mustafa Aslan, PhD, Istanbul University, Cerrahpasa Medical Faculty, Tip Fakultesi, Mikrobiyoloji ABD, Istanbul, 34303, TURKEY; T. Mehmet Karayel, BS, Ismail Cakir, PhD*, H. Bulent Uner, PhD*, and M. Yasar Iscan, Ph.D, Istanbul Univ, Istanbul Universitesi, Adli Tip Enstitusu, Cerrahpasa Kampusu, PK.10, 34303, Istanbul, 34098, TURKEY

After attending this presentation, attendees will appreciate how socio-cultural and epidemiological issues are integrated into forensic sciences.

This presentation will impact the forensic community by demonstrating how a forensic scientist can participate in enlightening socio-cultural problems encountered by a developing nation.

Forensic epidemiology has been an emerging forensic science discipline dealing with diseases that create legal issues. Recognition of any parasitic infections requires an understanding of factors such as clinical symptoms and anamnesis, migration, and geography of the human settlement. Among the parasitic diseases, Visceral Leishmaniasis (VL) is one of the most difficult agents to identify and control and in turn is an important disease for the population as a whole. Therefore to control its effect on people, among the initial steps is to track the course of the disease and to plan the therapy. Furthermore, elapsed time during the diagnosis of the illness should be limited to a minimum. Because when the diagnosis is delayed the treatment may take longer. This situation may kick back as a serious problem about the illness of the patient and the application of the treatment. In the meantime, problems encountered during treatment such as difficulties in diagnosing psychosocial disorders and inability to identify the problems in every health center, must be solved.

The purpose of this presentation is an epidemiological assessment of VL encountered by patients during the course of the illness and its sociocultural impact on their lives.

The study includes nineteen patients (with a range of 1-17 years with a mean of 7.5 years) who were initially diagnosed as suffering from VL. From each patient, blood samples (5 ml), bone marrow and a personal health history (anamnesis) were obtained. The blood and marrow samples were analyzed using standard diagnostic tests designed for VL.

Results of the diagnostic tests indicated that eleven (7 males, 4 females) of the nineteen patients showed VL. Of these affected people, six were from Istanbul, two from Kastamonu and the remaining from the cities of Kütahya, Izmit and Hatay. Migration (change of residence) history was not known for six (2 male and 4 female) patients. History was known for five (4 males and 1 female) patients who moved to a different town. However, before moving to a different town, children were first taken to a local hospital for diagnosis. This visitation may have taken anywhere from 1.5 to 8 months. Some parents were not content with the results and did not get the help they needed. Eventually, these families moved their residence to a place (with a distance of 100 to 1,000 km from hometown) where they thought there were better treatment facilities (state or university hospitals). In two cases families changed their residence three times; one from Kütahya, Afyon and then to Istanbul and the other from Bursa, Çanakkale, and back to Istanbul). Parents of three (affected by malaria, leptospirosis) of the remaining eight children also moved their household to Istanbul where there are better healthcare facilities. However, the decision to change residence from the eastern and southeastern towns to Istanbul is a commonly seen migration pattern in the country. Otherwise, almost all hospitals are well equipped to cope with malaria and leptospirosis.

With the improvement in socioeconomic level and income, it has become easy to change residence to far away places in Turkey. Yet such migration has also made the transmission of disease agents relatively simple. The study shows that VL is sporadically present in many parts of country. There is no clear evidence of the transmission of this blood parasite from a

host to a person. In one case in Istanbul the host was thought to be a wild street dog living in a relatively poor residential area. The study indicates that the disease is haphazardly handled primarily due to a lack of medical procedure and guidelines to follow in dealing an infectious disease. Some parents of such victims seem to have spent their life's earnings to search for a remedy for their children by moving from one town to another in search of a better hospital or treatment center. In conclusion, it should be stated that infectious diseases are extremely serious and must be handled by a state medical procedure. As an important aspect of forensic epidemiology, such information must be communicated to all medical centers in and around the country. This procedure in dealing with an infectious disease is also important for doctors to avoid potential legal issues arising from wrong diagnoses and causing hardship for the patient and family.

Forensic Epidemiology, Medical Guidelines, Visceral Leishmaniasis

G11 Child Abuse: Practical Case of Autopsical, Radiological, and Anatomopathological Studies

Fabrice Dedouit, MD, and Céline Guilbeau Frugier, MD, Caroline Capuani, and Annick Sevely, MD, Service de Neuroradiologie, Hôpital de Purpan, 1 Avenue du Professeur Jean Poulhès, TSA 50032, Toulouse Cedex 9, 31059, FRANCE; Philippe Otal, PhD, Hervé Rousseau, PhD, and Francis Joffre, PhD, Service de Radiologie Générale, Hôpital de Rangueil, 1 Avenue du Professeur Jean Poulhès, TSA 50032, Toulouse Cedex 9, AL 31059, FRANCE; Bernadette Delisle, PhD, Service d'anatomie Pathologique, Hôpital de Rangueil, 1 Avenue du Professeur Jean Poulhès, TSA 50032, Toulouse Cedex 9, 31059, FRANCE; and Daniel Rouge, PhD, and Norbert Telmon, PhD, Service de Médecine Légale, Hôpital de Rangueil, 1 Avenue du Professeur Jean Poulhès, TSA 50032, Toulouse Cedex 9, 31059, FRANCE*

The goal of this presentation is to illustrate the potential of postmortem multislice computed tomography (MSCT) and magnetic resonance imaging (MRI) in cases of death secondary to child abuse.

This presentation will impact the forensic community by providing an example of forensic application of the MSCT and MRI.

A 17-month-old male baby was discovered pale and unconscious in his bed by her mother at home. An attempt of cardio-pulmonary massage was immediately begun by the father of the child. The medical rescue team was called by the mother. The reanimation attempt was unsuccessful and the rescue physician could only objective the death of the child. The reanimation performed was slight, with oxygen mask apposition and cardiac massage. No injection was performed. The external examination performed at home revealed that rigor mortis was already present and revealed the presence of numerous ecchymoses. The explanation of the parents was thought to be inconsistent with the corpse examination. The police investigators discovered that the family of the baby was known by the social services. Furthermore, a brother of the dead child had already been taken away from his family because of neglect. The dead child had been hospitalized one month prior because of a left humeral fracture. The parents explained that the child suffered form minor beta thalassemia and heterozygous drepanocytosis. The circumstances of home death of this baby were unclear and a medicolegal autopsy was ordered. Postmortem multi-slice computed tomography (MSCT) and magnetic resonance imaging (MRI) examinations were performed in order to determine cause of death of the baby and make an exhaustive visceral and skeletal study.

Imaging study:

- A full body MSCT exploration was performed the day of death. Axial MSCT was performed with a 16 x 0.75 mm collimation on a Sensation 16 unit (Siemens, Erlangen, Germany). Two- (2D) and three dimensional (3D) reconstructions were obtained on a Leonardo workstation (Siemens, Germany). 2D reconstructions were obtained using Multi Plane Reconstruction (MPR) and Maximum Intensity

Projection (MIP) modes. 3D reconstructions were obtained using Volume Rendering Technique (VRT) mode. Image interpretations were performed by a board-certified radiologist.

- A focused cerebral postmortem MRI was also performed the day of death. Axial acquisitions were performed in spin-echo T1-weighted, T2-weighted, and T1-weighted gradient echo sequences. Image interpretations were performed by a board-certified pediatric neuroradiologist.
- A postmortem full body radiological study was performed in the medico-legal department. This study consisted of skull radiographs (antero-posterior and lateral incidences), thorax, abdomen and pelvis radiographs (antero-posterior incidence), upper and lower member radiographs.

Autoptical and anatomo-pathologic studies: autopsy was performed by two board-certified forensic pathologists. All three body cavities (cranium, thorax, and abdomen) were examined. Anatomo-pathology was performed after a fixation in 10% formalin.

Results of the different explorations were finally compared:

Imaging study:

- *MSCT:* On cranial CT, diffuse oedema was visible with loss of the gray/white matter differentiation. Spontaneous pericerebral hyperdensities were visible in left frontal and right temporo-parietal areas. No skull or face fracture was visible.
 > On thoracic CT, no pleural or pericardic effusion was noted. Lungs appeared oedematous-congestive. Bone analysis revealed presence of 4 left rib fractures, with different MSCT aspects. One fracture concerned the posterior arch of the 6th rib, with osteosclerosis of its edges, attesting of the beginning of its consolidation. Two concerned the anterior arc of the 7th and 8th rib with a MSCT visible callus, attesting to their old productions. The last fracture was on the 9th rib, displaced, without MSCT consolidation sign.
 > On abdominal and pelvic level, no bone traumatic lesions were visible. No visceral lesion was clearly visible, but the natural contrast due to lack of internal fat (as is common in adult cases) was obviously bad. However spontaneous intra hyperdensities were visible within the mesenteric root and in intra peritoneal situation behind the abdominal anterior wall. They were interpreted as possible fresh blood.
 > The appendicular skeleton exploration confirmed the presence of a right humeral fracture with a callus, attesting to its old production.
- *MRI:* Bilateral subdural haematomas were visible in subfronto-parieto-temporal areas with varying signal intensities. They appeared as acute hematomas, with spontaneously hyper- and hyposignals on T2-weighted images. Subdural pericerebral hypersignal on gradient echo images were visible in left frontal and right temporo-parietal areas. A right frontal meningeal hemorrhage was also present. Interpeduncular and intra ventricular haemorrhages were also noted. Petechial haemorrhages within the posterior part of the corpus callosum were suspected.
- *Plain X-rays exploration:* It confirmed the callus of the right humeral shaft. Three left ribs fractures were noted, affecting the 7th, the 8th and the 9th ribs. No other bone traumatic lesion was noted.

External inspection:

The body was thin stout build, naked, measuring 79 cm tall, weighted 8.6 kg. An immobilisation of the right upper member was noted, secondary to the fracture and the hospitalisation dating from one month. Anthropomorphic measurement revealed an increase cranial perimeter of 48 cm. Numerous ecchymoses were noted on the body. Red ecchymoses were noted on the face, in peribuccal localisation,

and bi frontal regions. Ruptures of fraenulum, the tongue, and the superior lip were noted. Red ecchymotic lesions were also visible on both lower members. Brown ecchymoses of 0.5 cm in diameter were noted at the anterior face of the left hemithorax.

Autopsy and anatomo-pathology:

The scalp had a large hemorrhagic infiltration at its deep part, in right fronto-parietal regions, more limited in left frontal and right occipital regions. The right temporal muscle presented a hemorrhagic infiltration. No endo or exo cranial skull fracture was visible. However, a bilateral subdural hematoma was noted in fronto-parietal areas. A hematoma was also visible around the posterior fossa. The cervical spine was surrounded by epidural hematomas.

The chest exploration revealed presence hemorrhage around the 6th, 7th, 8th, 9th left ribs. Three calluses were found for the 7th, 8th, 9th left ribs. A consolidated callus was noted for the 6th rib. The inferior part of the right lung presented a hemorrhagic infiltration.

A perumbilical ecchymosis at the deep part of the anterior abdominal muscles was present. Many small bowel loops presented a superficial hemorrhagic infiltration.

A hematoma of the right kidney artery was found, continued by a retro peritoneal hematoma. A limited hemorrhagic intra peritoneal effusion was present.

Microscopic studies confirmed the existence of the rib fractures. The fracture located to the 6th rib presented a remodelling bone callus. The fractures of the 7th, 8th, 9th ribs presented cartilaginous callous. The right humeral shaft presented an ossifying cartilaginous callus.

Haemorrhagic infiltration was confirmed around the aorta, within the mesenteric root, the tongue, and within the anterior abdominal wall. The peri aortic, peri umbilical, and left flank haemorrhages were antemortem, contemporary of the death. The tongue lesions consisted of recent and old haemorrhages. The mesenteric root haemorrhage was antemortem, with inflammatory elements, permitting determination that it dated from several hours before death.

The subdural hematoma was confirmed to be acute. It presented polymorphonuclears and ischemic neuronal damage associated with a recent cervical spine epidural haemorrhage.

Several authors have compared postmortem imaging and autopsy results in neonatal death. MRI offers high resolution images of the entire neonate while leaving the body intact. Compared with other imaging techniques such as conventional x-ray and CT scan, the high spatial resolution and the high tissue contrast that can be generated by MRI are advantages. The different tissue contrasts that T1-, T2- or proton density weighted MR sequences provide can give additional information about the lesions or disease processes. Compared with autopsy, postmortem MRI has proven to be especially useful in the evaluation of the central nervous system. The high water content of the neonatal brain makes it difficult to handle during autopsy, even when adequately fixed. Subdural haemorrhages are the commonest type of injury found and this is in keeping with pathological evidence and studies using computed tomography. They are caused by damage to the bridging veins, which drain from the cortex into the superficial venous sinuses. It is important to note that different signal intensities of subdural haematomas do not necessarily indicate repeated bleeds at different times. Subtemporal blood is not well seen on CT, especially with its decreased multiplanar imaging capability. Extra-axial fluid collections can have the same density as cerebrospinal fluid on CT, and it is difficult to differentiate enlargement of the subarachnoid spaces and subdural effusions. MR is superior to CT when differentiating these extra-axial collections. Isolated subarachnoid haemorrhages can be difficult to detect on MR studies. MRI is useful at postmortem to direct the autopsy and brain cutting to focal areas of axonal injury.

Hart et al. in 1996 investigated the correlation between postmortem MRI of the head and autopsy findings in suspected child abuse. Autopsy was more effective in detection of subarachnoid hemorrhage, suture separation, extracranial injuries and very small hematomas. According to

these authors, MRI findings were useful in directing the autopsy and brain dissection to focal areas of abnormality. They found that postmortem MRI and autopsy were complementary and that each may disclose abnormalities missed by the other. In half of the eight cases of child abuse examined in this study, the combination of MRI and autopsy added valuable information compared with the results of autopsy alone.

In this case, combination of MRI and MSCT were able to determine the diagnosis of child abuse. Indeed, multiple fractures, of different ages were diagnosed. Skeletal fractures were suggestive of non accidental injuries because of their localisations: posterior arch of one rib, and association of recent and old fractures. Presence of an old right spiral humeral fracture was suggestive of child abuse; spiral fractures are classically secondary to torsional force. Cranial MRI was highly suggestive of intentional trauma. The MRI aspects of peri-cerebral hematoma are clearly visible compared to MSCT images. This exploration confirmed the pericerebral bleeding and objectified lesion not visible at the autopsy time as intra ventricular hemorrhage.

Limits of the MSCT are well illustrated by this case: the lack of tissue contrast because of the lack of fatty tissue is the highest limit of the technique. It does not permit a correct examination of the visceral trauma and lesions. However, diagnosis of intra peritoneal bleeding was possible and confirmed by autopsy. For skeletal trauma evaluation, MSCT was more efficient in our case than plain X-Rays. However, Cattaneo stated that radiology detected only 47%, autopsy 65%, while CT scans detected 34% of rib fractures. Rib fractures are quite unusual even in the setting of severe accidental trauma in infants and rarely if ever result from vigorous cardiopulmonary resuscitation. These injuries are usually clinically occult and typically result from excessive anteroposterior compression of the chest during shaking or with impact. Involvement of the posterior arc of the rib is most common, although fractures occur at all rib sites in abuse. Rib fractures tend to occur at multiple levels at similar points along the arcs of adjacent ribs, are often symmetric, and most frequently involve the middle ribs.

In this case, the autopsy was superior to imaging for the diagnosis of hematoma of the right kidney with a retro peritoneal hematoma and cervical epidural spine hemorrhage. The anatomo-pathology study did not confirm the suspected petechial haemorrhage within the posterior part of the corpus callosum.

This case report illustrates the potential of MSCT and MRI concerning battered child exploration in terms of determination of cause of death, visceral and skeletal evaluations, and age determination of lesions thus permitting the diagnosis of child abuse.

AAFS, Forensic Sciences, Radiology

G12 Posterior Rib Fractures in Infants Associated With Cardiopulmonary Resuscitation

Jolene R. Clouse, MD, and Patrick E. Lantz, MD, Wake Forest University, School of Medicine, Department of Pathology, Medical Center Boulevard, Winston-Salem, NC 27157-1072*

The goals of this presentation are to: (1) describe the recommended method of chest compressions for infants by the American Heart Association, (2) describe the proposed mechanism causing posterior rib fractures due to child abuse, and (3) describe how chest compressions during cardiopulmonary resuscitation in an infant could cause posterior rib fractures.

This presentation is intended to educate the attendees that posterior rib fractures in infants can occur in circumstances other than child abuse; specifically they can be associated with chest compressions performed during cardiopulmonary resuscitation (CPR). This study will impact the forensic community and humanity by demonstrating that posterior rib fractures can be related to CPR chest compressions and should not automatically assumed to be a result of abuse without supporting evidence and investigation.

A commonly held belief by forensic pathologists, pediatricians and pediatric radiologists is that posterior rib fractures in infants are highly specific for child abuse and rarely if ever result from chest compressions during cardiopulmonary resuscitation. Those who concede that rib fractures may very rarely occur due to CPR contend that the injuries involve the anterior or anterior/lateral aspects of the rib. This issue is of particular importance as rib fractures in small children are most commonly the result of non-accidental injury and therefore may be strong evidence in support of child abuse. A complete autopsy and a thorough investigation of circumstances are critical in determining the manner of death in infants. Misclassification due to overinterpretation of a single finding could have devastating effects on caregivers who may be falsely accused of abuse and therefore face litigation.

The normal immature infant skeleton has increased plasticity compared to the adult skeleton making it relatively resistant to fracture unless there are congenital or acquired disorders of the collagen matrix or mineralization. However, with enough force applied to the costovertebral angle, minute fractures of the rib head and neck can occur. Current American Heart Association guidelines suggest that CPR for infants given by health care providers be performed using the two-handed method with thumbs on the sternum and fingers encircling the chest and back. In this manner, direct pressure not only depresses the sternum but also can lever the posterior ribs at their articulation with the vertebral column at the transverse processes of the thoracic vertebrae. In instances where untrained individuals provide CPR, improper technique may also contribute to fractures. As acute fractures in many cases are quite subtle and nondisplaced, they may be missed on antemortem and postmortem radiographs even when critically examined. These fractures may also be missed at autopsy particularly if the parietal pleura is not removed. In fact, the true incidence of infant rib fractures may be underestimated due to the difficulty in their detection.

Presented here are the gross, radiographic, and microscopic findings from four hospitalized neonates and infants, aged 1 day to 3 months, who died of natural causes but were noted to have posterior rib fractures at autopsy. Three cases showed evidence of acute fractures after terminal CPR attempts. In one case, remote fractures with callous formation were identified in an infant with multiple previous CPR episodes due to complications resulting from his premature birth. These infants and neonates spent the majority of their lives within the hospital. In all cases the infants had no history of abuse, no outward evidence of inflicted injury, and no additional internal injuries consistent with child abuse. It is imperative that the presence of posterior rib fractures in an infant not be ascribed impulsively to child abuse until a thorough investigation is conducted including assessment of resuscitative techniques.

Posterior Rib Fractures, Cardiopulmonary Resuscitation, Child Abuse

G13 Role of Preoperative 3D-CT Reconstruction in Depressed Skull Fractures Treated With Craniectomy: A Case Report of Forensic Interest

Guido Viel, MD, and Giovanni Cecchetto, MD, University of Padua, Via Faloppio 50, Padova, 35121, ITALY; Renzo Manara, MD, Istituto di Neuroradiologia, Padova, ITALY; and Donata Favretto, PhD, and Massimo Montisci, PhD, University of Padua, Via Faloppio 50, Padova, 35121, ITALY*

The goal of this presentation is to describe a new approach to cranial trauma treated with craniectomy: 3D-CT reconstruction based on preoperative scanning.

This presentation will impact the forensic science community by de-

monstrating how new radiological techniques and reconstruction can be utilized to assist the forensic pathologist in assessing cranial trauma after surgical intervention.

Patients affected by cranial trauma with depressed skull fractures and intracranial pressure increase generally undergo neurosurgical intervention. Since craniotomy and craniectomy remove skull fragments and generate new fracture lines, they complicate forensic examination and sometimes prevent a clear identification of skull fracture etiology.

To overcome this kind of problems a 3D reconstruction based on preoperative CT scanning, giving a picture of the "status quo" ante neurosurgery, can help the forensic examiner in identifying skull fracture origin and their means of production.

The authors report the case of a 41 year-old-man assaulted by his pusher: he presented at the emergency room with severe cranial trauma with a depressed skull fracture at the vertex, bilateral subdural hemorrhage, and multiple intraparenchymal contusions. The rapid impairment of GCS (Glasgow Coma Score) from 14 to 8 forced the surgeons to perform a craniotomy; despite such intervention neurological conditions kept on worsening (GCS of 4) and after a few hours a craniectomy was performed. The patient died after 40 days of hospitalization in an Intensive Care Unit (ICU) for multi-organ failure (MOF).

The forensic autopsy revealed the absence of various bone fragments at the vertex (consequences of the craniectomy), bilateral fractures at the anterior and medial fossa, bilateral cortical contusions at the frontal and parietal lobe, and a smaller cortical contusion at the right temporal lobe. Histological examination showed focal necrotic and hemorrhagic lesions surrounded by gliosis and several hemosiderin-laden macrophages, dating the trauma at about 30-50 days before autopsy.

Because of the absence of various bone fragments at the vertex the necropsy examination didn't allow a precise analysis of the skull fractures. Thus a 3D-CT reconstruction of the preoperative scanning was performed with SSD (surface shaded display) and MIP (maximum intensity projections) technique.

A comparative study between necropsy and radiological data differentiated the surgical from the traumatic lesions, which were produced by a cylindrical blunt object with a reduced area of impact.

A fit-matching analysis between virtual blunt objects and the skull fractures found out that the pusher had beaten the victim using a baton with a diameter of 3 cm and a length of about 1.50 meters.

These findings helped the police officers in searching for the crime weapon, which was found hidden in a bush not far from the site of the assault.

Computed tomography techniques with tridimensional reconstruction have been developed over the last 10 years and have found various applications in the forensic field. The most recent development is multislice computed tomography combined with photogrammetry-based surface optical scanning and image rendering techniques. The combination of these different techniques can be used to produce three-dimensional images of injury patterns for comparison with suspect weapons.

This technology is generally used in postmortem examination to complete or replace forensic autopsy (Viropsy®).

However, when patients suffering a trauma undergo surgical intervention, which modifies wound morphology and complicates forensic examination, a 3D-CT reconstruction based on preoperative scanning gives a picture of the "status quo" before surgical procedures and thus helps the forensic examiner in identifying wounds etiology and their means of production.

Depressed Skull Fractures, 3D-CT, Craniectomy

G14 Subway Train Related Fatalities in New York City: Accident vs. Suicide

Peter T. Lin, MD, and James R. Gill, MD, Office of Chief Medical Examiner; 520 First Avenue, New York, NY 10016*

This study aims to describe the characteristics of subway train-related fatalities, including scene investigation, police investigation, autopsy, medical and psychiatric history, and toxicology studies.

This presentation will impact the forensic science community by contributing to literature by attempting to identify factors which will be helpful in differentiating accidental from suicidal deaths.

Determination of the cause of death in subway train-related fatalities usually is obvious. However, determination of the manner of death can be challenging. A common dilemma is the differentiation between accidental and suicidal death. In order to accurately determine the manner of death, all relevant factors must be considered, including: eyewitness accounts, physical injuries, medical and psychiatric history, scene investigation, and toxicology results. The characteristics of subway train-related fatalities were examined in order to determine which factors may be helpful in differentiating accident from suicide. Subway train-related deaths with homicide and undetermined manners also are included.

A computerized search of all medical examiner death certificates issued between January 1, 2003 and May 31, 2007 was performed for the words "subway", "train", or "tracks" to identify all subway train-related fatalities. The autopsy data, scene investigation report, police report, toxicology results, and other relevant documents in the OCME file were reviewed for each case.

Two-hundred and eleven (211) consecutive subway train-related fatalities were investigated by the Office of Chief Medical Examiner of the City of New York during the study period (approximately 1 per week). Of these 211 deaths, 175 underwent autopsy and 36 were examined only externally. External examination without full autopsy usually was done pursuant to a religious objection which must be honored under New York law unless there is a suspicion of homicide or an imminent threat to public health. The distribution of deaths by manner was: suicide (111), accident (76), undetermined (20), and homicide (4). The causes of death were either blunt trauma (206) or electrocution (5). The average age was 44 years with a range of 14 to 85, and a male to female ratio of approximately 5 to 1.

Witness accounts were available in 66% of the accidental deaths and 95% of the suicidal deaths. Ethanol was detected in 42% of the accidental deaths with an average blood alcohol concentration of 0.20 gm%, compared to 14% of suicides with an average blood alcohol concentration of 0.16 gm%. Antidepressant medications were detected in 8% of the accidental deaths compared to 21% of the suicides. Cocaine and/or benzoylecgonine were detected in 25% of the accidental deaths, compared to 3% of the suicides. Head, torso, and extremity injuries occurred in 84%, 70%, and 62% of accidental deaths compared to 90%, 80%, and 77% of suicides, respectively. There were skull fractures in 53% of accidental deaths compared to 65% of suicides. Decapitation and torso transection occurred in 1% and 3% of accidental deaths compared to 7% and 8% of suicides, respectively.

There were 20 deaths with an undetermined manner; all due to blunt trauma. Only 35% of the undetermined deaths were witnessed. There were four homicides of which two victims were pushed into the path of a subway train. In one homicide, the victim was chased into a tunnel and subsequently struck by a train. The remaining homicide involved an un-witnessed assault followed by a fall onto the subway tracks and electrocution by contact with the third rail.

Eyewitness accounts are the most helpful factor for determining the manner of these deaths. The finding that suicides have a higher rate of eyewitness accounts than accidents may be a reflection of the requirement to demonstrate intent in order to certify a death as a suicide. Without evidence of clear suicide intent, these deaths typically would be certified as accidents

or undetermined manners. A suicide note, prior expression of intent, and prior suicide attempt are other helpful factors. Physical injuries and toxicology findings are, by themselves, non-specific, but in conjunction with other factors, may be helpful. Torso transection and extremity amputation were more frequent in suicides, but occurred in accidental deaths as well. Antidepressant medications were more frequently detected in suicides, whereas cocaine and ethanol were more frequent in accidents. These factors should not be interpreted in isolation when determining the manner of death. Although there is no pathognomonic autopsy finding that determines the definitive manner of these deaths, these results may be weighed in the context of the entire evaluation along with other circumstantial and investigative findings. In un-witnessed deaths where additional information is unavailable or discrepant, the most appropriate manner of death usually is undetermined.

Subway, Accident, Suicide

G15 Cardiovascular Trauma in Motor Vehicle Collisions: A 20 Year Retrospective Study and Review of the Literature

Kelly L. Rose, MD, and Kim A. Collins, MD, Medical University of South Carolina, Department of Pathology and Laboratory Medicine, 165 Ashley Avenue, Suite 309, PO Box 250908, Charleston, SC 29425*

The goal of this presentation is to identify and classify cardiovascular trauma and injuries sustained in motor vehicle collisions. The audience participants will be able to determine cause of death due to cardiovascular injuries in motor vehicle collisions and become familiar with injury patterns and the corresponding motor vehicle collision scenarios. In addition, autopsy techniques applicable to motor vehicle collisions will be reviewed.

The motor vehicle collision has been, is, and will remain a major cause of death in the United States and internationally. Previous studies of motor vehicle collisions have led to significant advances in automobile safety and safety precautions. This presentation will impact the forensic science community by demonstrating how it is essential to continue to study motor vehicle collisions, so that even greater safety advancements and initiatives can be developed.

The motor vehicle collision (MVC) is the major cause of accidental injury and death in the United States and developed countries. Previous studies of traumatic injuries sustained in MVC have led to significant advances in safety precautions and devices. Resultant cardiovascular trauma resulting in death includes great vessel rupture, cardiac rupture, cardiac contusion, commotio cordis, and coronary artery dissection. The authors retrospectively reviewed all cases referred to the Forensic Pathology Section of the Medical University of South Carolina (Charleston, SC) over a twenty-year period from January 1988 through December 2007. Cases of MVC autopsies were examined for the presence or absence of any cardiovascular trauma. Cardiovascular trauma was defined as trauma to the heart proper as well as to the pulmonary arteries, vena cava, aorta, and major tributaries of the aorta. Other variables reviewed were the type of vehicle, number of vehicles involved, location in the car of the decedent, seat belt usage, element of ejection, airbag deployment, type of collision, site of vehicle impact, decedent demographics, injury-to-death time interval, cause and manner of death, and toxicological findings. Cases in which the cardiovascular trauma was the cause of death were further examined. Useful autopsy procedures and ancillary studies are discussed.

Motor Vehicle Collision, Cardiovascular Trauma, Autopsy Techniques

G16 Right Ventricular Lipomatosis and Fibrous Tissue in Cases of Non-Cardiac Deaths and Arrhythmogenic Right Ventricular Cardiomyopathy

Carol Kaluen Lee, MD*, New Mexico Office of the Medical Investigator, MSC11 6030, 1 University of New Mexico, Albuquerque, NM 87131-0001; Charles Lee, MD, Vancouver General Hospital, Department of Forensic Pathology, 855 West 12th Avenue, Room 1352, Vancouver, BC V5Z 1M9, CANADA; and Michael Allard, MD, James Hogg iCapture Centre for Cardiovascular and Pulmonary Research, Room 387, St. Paul's Hospital, 1081 Burrard Street, Vancouver, BC V6Z 1Y6, CANADA

Upon attending this presentation, the audience will have a better appreciation for the fat and fibrous tissue content of the normal right ventricular myocardium, as compared to cases of arrhythmogenic right ventricular cardiomyopathy, and also appreciate the importance of selective sampling of the right ventricle to properly assess fat and fibrous tissue content.

This presentation will impact the forensic community by highlighting the regional differences normally present in the heart, which significantly impact upon the diagnosis of arrhythmogenic right ventricular cardiomyopathy, particularly in the posterior basal right ventricular myocardium.

Arrhythmogenic right ventricular cardiomyopathy (ARVC), defined as variable replacement of the myocardium of the right ventricular (RV) free wall by fatty or fibrofatty tissue with degenerative changes in entrapped myocytes, is a form of cardiomyopathy that is often familial and typically presents as sudden death in young healthy individuals. Currently, a definitive pathologic diagnosis of ARVC diagnosis is often difficult because a certain amount of fat is always present within the RV myocardium that tends to increase with age, particularly in the anterior and lateral apical regions. We aim to quantitatively establish a normal range for regional RV lipomatosis and fibrous tissue to provide a basis for the pathologic diagnosis of ARVC. Anterior, lateral, and posterior regions of apical and basal RV myocardium were sampled from autopsy cases where deaths were due to non-cardiac causes (control; n=10; age = 21-84 years) and from individuals who had documented ARVC (ARVC; n=10; age = 15-60 years). Area fractions of RV myocardium (%) occupied by myocytes, fat, fibrous tissue, or blood vessels were measured on trichrome-stained slides by computer-assisted point counting, excluding epicardial adipose tissue and subendocardial trabeculations.

The results highlight significant regional differences in lipomatosis normally present in the heart, with apical regions having significantly more lipomatosis than corresponding basal regions of Control cases ($p<0.05$). The anterior apex showed the most lipomatosis ($29.9 \pm 4.2\%$), whereas the posterior base had the least lipomatosis ($3.8 \pm 1.1\%$). Comparatively, ARVC cases had a significantly greater amount of fat than Control cases ($p<0.05$), which was most apparent between corresponding posterior regions, particularly in the basal RV myocardium, which showed a seven-fold increase in lipomatosis ($26.4 \pm 8.5\%; p<0.05$). The large content of fat normally present in anterior and lateral apical RV myocardium indicates that diagnosis of ARVC may be difficult if based solely upon lipomatosis in these areas. Significant regional differences in fibrous tissue were not seen in Control hearts, but the amount of fibrous tissue within the posterior base of ARVC hearts was significantly higher than that of Control hearts ($20.9 \pm 3.7\%$ and $12.2 \pm 1.6\%$, respectively; $p<0.05$). Thus, the substantial amount and regional variation of lipomatosis that exists in normal RV myocardium indicate that changes in lipomatosis in posterior RV myocardium, particularly at the base, are the most reliable means of making a definitive diagnosis of ARVC. This interpretation also has relevance to cardiac imaging as it relates to diagnosis of ARVC.

Arrhythmogenic Right Ventricular Cardiomyopathy, Lipomatosis, Right Ventricle

G17 Sodium Channelopathies Linked to Sudden Cardiac Death (SCD) - What is the Meaning of Carrying a Genetic Mutation?

Antonio Oliva, MD, PhD*, Catholic University, Italy, Largo Francesco Vito 1, Rome, 00168, ITALY; Preben Bjerregaard, MD, St Louis University Hospital, Cardiology Department, 3635 Vista Avenue, St. Louis, MO 63110; Kui Hong, MD, PhD, Nanchang University, Jiangxi Province, 235 Nanjing East Road, Jiangxi; Steven Evans, MD, Beth Israel Medical Center, Cardiology Division, First Avenue at 16th Street, New York, NY 10001; Kevin Vernooy, MD, PhD, Academic Hospital, Maastricht, Department of Cardiology, Maastricht, NETHERLANDS; Jorge McCormack, MD, Pediatric Cardiology Associates, Tampa, FL; Josep Brugada, MD, PhD, Hospital Clinic Barcelona, Arrhythmia Unit, Villaroel 32, Barcelona, SPAIN; Pedro Brugada, MD, PhD, Free University of Brussels, Department of Cardiology, Brussel, BELGIUM; Vincenzo L. Pascale, MD, PhD, Catholic University, Institute of Forensic Medicine, Largo f. Vito 1, Rome, ITALY; and Ramon Brugada, MD, Montreal Heart Institute, Montreal, CANADA

The goal of this presentation is to describe the use of genetic testing directed toward identifying sodium channel mutations linked to Sudden Cardiac Death as a diagnostic tool in the forensic field.

This presentation will impact the forensic community by developing guidelines on how to approach the results of postmortem molecular analysis of Sudden Cardiac Death Cases and the immediate consequences of genetic testing of the relatives.

Mutations in the SCN5A gene have been linked to a variety of diseases causing sudden cardiac death, with important variability in expression and phenotypic overlap. With the availability of postmortem molecular analysis and genetic testing of family members, it is now possible to identify carriers based solely on the presence of the genetic defect. Clinical decision making in this situation is complex and generates important ethical and medico-legal issues.

Two families, 24-328 and 24-588, originally diagnosed with Brugada syndrome after the probands experienced cardiac arrest. Clinical and genetic analysis in their members were performed. Both families had members with various electrocardiographic abnormalities including some with Brugada syndrome, long QT syndrome and conduction system disease. Both families had an important family history of sudden cardiac death. Direct sequencing of exons and exon-intron boundaries of the sodium channel gene SCN5A identified mutations in both families.

These two families illustrate an increasingly common scenario when encountering families with ion channelopathies. Because defibrillator is the only available therapeutic option at present in Brugada syndrome, physicians and forensic pathologists will be faced with extremely difficult therapeutic decisions that also have important legal, social and ethical implications, especially in children. These data indicate the need to develop guidelines on how to approach the results of postmortem molecular analysis and genetic testing of the relatives as well, especially in asymptomatic individuals.

Sudden Cardiac Death, Genetics, Brugada Syndrome

G18 SCN5A Gene Mutation Associated With Acute Myocardial Infarction

Antonio Oliva, MD, PhD, Catholic University, School of Medicine, Institute of Forensic Medicine, Largo Francesco Vito 1, Rome, ITALY; Dan Hu, MD, PhD, Masonic Medical Research Laboratory, 2150 Bleecker Street, Utica, NY 13501-1738; Sami Viskin, MD, PhD, Department of Cardiology, Tel-Aviv Sourasky Medical Center, 6 Weizmann Street, Utica, ISREAL; and Jonathan M. Cordeiro, PhD, Tabitha Carrier, BS, Hector Barajas-Martinez, PhD, Yuesheng Wu, MS, Elena Burashnikov, BS, Serge Sicouri, MD, and Ramon Brugada, MD, Masonic Medical Research Laboratory, 2150 Bleecker Street, Utica, NY 13501-1738; and Rafael Rosso, MD, Sackler School of Medicine, Tel-Aviv University, 6 Weizmann Street, Tel Aviv, ISREAL; and Alejandra Guerchicoff, PhD, Guido D. Pollevick, PhD, and Charles Antzelevitch, PhD, Masonic Medical Research Laboratory, 2150 Bleecker Street, Utica, NY13501-1738*

The goal of this presentation is to describe the first sodium channel mutation to be associated with the development of an arrhythmic storm during acute ischemia.

This presentation will impact the forensic science community by presenting findings which suggest that a loss of function mutation in SCN5A gene (cardiac sodium channel) may predispose to ischemia-induced arrhythmic storm and sudden cardiac death.

Ventricular tachycardia and fibrillation (VT/VF) complicating Brugada syndrome, a genetic disorder linked to SCN5A mutations, and VF complicating acute myocardial infarction (AMI) have both been linked to phase 2 reentry. Because of these mechanistic similarities in arrhythmogenesis, the contribution of SCN5A mutations to VT/VF complicating AMI were examined.

Nineteen consecutive patients developing VF during AMI were enrolled. Wild-type (WT) and mutant SCN5A genes were co-expressed with SCN1B in TSA201 cells and studied using whole-cell patch-clamp techniques.

One missense mutation (G400A) in SCN5A was detected in a conserved region among the cohort of 19 patients. A H558R polymorphism was detected on the same allele. Unlike the other 18 patients who each developed 1-2 VF episodes during acute MI, the mutation carrier developed six episodes of VT/VF within the first 12 hours. All VT/VF episodes were associated with ST segment changes and were initiated by short-coupled extrasystoles. A flecainide and adenosine challenge performed to unmask Brugada and long QT syndromes were both negative. Peak G400A and G400A+H558R current were 70.7% and 88.4% less than WT current at -35mV ($P \leq 0.001$). G400A current decay was accelerated and steady-state inactivation was shifted -6.39 mV ($V_{1/2} = -98.9 \pm 0.1$ mV vs. -92.5 ± 0.1 mV, $P \leq 0.001$). No mutations were detected in KCNH2, KCNQ1, KCNE1, or KCNE2 in the G400A patient.

The first sodium channel mutation to be associated with the development of an arrhythmic storm during acute ischemia is described. These findings suggest that a loss of function in SCN5A may predispose to ischemia-induced arrhythmic storm and sudden cardiac death.

Sudden Cardiac Death, Myocardial Infarction, Ventricular Fibrillation

G19 Arrhythmogenic Right Ventricular Dysplasia/Cardiomyopathy a Not So Infrequent Cause of Sudden Death - A Danbury Hospital Five Year Experience (June 2002 - June 2007)

Juan A. Merayo-Rodriguez, MD, Frank Braza, and Jeffrey West, Danbury Hospital, 24 Hospital Avenue, 2 Tower Lab, Danbury, CT*

The goal of this presentation is to increase the database of deaths due to arrhythmogenic right ventricular dysplasia/cardiomypathy in USA.

This presentation will impact the forensic science community by illustrating the victim, scenario, and autopsy findings of arrhythmogenic right ventricular dysplasia/cardiomypathy deaths so that proper cause and manner of death can be classified and the epidemiology understood.

Ten(10) cases of ARVD/Cardiomypathy were reviewed that were autopsied at Danbury Hospital, CT, since June 2002 until June 2007. This number represents 3.75% of the total (270) adult full autopsies performed in our institution during the same period.

Age, sex, and ethnic background were noted. Associated cardiac and non cardiac related diseases were reviewed.

Medications, social and family history (sudden death of sibling), as well as body habitus (obesity) were tabulated. Prior symptoms (fainting episodes, palpitations) and pre-terminal circumstances (place of death) were examined. Autopsy findings (cardiovascular and systemic) were correlated. Conclusions are compared with recent literature including review articles.

Arrhythmogenic, Right Ventricle, Dysplasia

G20 Sudden Cardiac Death in Professional Sports Persons: Natural vs. Anabolic Steroid Induced Lesions and Experimental Rabbit Model

Laurent Fanton, MD, Alain Tabib, MD, Stéphane Tilhet-Coartet, MD, Maire Joly, and Daniel Malivier, MD, Institut of Legal Medicine, 12 Avenue Rockefeller, Lyon, 69008, FRANCE*

This presentation will increase awareness of anabolic steroid-induced cardiac lesions in professional sports-persons and illustrate comparative lesions in the rabbit model.

This presentation will impact the forensic science community by demonstrating that because controlling or banning doping in professional sports is not feasible in the present state of affairs, treating with apoptosis inhibitors might hold out hope of limiting the incidence of severe evolutive cardiac lesions.

Out of 15,000 forensic autopsies performed on coroner's orders over a 24-year period (Jan 1981-Dec 2003) in the area of Lyon, France (population: 2,000,000), WHO criteria identified 2,250 cases of unexpected sudden cardiac death. Among these, 120 were found to have occurred during recreational sport and 12 in professional sports persons. In the latter category, the associated cardiac lesions were primitive: natural in 6 cases, and, according to inquest findings, induced by anabolic steroids in the other six. To shed light on the induced lesions, animal experiments were performed, administering Norethandrolone to rabbits which were then sacrificed and subjected to pathologic examination and caspase-3 assay by fluorometry on cardiac fragments.

The natural primitive lesions were classical for such cases. The anabolic steroid-induced lesions comprised coronary thrombosis associated with left ventricle hypertrophy and lesions analogous to toxic or adrenergic myocarditis. The same lesions were found, to varying degrees, in the rabbit

models, which showed significantly elevated Caspase-3 activity as compared to controls.

Anabolic steroids would seem, to varying degrees, to induce lesions analogous to those found in myocardopathy and toxic myocarditis. Their elevated Caspase-3 activity makes these lesions apoptotic in nature.

Doping, Cardiac Lesions, Apoptosis

G21 Cocaine Induced Intracerebral Hemorrhage in a Patient With Cerebral Amyloid Angiopathy: A New Risk Factor for Stroke in Cocaine Users

Daniel G.K. Phillips, MD, University of Maryland, Baltimore, Department of Pathology, 22 South Greene Street, Baltimore, MD 21201; Joyce L. deJong, DO, and Michael A. Markey, MD, Sparrow Forensic Services, Sparrow Hospital, 1215 East Michigan Avenue, Lansing, MI 48909-7980; and Rudy J. Castellani, MD, University of Maryland, Department of Pathology, 22 South Greene Street, Baltimore, MD 21201*

The goals of this presentation are to: (1) understand the association between intracerebral lesions and cocaine use, (2) recognize amyloid angiopathy, its relationship with stroke as well as age, and its immunohistochemical detection, and (3) recognize amyloid angiopathy as a possible contributing factor for hemorrhage in cocaine use.

Because this case represents the first reported association between cocaine-induced hemorrhage and cerebral amyloid angiopathy, this presentation will impact the forensic science community by bringing to light that amyloid angiopathy may be an under-recognized but significant risk factor for hemorrhage in older cocaine users.

Hemorrhagic stroke is a common complication of recreational cocaine use. The precise mechanism of hemorrhage in such patients is unclear, although vasospasm, ischemia, vascular thrombi/thromboemboli, elevated blood pressure, and vasculitis have all been implicated. Systemic hypertension and saccular aneurysms are generally accepted as predisposing factors for cocaine-induced stroke. The authors report the case of a 62-year-old woman who suffered left parieto-occipital intracerebral hemorrhage with herniation and death, following a cocaine binge. In addition to the gross neuropathological findings, microscopic examination showed marked cerebral amyloid angiopathy in the vicinity of the hemorrhage as well as cortical areas. To explore the issue of chronic cocaine use as a risk factor for cerebral amyloid angiopathy per se, we additionally studied brain tissue in eight patients between the ages of 60 and 80 who were positive for cocaine metabolites at autopsy, with the presumption being that patients in this age group with evidence of cocaine use at autopsy were most likely chronic cocaine users. None of these additional subjects had vascular deposits of amyloid-beta by immunohistochemistry.

In conclusion, to the best of our knowledge, this report represents the first case of cerebral amyloid angiopathy-associated intracerebral hemorrhage precipitated by cocaine. It is suspected that other cases occur but go under-reported, on the one hand because cocaine-induced stroke is widely recognized and additional predisposing factors (e.g., amyloid angiopathy) may not be specifically sought, and on the other because cocaine may not be suspected in the advanced age at which amyloid angiopathy typically presents. It is further suggested that cerebral amyloid angiopathy occurs independently of the effects of cocaine, as no vascular labeling was found for amyloid-beta in eight older subjects who were cocaine users.

Cocaine, Amyloid Angiopathy, Intracerebral Hemorrhage

G22 Can Immunohistochemical Stains Aid to Rule Out Pitfalls in Suffocation Deaths?

Antonina Argo, Rosa Liotta, Emiliano Maresi, Stefania Zerbo, Rosaria Vitale, Pierangela Fleres, and Paolo Procaccianti, Via del Vespro, n. 127, Palermo, 90100, ITALY*

The goal of this presentation is show the quantitative and qualitative expression of selected markers in specimens of tissues that are affected by various degrees of hypoxic insult using immunohistochemical methods.

This presentation will impact the forensic community by providing data that may be helpful in determining the presence of early hypoxic tissue damage via immunohistochemical methods.

In forensic practice, the identification of mechanical asphyxiation is often very difficult, especially in cases of attempted masking of the homicide, or because of putrefactive alterations of the body. In addition, postmortem dissection artifacts of the neck and their differentiation from ante-mortem bruises sometimes leave doubts at the pathologist examination.

The target of current research is focused on detecting severe tissue hypoxia by a great battery of techniques now available. However, even this limited objective has not been yet obtained with the degree of reliability required for legal purposes.

Cell death, especially in neurons or myocytes, due to hypoxic damage is the most common focus for research. However, the main problem, in the forensic context, is that a considerable period of hypoxia – usually a minimum of many minutes or even hours - is needed before changes can be detected. In autopsy samples the postmortem and agonal changes may interfere with the early changes of hypoxic damage.

Quantitative and qualitative expressions of selected markers in specimens of tissues that are affected by various degrees of hypoxia insult were evaluated by immunohistochemical method. The relationships between the expression of selected markers and temporal evolution in human tissues were evaluated: the antibody HIF-1 α , as a marker of early myocardial ischemia, due to asphyxia. HIF-1 α is the major transcription factor involved in adaptive cardiac response to hypoxia, whose expression can be a useful tool in those cases with short survival period (as recently shown by Pampin and Coll).

The authors also attempted to use TGF- β expression in neck skin, as a marker of a vital lesion and duration of survival period. TGF- β plays a general function in skin response to injury, both in inflammation and in tissue repair; and it shows different immunohistochemical expression patterns in relation to post-injury time interval.

Finally, the number of pulmonary macrophages with CD68 immunohistochemical stain was estimated.

The results were evaluated considering the possibility of false negative immunohistochemical staining in tissue with putrefactive alteration.

A total of thirteen cases of suffocation death were studied: 5 cases of strangulation, 6 of hanging, 2 of choking. Negative controls were gained from cases of precipitous death in young people and positive controls from cases of confirmed asphyxial deaths. HIF-1 α was tested in myocardial tissues, TGF- β in neck skin samples and CD68 in lung samples.

The results of the retrospective analysis encourage the authors to continue this study in further cases in order to evaluate the applicability of these tests in routine forensic practice.

Asphyxial Death, Putrefactive Alterations, Immunohistochemistry

G23 Alcohol Related Accidental Drowning in Virginia: An Epidemiological Review

Shane Chittenden, DO, Anna Noller, PhD, and Marnie Wood, MD*, Office Chief Medical Examiner, 400 East Jackson Street, Richmond, VA 23219*

The goal of this presentation is to give viewers an understanding of the epidemiology of alcohol related accidental drowning in the Commonwealth of Virginia over a ten year period. Viewers should understand the cohorts at increased risk, which may benefit from targeted prevention strategies.

The impact of this poster on the forensic community and humanity is to identify those groups at most risk of alcohol associated accidental drowning. Targeted preventative measures may reduce from three hundred and sixty-three, the number of Virginians to die potentially preventable deaths over the next ten years. This data may also be used to develop studies and/or preventative strategies in other jurisdictions.

Certain racial, gender, and/or age groups are at higher risk of alcohol-related accidental drowning.

The Office of the Chief Medical Examiner of Virginia database was queried for cases in which the fatal agency was drowning, resulting in 1129 cases from January 1997 to December 2006. Of these, 972 were accidental in manner. Data was collected from the database on the sex, race, age, alcohol presence, and blood alcohol level of those drowning accidentally. Rates were calculated only for Virginia residents and based on population data obtained from the Virginia Department of Health Office of Vital Statistics. The 2006 population data was estimated based on changes in the population groups for the previous nine years.

Accidental drownings comprised 86.2% of the total cases studied. Of those, 37.3% were associated with alcohol. Males accounted for 92.3% of these cases. The highest number of alcohol associated accidental drownings occurred in whites (63.3%), followed by blacks (29.8%), and Hispanics (5.5%). Those aged 35 to 45 years represented 25.6% of alcohol associated accidental drownings, those 45 to 54 years 19.8%, those 25-34 years 17.4%, and 20 to 24 years 10.7%. Of those aged 18 to 64 years, 61.3% had a blood alcohol concentration at or above the Virginia legal limit of 0.08% w/v (for driving a motor vehicle).

Of all alcohol associated accidental drowning, the great majority occurred in males. Those aged 35 to 44 years comprised 25.6%, while 61% occurred in those aged 20 to 54 years. This group may over-estimate their ability to function safely around water while under the influence of alcohol. Although the majority of these individuals had blood alcohol concentrations at or above 0.08% w/v, 38.7% did not. Preventative measures should target this potentially overlooked cohort, and emphasize abstaining from alcohol while engaging in water-related activities.

Drowning, Accidental, Alcohol

G24 Cytomegalovirus Enteritis With Profuse Gastrointestinal Bleeding Diagnosed at Autopsy: A Case Report and Review of the Literature

Benjamin J. Havard, MD, Kelly L. Rose, MD, and Kim A. Collins, MD, Medical University of South Carolina, Department of Pathology and Laboratory Medicine, 165 Ashley Avenue, Suite 309, PO Box 250908, Charleston, SC 29425*

The objectives of this presentation are to discuss the causes of gastrointestinal hemorrhage and gastroenteritis with specific emphasis on the diagnosis of CMV enteritis and its potentially fatal outcome.

This case report and review of the literature will impact the forensic community by helping the medical and forensic community become aware of the potentially fatal outcome of CMV enteritis.

A diverse group of pathologic factors can produce profuse gastrointestinal hemorrhage. Common causes include peptic ulcer disease, esophageal varices, arteriovenous malformations, and Mallory-Weiss tears. Aortoenteric fistulas, chemical ingestions, tumors and viruses are among the rare entities that are associated with gastrointestinal hemorrhage. Often, when gastrointestinal hemorrhage is encountered at autopsy, the causality is straight forward. However, at times, the cause of hemorrhage is more obscure and the pathologist must consider those possibilities that are less common in order to identify the etiology.

We report a case of a 74-year-old African American female who succumbed to profuse gastrointestinal bleeding secondary to cytomegalovirus (CMV) enteritis. The decedent had a history of end stage renal disease secondary to Wegener Granulomatosis. She had recently been diagnosed with inflammatory bowel disease and diabetes. She was HIV negative. Prior to her death she was hospitalized after undergoing right hip hemiarthroplasty for a right femoral fracture. Her immediate post operative hospital course was uneventful. However, while hospitalized she developed bilateral arm tremors, weakness, and decline in her mental status. She was given the preliminary diagnosis of encephalopathy and it was felt that this was due to her chronic renal failure and a metabolic derangement. In the proceeding days, her blood pressure became labile, and despite full medical treatment she died. At autopsy profuse gastrointestinal hemorrhage and multiple gastrointestinal ulcerations were found. Microscopic examination revealed transmural necrosis and mucosal erosion of the large intestine and ulceration with chronic inflammation penetrating to the muscularis propria of the small intestine. In addition, scattered intestinal epithelial cells demonstrated "smudged" nuclear chromatin suggestive of viral infection. Subsequent special staining for cytomegalovirus was positive. Causes of profuse gastrointestinal hemorrhage and cytomegalovirus enteritis are discussed.

Gastrointestinal Hemorrhage, Cytomegalovirus (CMV), Autopsy Ancillary Studies

G25 Ethyl Chloride Toxicity in a Case of Unsuspecting Abuse

Valerie S. Green, MD, Stephen K Wilson, MD, Terry J. Danielson, PhD, Ashraf Mozayani, PhD, and Luis A. Sanchez, MD, Harris County, Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054*

The goal of this presentation is to present a case study to increase the awareness about the compound ethyl chloride, its medicinal and industrial uses, its abuse and potential toxicity to those who choose to abuse it, and its postmortem detection in blood and tissue samples.

This presentation will impact the forensic community by emphasizing that ethyl chloride is a potentially harmful and fatal chemical when abused and can be mistaken for ethanol intoxication and may not be anticipated because of its uncommon association with death.

Ethyl chloride is a colorless gas with general anesthetic properties in humans and animals. Its use as a general anesthetic was discontinued because of its flammability, cardiotoxicity, and possible severe respiratory depression. Its major uses are for tetraethyl lead production and as a solvent, alkylating agent, refrigerant and topical anesthetic.

Ethyl chloride has gained increasing popularity since amyl nitrite and other volatile alkyl nitrite substances have been removed from the lay market because of their high abuse potential. The three most common means of inhalation of ethyl chloride are "sniffing", "huffing", and "bagging". Sniffing is perhaps the most popular means of inhalation in those who are episodic abusers. The individuals who chronically use inhalants prefer bagging because of the higher concentration of the substance being inhaled. Ethyl chloride can be purchased without prescription at underground establishments, on the internet and at places selling drug paraphernalia. It is sold as a video head cleaner, which is a legitimate use, but it is also marketed as a means of experiencing a euphoric feeling and enhancement of sexual pleasure. Many of the products containing ethyl chloride have provocative names such as Rush, Jungle Juice Plus, Maximum Impact, Black-Jac, and Macho and are

generally referred to as “poppers”. Acute exposure results in feelings of euphoria, drunkenness, ataxia, dysarthria, nystagmus, confusion, dizziness, hallucinations, impairment of short-term memory, and unconsciousness. The long term effects of ethyl chloride in humans are unknown.

The case presented is that of a 38-year-old Caucasian man found dead in an adult video store viewing room. Review of the store time records revealed that the man visited the store and returned to his vehicle six minutes later. After being at his vehicle for one minute, he returned to the store again. He was found alone in the viewing room approximately five hours later. No bottles or aerosol cans were found inside of the viewing room or on his person. Inspection of his vehicle revealed miscellaneous clothing, food containers, aerosol cans, construction equipment, and two child car seats. Several bottles of exercise supplements were in the center console of the car. It is unknown if any of the aerosol cans inside the vehicle contained ethyl chloride. There was no known prior illness or substance abuse history. His social history was unknown except the obvious visit to an adult video store.

An autopsy was performed approximately eight hours after death. His autopsy findings consisted of pulmonary congestion and edema (combined lung weight 1300 grams). The left ventricular wall of the heart was hypertrophied (1.4 – 1.5 centimeters in width). The major branches of the coronary arteries were without significant atherosclerotic change (less than 10% stenosis).

Ethanol, methanol, isopropanol and acetone were tested for by head space injection on a dual column gas chromatograph (Restek BAC-1, BAC-2). An unidentified peak with a set time of 1.156 minutes on the BAC-2 column eluted at 1.243 minutes on the BAC-1 column as an overlying peak with the same retention time as ethanol. Gas chromatographic/mass spectrometric analysis of blood and liver identified this substance as ethyl chloride. An alcohol dehydrogenase method (DRI Ethyl Alcohol Assay, Microgenics) was used for the quantitation of ethanol in the heart blood (0.09 g/dL), the urine (0.8 g/dL), and in the vitreous humor (0.07 g/dL). Cocaine metabolite(s), benzodiazepines, barbiturates, phencyclidine, amphetamine/methamphetamine, opiate(s), and methadone were not detected.

This case illustrates the importance of careful toxicological analysis and scene investigation in an instance where inhalant abuse was not suspected. Although ethyl chloride inhalation is not a common cause of death, it can be lethal when abused. The forensic community needs to be aware of its potential toxicity especially in cases such as this where there was no known history of “sniffing” or “huffing” and no obvious evidence of inhalant abuse at the scene.

Ethyl Chloride, Inhalant, Poppers

state of Vermont provides a practical example of how trends can be identified, and recommendations derived.

Motorcycle rider fatalities have been increasing nationwide since 1997, according to the National Highway Traffic Safety Administration reports. In the State of Vermont, the number of endorsed motorcycle operators increased by 7,550 from 1995-2005, and the number of motorcycle fatalities reported to the Office of the Chief Medical Examiner (OCME) doubled (8 vs. 16 cases). Through a combination of review of medical examiner reports, death certificates, hospital medical records, police reports, and Fatality Analysis Reporting System (FARS) Web-Based Encyclopedia, the OCME analyzed the 73 motorcycle fatalities who expired in Vermont from 1995-2005.

The majority of decedents (71%) held valid motorcycle licenses. None had completed the Vermont Rider Education Program (VREP)—a voluntary training program to improve motorcycle operator safety established in 1990—though one decedent had attempted, but failed the course. The state of Vermont has had a universal motorcycle helmet law since 1968, and the majority of decedents (89%) were wearing helmets. Three of these helmets, however, were not Department of Transportation (DOT) approved models. Of those with no helmets, drug and/or alcohol screens were positive forty percent of the time. Overall, thirty-eight percent of decedents had positive drug and/or alcohol screens. The average blood alcohol concentration (BAC) was 0.15%: in four cases, the BAC was less than the legal intoxication limit of 0.08%. Six decedents had a history of prior DWI convictions, and of these, five had elevated BACs at death. When examined in terms of decades, the largest group of fatalities occurred in the 20-29 year old population, though the 40-49 year olds represented the fastest growing group.

The majority of motorcycle fatalities were not attributable to poor visibility/weather, as most occurred during summer daylight hours on dry black-top roads. Neither did traffic play a major role: in 86% of motorcycle fatalities, the roadways were classified as rural rather than urban, and in greater than two-thirds of cases, the rider was lone rather than in a group. In 51% of cases, the collision was with a stationary object (e.g. guardrail, tree, bridge). In 41% of cases, the primary impact was with other motor vehicles. In 3% of cases, an animal was involved (e.g., deer, moose), and in 6% of cases the primary impact site remains unknown. Excess speed and road curvature showed a positive correlation with fatalities: per police report, 52% of decedents were driving too fast for road conditions and/or legal limits, and greater than 70% of accidents occurred at road curves. In all cases, the cause of death was blunt impact injury—usually to the head—although concurrent spinal, thoracic, abdominal, and extremity injuries were often seen.

While many factors contribute to motorcycle fatalities, those which are most important in Vermont appear to be operator-dependant. Excess speed and drug/alcohol use are two major modifiable risk factors for motorcycle fatalities in Vermont. All operators should be strongly encouraged to enroll in rider safety courses where they can receive appropriate risk education. Public safety advertising should be targeted toward the 20-29 and 40-49 year old age groups.

Motorcycle, Crash, Fatal

G26 Motorcycle Fatalities in the State of Vermont: 1995-2005

Erin G. Brooks, MD, University of Vermont, Fletcher Allen Health Care, Department of Pathology, 111 Colchester Avenue, Burlington, VT 05401-1473; and Steven L. Shapiro, MD, and Brittany N. Philbin, BS*, Vermont Office of the Chief Medical Examiner, 111 Colchester Avenue, Baird 1, Burlington, VT 05401*

The goals of this presentation are to: (1) investigate the etiology and demographics of motorcycle fatalities in the state of Vermont via review of Office of the Chief Medical Examiner (OCME) forensics reports and Fatality Analysis Reporting System (FARS) Web-Based Encyclopedia, (2) to provide recommendations on how to reduce motorcycle fatalities and/or serious motorcycle injuries in Vermont, and (3) to provide a model for similar analysis of motorcycle fatalities in other states.

This presentation will impact the forensic community by illustrating that nationwide motorcycle fatality trends are not necessarily the same as those seen at the state level. Analysis of motorcycle fatality data from the

G27 Progressive Isolated Hypoglossal Nerve Palsy and Sudden Asphyxial Death

Emiliano Maresi*, Antonina Argo, Massimo Grillo, Valentina Murgo, Filippo M. Cascino, and Paolo Procaccianti, Palermo University, Via del Vespro, n. 127, Palermo, 90100, ITALY

The goal of this presentation is to illustrate the direct connection between sudden asphyxial death and isolated hypoglossal nerve palsy secondary of his dissection resulting from cranial trauma.

This presentation will impact the forensic community by illustrating sudden death due to cranial nerve damage.

Unilateral hypoglossal nerve palsy is a rare clinical entity due to the lesions of the nerve in one of its segments (medullar, cisternal, of the base of the skull, carotid, sublingual). A Caucasian male who, during a struggle, received severe stab wounds to his head from a screwdriver resulting in hemorrhage of the perimesencephalic cistern and the frontal portion of the left cerebral ventricle. He was operated on to empty the cisternal hemorrhage. He had a normal postoperative course but showed considerable deglutition's incapacity and dysarthria. A few months after surgery, the man died while eating secondary to asphyxia due to sudden obstructive lingual palsy; autopsy showed a hemorrhagic dissection of the hypoglossal nerve on his bulbar brainstem. This case report appears to be unique because the unilateral hypoglossal nerve palsy is not resulting from postoperative pneumocephalus (most frequently reported in literature), but rather from progressive axonal dissection just distal to its bulbar origin, caused by a cisternal hematoma resulting from cranial trauma. The resulting ipsilateral tongue palsy caused dysarthria and deglutition incapacity and occlusion of the proximal third of larynx by alimentary bolus. Incoordination of the muscles innervated by the hypoglossal nerve resulted in fatal acute asphyxia.

Stab Wound, Isolated Hypoglossal Nerve Palsy, Sudden Death

G28 Medico-Legal Importance of Posttraumatic Hypopituitarism

Vladimir Zivkovic, MD, MSc, Djordje Alempijevic, MD, PhD, Slobodan Savic, MD, PhD*, Ivanka Baralic, Dragan Jecmenica, MD, PhD, and Branimir Aleksandric, University of Belgrade, School of Medicine Institute of Forensic Sciences, Faculty of Medicine, 31a Deligradska Street, Belgrade, 11000, SERBIA AND MONTENEGRO; and Vera Popovic, PhD, Institute of Endocrinology, Clinical Centre of Serbia, Dr. Subotic Street 13, Belgrade, , SERBIA AND MONTENEGRO

The goal of this presentation is to inform the public of existence of hypopituitarism after traumatic brain injury and possible significance for both criminal and civil cases.

This presentation will impact the forensic community by demonstrating how some form of hypopituitarism occurs in 35% of patients with moderate to severe head injury.

Recent studies have demonstrated that different forms of hypopituitarism are common among survivors of traumatic brain injury (TBI) tested several months or years following trauma.

The results of endocrine evaluation in a group of 109 patients (68 male and 41 female, mean age 37.9 ± 1.4 yrs.; body mass index (BMI) 24.8 ± 0.5 kg/m²) who had suffered moderate to severe TBI (Glasgow Coma Scale ≤ 13), at least one year prior to the assessment (mean 3.4 ± 0.5 yrs) are presented. After fasting overnight, at 08:00, serum samples were taken for T4, TSH, FSH, LH, testosterone (men), cortisol, and prolactin. GH/IGF-1 axis was evaluated by a provocative GHRH+GHRP-6 test and IGF-1 measurement, and results were compared with those from 85 healthy control subjects (59 male and 26 female, mean age 36.5 ± 1.4 yrs, BMI 24.2 ± 0.4 kg/m²).

Three groups of TBI patients were formed based on the established normal peak GH cut-off (>20 mg/L) and cut-off for severe GH deficiency (<10 mg/L). These groups are defined as *severe GH deficient* (GHD, n=16,

mean GH peak: 5.6 ± 0.7 vs. 46.1 ± 1.9 mg/L in healthy subjects; $p < 0.01$), *GH insufficient* or the so called "grey zone" group (GHI, n=17, mean GH peak: 15.9 ± 0.7 vs. 46.1 ± 1.9 mg/L; $p < 0.01$), and those with *normal GH secretory capacity* (GHS, n=76, mean GH peak: 44.4 ± 2.4 vs. 46.1 ± 1.9 mg/L; $p > 0.05$). Results show that lower GH responses during the provocative test were associated with older age ($p < 0.01$), higher BMI ($p < 0.01$), lower IGF-1 ($p < 0.01$) and the time since trauma ($p = 0.024$), but unrelated to GCS scores ($p = 0.095$), sex ($p = 0.628$) or presence of traumatic subarachnoid hemorrhage ($p = 0.615$). These results also indicate that 6.4% of TBI patients had hypogonadism, 2.8% had hypothyreosis and 2.8% had hypocortisolism; also 5.5% had hypoprolactinemia and 2.8% hyperprolactinemia.

A significant number of patients (33.9%) express some form of hypopituitarism after traumatic brain injury, which is not related to severity of injury. From medicolegal point these observations might be significant both for criminal and civil cases.

Posttraumatic, Hypopituitarism, Medico-Legal

G29 Massive Fat Pulmonary Embolization Secondary to a Liposuction Procedure With Tumescent Technique Diagnosed Postmortem in an Embalmed and Buried Body

Jose A. Garza-Leal, MD*, Alberto Montemayor-Martinez, MD*, and Magdalena Gomez*, Medfor-Lab S.A. DE C.V., Cholula 106, Colonia Mitras Centro, Monterrey, 64460, MEXICO

After attending this presentation, attendees will understand that all deaths occurred during whatever medical surgical procedure where death is not expected should undergo a medico-legal autopsy and how to avoid problems and complications produced by previously embalmed and buried bodies with marked external and internal postmortem changes that obscure the true cause and manner of death. Attendees will additionally understand that, though an autopsy initially was not performed, a thorough, methodical postmortem investigation may be able to find the true cause and manner of death in many cases.

This presentation will impact the forensic community by serving as a methodical parameter in the evaluation and investigation of cases where the deceased was previously embalmed and buried without an autopsy initially being performed.

A case of massive fat pulmonary embolization diagnosed 80 days postmortem in a previously embalmed and buried body of a 32-year-old woman who underwent an elective liposuction plastic surgery with tumescent technique is presented. The patient received a pre-surgical medical and laboratory evaluation by a cardiologist who considered that the patient was healthy enough for the elective surgery. General anesthesia was administered and the liposuction procedure was performed without complications; however, at the end of the surgery the patient developed sudden cardiac arrest. Cardiopulmonary resuscitative measures were done with no response; simple chest x-rays were performed and showed suggestive changes of a thromboembolic pulmonary process. The patient was declared dead and the surgeon erroneously signed the death certificate with the cause of death was a cardio-respiratory arrest. The body was embalmed with formaldehyde and buried the next day with no performance of an autopsy. The plastic surgeon was sued for medical malpractice and the body was exhumed and autopsied 80 days later as evidence. In spite of the deceased being embalmed and buried previously with marked external and internal postmortem changes, the macro micro pathological findings correlated well with clinical symptoms, radiological changes, and toxicological studies and revealed that the cause of death was a massive pulmonary fat embolization, an inherent risk of the surgical procedure.

Pulmonary Fat Embolism, Fat Embolism, Liposuction

G30 Lethal Inhalation of Isomers of Butylene: A Case Report

Giovanni Cecchetto, MD*, and Guido Viel, MD, University of Padua, Via Faloppio 50, Padova, 35121, ITALY; and Attilio Cecchetto, PhD, Istituto Anatomia Patologica, Via Gabelli 61, Padova, 35121, ITALY; Claudio Terranova, University of Padova, Section of Legal Medicine, via Faloppio n.50, Padova, 35121, ITALY; and Massimo Montisci, PhD, and Santo Davide Ferrara, PhD, University of Padua, Section of Legal Medicine and Forensic Toxicology, Via Faloppio 50, Padua, 35121, ITALY

The goal of this presentation is to clarify the pathophysiology of butylene induced damage in humans by means of histological, histochemical and immunohistochemical investigation.

This presentation will impact the forensic community by serving as an educational resource on the pathophysiology and dangers of inhaling butylene isomers.

There has been a steady increase in the number of deaths resulting from inhalation of volatile substances, which can be a suicide or an unintended consequence of "sniffing abuse". Intentional inhalation of a volatile substance indeed is an under-recognized form of substance abuse in children and adolescents with a high morbidity and mortality.

Fatal outcome of inhalant abuse has been discussed due to several mechanisms: suffocation, trauma after dangerous behaviour, vagal inhibition, respiratory depression and the "sudden-sniffing death syndrome" following cardiac arrhythmia. However, the reason of sudden death related to volatile sniffing is rarely clear even after toxicological analysis. In most cases, reported aerosol propellants, n-propane or n-butane or mixtures of n-propane, n-butane, and isobutane are involved.

Sudden death due to the inhalation of butylene isomers has not yet been described in forensic literature.

There are four isomers of butylene (α -butylene, cis- β -butylene, trans- β -butylene, isobutylene), which are all gases at room temperature and pressure, but can be liquefied by lowering the temperature or raising the pressure on them, in a manner similar to pressurized butane. These gases are colourless, but do have distinct odours, and are highly flammable. Although not naturally present in petroleum in high percentages, they can be produced from petrochemicals or by catalytic cracking of petroleum. There are few reports on the toxicology of this compounds in animals and humans; it is not clear if isomers of butylene can produce direct damage on lung endothelial cells or myocardial tissue like butane does, or if the injury is mediated by other mechanisms.

A 20-year-old male was found dead in his jail cell where a plastic bag and a portable cooking stove were present.

Forensic autopsy revealed cerebral edema, hemorrhagic edema of the lungs, and acute congestion of all inner organs. Histology (E&E) confirmed autopsy's results.

Toxicological analysis on the cooking stove gas and on biological specimens (blood and tissues) were performed. The cooking stove gas was formed by α -butylene (71%), cis- β -butylene (17%) and trans- β -butylene (12%). Lorazepam (85 ng/ml), GHB (800 ng/ml) and isomers of butylene (α -butylene = 550 ng/ml; cis- β -butylene = 130 ng/ml; trans- β -butylene = 270 ng/ml) were determined in blood samples collected during autopsy.

The histochemical (Van Gieson and Azan Mallory) and immunohistochemical (myoglobin, actin, and desmin) investigations on myocardial samples showed interstitial fibrosis with acute necrosis and myocardial contraction bands.

The immunohistochemical examination (CD-34 and VIII factor) on lung specimens did not reveal endothelial damage.

These results suggest an acute electrical myocardial death due to adrenergic overdrive as a pathophysiologic mechanism of butylene induced sudden death.

To the authors knowledge, this is the first case study of sudden death due to the inhalation of isomers of butylene described in literature. The lack of knowledge of the exact biological effects of this compounds and the steady increase in the number of deaths resulting from inhalation of volatile sub-

stances need further investigations in toxicological and pathological fields.

Isomers of Butylene, Lethal Inhalation, Toxicology

G31 Lethal Neglect: A Case of Extreme Intrafamilial Child Torture

Biagio Solarino, MD*, University of Bari, Sezione di Medicina Legale, Piazza Giulio Cesare, 11, Bari, 70100, ITALY; Vito Romano, MD, U.O.C. di Medicina Legale - Ospedale "Miulli", Acquaviva delle Fonti, (Bari), 70021, ITALY; Giuseppe Troccoli, MD, University of Bari, Department of Criminology and, Forensic Psychiatry, Largo Giordano Bruno 65, Bari, 70121, ITALY; Ignazio Grattagliano, PsyD, and Roberto Catanesi, MD, University of Bari, Section of Forensic Psychiatry, Piazza Giulio Cesare, Bari, 70125, ITALY

After attending this presentation, attendees will have an understanding of some peculiar aspects of intrafamilial child neglect ending in death from starvation.

This presentation will impact the forensic community by providing forensic evaluation of lethal child neglect as a consequence of combining forms of malnutrition, maltreatments, and psychological abuse levied by parents.

Deliberate starvation of an infant/child is a severe and rare form of child abuse, especially in industrialized countries. The goal of this presentation is to highlight the importance of forensic assessment in complex cases of child homicide.

Child neglect can be defined as the failure of a caregiver to provide a child with the necessities of life, including physical safety and protection, food, hydration, clothing, shelter and medical care. Failure to fulfil these responsibilities may constitute active or passive neglect. Forensic investigation of lethal child neglect requires complete autopsy findings, full investigation of scene and case history, past medical records, family history, and social background.

This presentation reports a case concerning a female infant aged 16 months who was brought to the Emergency Department where physicians established she was already dead. They noted the child cachectic state and multiple bruises over the whole body. The child's mother stated she had not been eating well in the last week.

Autopsy showed the child weighed 5700 grams (12.6 pounds) for a length of 76 cm (29.9 inches); she was severely dehydrated with the muscles of head, face, trunk, lower and upper extremities flaccid, redundant, wrinkled skin, and resultant prominent bones. The orbital adipose tissue was essentially absent leaving sunken appearing eyes. Examination of the head revealed multiple abrasions and ecchymoses at varying healing stages and focal alopecia.

Multiple cutting stab wounds were present on the left auricle and on the neck. There were bruises located on the chest and on the upper extremities; radiographic examination revealed fracture of left forearm overlaying an old arm contusion. Decubitus ulcers were located on the lumbar area and pelvis.

The thymus had atrophied. The stomach and large intestine were empty and exhibited some ulcerative lesions; there was a very little stool in the rectum. The weights of most of the child's organs were markedly less than normal averages.

Microscopic findings showed acute bronchopneumonia, hepatic fibrosis and no glycogen in the liver on PAS (para-amino-salicylic acid) stain.

The child lived in a reconstituted family. The mother had two children from the first marriage and another one from the present husband. The victim was conceived during a brief affair between the mother and a man who left her soon after she got pregnant.

The other children were healthy and well nourished.

Home inspection revealed the victim spent all day sitting in a stroller located in the parents' bedroom and placed in front of the wall.

The parents confessed they fed her intermittently with water and sugar,

small portions of milk occasionally adding breadcrumbs. Sometimes she ate leftover food from the other children. When the victim cried because she was hungry, the “caregivers” would beat her or throw objects (biberon, toys, etc.) from their bed at her head. The parents pled guilty and received life sentence.

In cases of malnutrition/starvation, only a complete forensic investigation may reveal that the caregivers history of the child not eating well for a few days, is hiding a case of extreme intrafamilial child abuse.

Starvation, Child Abuse, Parental Rejection

G32 Multiple Histories: A Statistically Significant Indicator of Non-Accidental Injury in Children

M.G.F. Gilliland, MD, Brody School of Medicine at ECU, Pathology & Lab Medicine, Brody Building, Greenville, NC 27858-4354*

After attending this presentation, attendees will be able to describe circumstances under which multiple histories are provided by caregivers and describe the validity of using multiple histories as a marker of non-accidental injuries in children.

This presentation will impact the forensic science community by allowing forensic scientists to have a scientific basis for the use of multiple histories as a marker of non-accidental injuries in children.

Forensic pathologists are increasingly being asked to state the bases for conclusions. How do we know that multiple histories are a marker of non-accidental injury in children? The early descriptive studies have shown that many shifting histories are associated with the “Battered Baby” syndrome, recently described as non-accidental or inflicted injuries in children. In individual cases, more than one history provided by the caregiver is excused as the result of a caregiver feeling “upset” at the child’s injury and death, or simply a matter of providing an initially incomplete history. The usefulness of considering the number of caregiver histories in a variety of causes of death can be assessed by reviewing a group of child death investigations.

Examining the causes and manners of death, and the number of trauma histories for a group of 169 child deaths provides additional support for suspicion raised by multiple histories. Cause and manner of death and the number of trauma histories was gathered as part of investigations of a group of 169 randomly selected child deaths examined over a seven year period. The child deaths occurred as the result of non-accidental injury as well as motor vehicle collisions, falls, drownings, various asphyxial deaths, and natural diseases. Non-accidental injury was distinguished from accidental injury, undetermined causes, and natural disease by investigation of medical and social history, and circumstances surrounding collapse as well as autopsy findings.

The causes of death included: 11 asphyxias (6.5%), 13 central nervous system diseases (7.7%), 80 head injuries (47.3%), 8 drownings (4.7%), 3 heart diseases (1.8%), 5 infections (3.0%), 2 other disease deaths (one each: volvulus and dehydration, 1.2%), 11 respiratory diseases (6.5%), 13 Sudden Infant Death Syndrome (7.7%), 13 blunt force injuries of trunk (7.7%), and 10 undetermined (5.9%).

Only two of the asphyxial deaths were non-accidental injuries and in both, one trauma history was provided. In one it was a confession, the other was unrelated to the cause of death. Most of the head injury deaths, 61, were non-accidental. In 11, no history was provided. One and two histories were given in 21 and 22 cases respectively. “Multiple histories” (more than two) were found in seven death investigations: four cases had three histories, two cases had four histories, and one case had five. The 2nd through 5th histories were closer approximations of mechanisms of sufficient magnitude to produce the injuries found at autopsy. All of the trunk injury deaths were non-accidental. Five cases had no trauma history, six cases had one trauma history which was usually inadequate to account for the injuries found, but only two provided a second history.

Most (six) of the nine accidental asphyxial deaths had one adequate

history to explain the injuries. In two cases no one knew what had happened, and in one other misinformation provided two histories. Most (sixteen) of the accidental head injury deaths had one adequate history. In three others a second history was needed to conclude that the explanation was adequate. All eight drownings had one adequate history.

Only two of forty-one natural deaths had even one trauma history. One child with a medulloblastoma had fallen off the couch a week prior to his collapse. The other child suffered a spontaneous subarachnoid hemorrhage and hit her head when she collapsed.

In this group, 31/76 (40.8%) with non-accidental deaths had two or more histories. For accidental and natural deaths (omitting the ten undetermined deaths), 4/83 (4.8%) had more than one trauma history. In a 2x2 table more than one history had a sensitivity of 40.8% for non-accidental injury deaths. The specificity of fewer than two histories and accidental or natural disease was 95.2%. The predictive value of non-accidental injury when many histories were provided was 88.6%. The predictive value of finding accidental or natural disease when fewer than two histories were provided was 64.8%. A Yates corrected Chi square is 23 with a P value of <<0.01 and odds ratio of 0.11 (with confidence interval of 0.04-0.58) for non-accidental injuries being found when fewer than two histories are provided by the caregiver.

Non-Accidental Injury, Multiple Histories, Child Abuse

G33 Recognizing Classic Metaphyseal Lesions in Child Abuse: An Autopsy Technique

Jennifer C. Love, PhD, and Luis A. Sanchez, MD, Harris County, Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054*

The educational objectives of this presentation are to review the difficulties associated with recognizing classic metaphyseal lesions in infants and to present a new autopsy technique which enables the visualization and documentation of these fractures.

This presentation will impact the forensic community by introducing a new autopsy technique developed to improve the recognition and documentation of injury pattern in child abuse.

Complete recognition and documentation of injury pattern is key in the diagnosis of child abuse. Classic metaphyseal lesions (CML) in infants are highly suggestive of child abuse but difficult to recognize. A CML is a planar fracture through the most immature portion of the metaphyseal primary spongiosa. It may occur as a partial or complete fracture and results in the epiphyseal cap separating from the metaphysis. In infants the primary spongiosa or newly formed trabecular bone at the chondro-osseous junction (COJ) is the weakest point of the long bone. The rapid rate at which the growing bone lengthens generates relatively thin and weak metaphyseal trabeculae. With age the growth rate decreases and the metaphyseal trabeculae become thicker and stronger. CML is typically the result of torsional and tractional forces applied in a direction perpendicular to the long axis of the bone as an infant is pulled or twisted by a limb, also by the acceleration and deceleration as an infant is shaken (Kleinman 1998).

A CML is difficult to recognize both in radiographs and at autopsy. Radiographically, a CML may appear as a radiolucency in the sub-physis region of the metaphysis. However, it may not be visible in all views or if the trabecular disruption is insufficient (Kleinman 1998). Crawford and Al-Sayyad (2003) note that most distal tibia metaphyseal fractures are diagnosed as ankle sprains or strains on initial radiographs because no definite fracture can be identified. Furthermore, CML rarely causes hemorrhage at the fracture site or in the surrounding tissue. Subperiosteal new bone formation is not prominent at a healing fracture site. Histologically, a CML appears as a series of microfractures at the mineralized regions of the distal zone of hypertrophic chondrocytes of the physis and a thin portion of the metaphyseal primary spongiosa, a difficult section to read (Kleinman 1998). In the healing bone, the CML may appear with chondrocytes deeper than

expected within the primary spongiosa or as a broad region of thickened hypertrophic zone (Kleinman 1998).

As a result of the difficulty to recognize a CML, a new autopsy technique has been developed. The first step is to expose and visually examine the COJ of the long bones by cutting the muscle from the long bone ends and reflecting the periosteum. An acute CML appears as either an open fracture or a slight line of hemorrhage. A healing fracture may appear as an oddly shaped COJ. When a fracture is suspected but not obvious, the end of the long bone is removed and processed by soaking it in a water soap bath at a steady but elevated temperature (~60C) for 24 hours. The result is a metaphysis without the epiphyseal cartilage or periosteum. Partial and complete CMLs are completely visible grossly. This technique is far more invasive and time intensive than standard flaying of the dermis but yields excellent results and eliminates any question about the presence of a CML. This technique is recommended for all infant deaths in which a non-accidental traumatic cause of death is suspected.

Classic Metaphyseal Fractures, Child Abuse, Autopsy Techniques

G34 Comprehensive Molecular Genetic Testing for the Cardiac Channelopathy Genes in 42 Cases of Sudden Infant Death and Sudden Unexplained Death in the City of New York Revealed High Mutation Rate

Yingying Tang, MD, PhD, Erik T. Bieschke, MS, Erin Labitzke, Jennifer D'Andrea, MSFS, Stacey Sainte-Marie, MSFS, Dawei Wang, Jean Jeudy, Yoonhee A. Kim, Stephanie Pack, Lucy En, Barbara A. Sampson, and Mechthild K. Prinz, PhD, Office of Chief Medical Examiner, Department of Forensic Biology, 421 East 26th Street, New York, NY 10016*

The goal of this presentation is to investigate the mutation rate of the channelopathy genes in the SIDS/SUDS population.

This presentation will impact the forensic science community by highlighting the importance of implementing molecular genetic testing for the channelopathy genes in routine SIDS/SUDS investigations to assist medical examiners in the determination of cause and manner of death.

Sudden infant death syndrome (SIDS)* and sudden unexplained death syndrome (SUDS)* are vexing challenges in the field of Forensic Pathology. SIDS and SUDS are recognized as complex and multifactorial, requiring interaction between genetic and acquired risk factors during sensitive developmental stages or growth phases. It has been reported that 2-5% of apparent SIDS/SUDS cases are in fact due to a group of cardiac arrhythmia syndromes, collectively called channelopathies, where at least eight causative genes are known. Since the channelopathies affect the cardiac electric conduction system and cause arrhythmias, the diseases leave no structurally demonstrable autopsy findings. Currently, the only available means to allow postmortem diagnosis of channelopathies is through the use of molecular genetic testing to detect mutations in the causative genes.

In order to investigate the mutation rate of the channelopathy genes in the SIDS/SUDS population, our laboratory has validated methodologies in genetic mutation analysis. Presented in this study is a comprehensive mutational analysis of multiple channelopathy genes: a cardiac sodium channel gene, *SCN5A*; three cardiac potassium channel genes, *KCNE1*, *KCNE2*, and *KCNQ1*; and a cardiac ryanodine receptor gene, *RyR2*. The study population consisted of 42 cases with the cause of death certified as "SIDS" or "undetermined" by the New York City Office of Chief Medical Examiner. The methods utilized were designed to be highly sensitive, specific, reproducible, cost-effective and high throughput. This was accomplished using DNA-based PCR and cycle sequencing analysis to detect any nucleotide changes in the protein coding region. Heart, liver and spleen samples were used.

In testing the *SCN5A* gene, five cases carried a known pathogenic missense mutation, S1103Y; one case carried a known pathogenic missense mutation L619F; two cases carried an unknown, but likely pathogenic missense mutation, P656L; and one case carried an unknown, but likely pathogenic

missense mutation, I1837T. In testing the *KCNE 1&2* genes, we found that two cases carried two different known mutations, D85N (in *KCNE1*) and Q9E (in *KCNE2*). These two mutations previously have been shown to be associated with acquired Long QT syndrome. In testing the *RyR2* gene, the authors found that one case carried an unknown, but likely pathogenic missense mutation, G4471R. Genetic testing for *KCNQ1* gene is still in progress. All of the mutations identified in this study are heterozygous. Collectively, the pathogenic mutation rate is about 28% (12/42). Specifically, the mutation rate is most frequent in *SCN5A* gene 21% (9/42), while the mutation rates in other genes are less common.

This study highlights the importance of implementing molecular genetic testing for the channelopathy genes in routine SIDS/SUDS investigations to assist medical examiners in the determination of cause and manner of death.

* SIDS is defined as the sudden death of an infant under one year of age, which remains unexplained after a thorough investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history.

* SUDS is the sudden death of an individual over one year of age and like SIDS, the death remains unexplained after a thorough case investigation, which includes performance of a complete autopsy, examination of the death scene, and review of the clinical history.

Molecular Genetic Testing, Channelopathy, SIDS/SUDS

G35 Primitive Neuroectodermal Tumor (PNET) Masquerading as Non Accidental Head Trauma in an Infant: Lessons for Multiple Disciplines

Michael J. Caplan, MD, and Kelly Rose, MD, Medical University of South Carolina, Department of Pathology and Laboratory Medicine, 165 Ashley Avenue, Suite 309, PO Box 250908, Charleston, SC 29425*

After attending this presentation, attendees will understand the process of evaluating intracranial pathology in an infant and how to identify spontaneous as well as traumatic causes of intracranial hemorrhage, specifically, hemorrhage resulting from a supratentorial primitive neuroectodermal tumor.

The ability to discriminate not only between nonaccidental and accidental head trauma, but also between spontaneous and traumatic etiologies of intracranial hemorrhage, while keeping an open mind to all of the possibilities during the descision-making process, is among the most challenging of intellectual tasks that confront the forensic pathologist.

The appropriate recognition and accurate documentation of fatal nonaccidental craniocerebral trauma in infants and young children are among the most important contributions to be made by a forensic pathologist. Equally crucial, however, is the ability to identify both accidental causes of head trauma and spontaneous (nontraumatic) etiologies of intracranial pathology.

A rare cause of spontaneous intracerebral, subarachnoid, and subdural hemorrhage in a 3-month-old child resulted from a supratentorial primitive neuroectodermal tumor (PNET) with glial differentiation, emphasizing that not all forms of intracranial pathology are inflicted, or even traumatic. Furthermore, because the various interpretations of the imaging studies created significant controversy and disagreement regarding the assessment of the disease process findings, the potential problems that exist with neuroradiologic interpretations of lesions in this age group are emphasized.

An 11-week-old male infant presented to the MUSC Pediatric Emergency Department (ED) with a 2-day-long history of lethargy, decreased oral intake and urine output, and favoring of the left side of his face. His mother stated that his left eye had appeared "abnormal" for the past few weeks. In the ED, he was found to have a bulging fontanelle and a fixed and dilated left pupil with a minimally reactive right pupil. Of note, prenatal history was unremarkable; he was born at 39 weeks gestation with 1- and 5-minute Apgar

scores of 9 and 9. He had been essentially healthy up to his current presentation. A head CT scan demonstrated obstructive hydrocephalus and transtentorial herniation, prompting admission to the Pediatric Intensive Care Unit (PICU) with ventriculostomy placement for elevated intracranial pressure (ICP). However, he succumbed to refractory intracranial hypertension and was declared clinically brain dead on the 7th hospital day. Reports from imaging studies were notably discordant, with one interpreting the findings as "multiple trauma of varying ages", the other as a "mass". Autopsy revealed an extensively necrotic and hemorrhagic, supratentorial mass with resultant swelling, softening, and hemorrhage of the adjacent brain parenchyma bilateral thin-layered subdural hemorrhages accompanied by thin-layered subarachnoid hemorrhage, both overlying the cerebral convexities; subgaleal edema and hemorrhage confined to the ventriculostomy site; and anasarca with bilateral serous pleural effusions (15 mL each), and serous ascites (30 mL). There were no other injuries. The eyes were not examined. Microscopic examination of the subdural hemorrhage revealed predominantly red blood cells with rare fibroblasts, and sparse hemosiderin-laden macrophages, consistent with a recent origin (of ~6 days' duration). Sections of the mass demonstrated sheets of spindled to epithelioid cells with large, eccentric nuclei, punctate, "salt and pepper" chromatin, and inconspicuous nucleoli; some cells contained eosinophilic, smooth, "glassy" cytoplasm. The mass was accompanied by scattered hematoidin pigment and extensive, confluent necrosis. There was no significant nuclear atypia or vascular endothelial proliferation. An immunohistochemical battery employing antibodies to glial fibrillary acid protein (GFAP), synaptophysin, chromogranin A, vimentin, smooth muscle actin (SMA), pancytokeratin (AE1/AE3), low-molecular weight cytokeratin (CM 5.2), CD99, and epithelial membrane antigen (EMA) showed the tumor cells to express only GFAP and none of the other antigens. The collective histopathologic features and immunohistochemical profile of the tumor were most compatible with a PNET manifesting purely glial differentiation.

Sound critical thinking and an open mind on the part of the forensic pathologist when confronted with significant intracranial pathology in an infant is of great importance. Although the impressions of the imaging studies and the presence of bilateral thin-layered subdural and subarachnoid hemorrhages appropriately raised the suspicion of inflicted head trauma, the identification of a reasonable underlying etiology for the hemorrhage, the absence of injuries to suggest a pattern of repeated abuse, and the mother's description of neurologic signs entirely consistent with increasing ICP collectively provided strong evidence of a nontraumatic etiology for this baby's condition.

Primitive Neuroectodermal Tumor, Nonaccidental Head Trauma, Infants and Children

G36 Sudden Death of a 17-Year-Old Boy Due to Suspected Williams Syndrome - A Case Report

Stojan Petkovic, MD, Clinical Center Vojvodina, Institute of Forensic Medicine, Hajduk Veljkova 5, Novi Sad, 21000, SERBIA AND MONTENEGRO; Slobodan Savic, MD, PhD, University of Belgrade, School of Medicine, Institute of Forensic Medicine, Deligradska 31a, Belgrade, 11000, SERBIA AND MONTENEGRO; and Milan Simic, MD, PhD, Clinical Center Vojvodina, Institute of Forensic Medicine, Hajduk Veljkova 5, Novi Sad, 21000, SERBIA AND MONTENEGRO*

After attending this presentation attendees will be well acquainted with the external and internal findings/characteristics of the rare genetic syndrome – Williams syndrome which can cause sudden death in young population.

The presentation will impact the forensic community by the fact that every case of sudden death must be scrutinized carefully both by revealing all the circumstances of the case with collecting relevant heteroanamnestic data and need to perform thorough examination of the body (external and inter-

nal). Finally, in order not to have only suspicion on some genetic disorder such as Williams syndrome, but to confirm it with the highest certainty, it is necessary to assign the task to develop genetic tests like FISH.

Sudden and unexpected death is one of the frequent problems in common medicolegal practice, which attracts special attention when it pertains young and previously apparently healthy individuals. One of the potential causes of such death could rarely be Williams syndrome (WS) due to specific cardiovascular abnormalities. This syndrome was initially described by Williams et al. in 1961, and Beuren et al. explained the phenotype. WS is a sporadic genetic syndrome, with an estimated incidence of 1 in 20.000 live births, caused by a deletion of elastin gene and other contiguous genes at chromosome 7, with variable phenotypic expression, associated with dysmorphic facies, neurological manifestations, idiopathic hypercalcemia, and cardiovascular features, particularly supravalvular aortic stenosis. Namely, more than 90% of the patients with WS exhibit a submicroscopic deletion spanning at least 114 kb, at 7q11.23. Hemizygosity of the elastin gene could account for all connective tissue, especially the vascular, abnormalities seen in WS.

The case concerns the 17-year-old boy who was playing with his brother in the yard of their family house during wintertime, when he suddenly fell down to the snow and died shortly after. Hetero-anamnestically, his mother stated that in his childhood, the boy suffered from abdominal pains periodically, denying however, any illness diagnosed by the physicians. In addition, she mentioned his constant problems with learning and relationship with his friends as well (slight mental retardation and nervousness). Since the boy had not been medically examined, no other clinical data could be obtained. At the autopsy, external examination revealed elfin face with short and slightly upturned nose, long filtrum and very bad dental condition – black-greenish coloration of the crowns of the front teeth. There were no signs of mechanical injuries on the body. Internal examination showed severe narrowing (the circumference 4 cm) of the ascending aorta, some 4 cm above the semilunar valves (supravalvular aortic stenosis) with mild enlargement of the heart, weighted 340 grams and significant thickening of the left ventricular myocardium, measured 2,3 cm. With exception of hypertrophy of the myocardial fibers, the histological findings disclosed no pathological abnormalities in all other organs. Toxicological screening was negative. Primarily based upon the internal findings along with case circumstances, in the autopsy record it was inferred that death of the teenager was of natural manner, the most probably due to inherited cardiovascular abnormalities (narrowing of the aorta and hypertrophy of the left ventricular myocardium). Regardless the fact that the case had been solved concerning manner and cause of death, yet the forensic pathologists posed a question to themselves – what might be the origin of such peculiar combination of external and internal autopsy findings. The attention was focused on his specific facial appearance together with the cardiovascular status and obtained heteroanamnestic data, which raised a suspicion on Williams syndrome.

Since WS is a genetic disorder, besides the above mentioned clinical manifestations and morphological findings, for definite diagnosis it is necessary to perform specific genetic analysis - the FISH test, which is a type of specialized chromosome analysis utilizing specially prepared elastin probes. Unfortunately, at the moment, neither the Institute of Forensic Medicine in Novi Sad, nor that in Belgrade is equipped for such test.

Williams Syndrome, Sudden Death, FISH Test

G37 Sudden Cardiac Death in Professional Sports Persons: Natural vs. Anabolic Steroid Induced Lesions, and Experimental Rabbit Model

Laurent Fanton, MD, Alain Tabib, MD, Stéphane Tilhet-Coartet, MD, Maire Joly, and Daniel Malicier, MD, Institut Medico Legal, 12 Avenue Rockefeller, Lyon, 69007, FRANCE*

The goal of this presentation is to report the anabolic steroid-induced cardiac lesions in professional sports-persons and in experimental study (rabbit model).

This presentation will impact the forensic science community by demonstrating how controlling or banning doping in professional sports being unfeasible in the present state of affairs, however, associating apoptosis inhibitors might hold out hope of limiting the incidence of severe evolutive cardiac lesions.

Anabolic steroid-induced cardiac lesions in professional sport-persons are compared with a rabbit model. Out of 15,000 forensic autopsies performed on coroner's orders over a 24-year period (Jan 1981-Dec 2003) in the area of Lyon, France (population: 2,000,000), WHO criteria identified 2,250 cases of unexpected sudden cardiac death. Among these, 120 were found to have occurred during recreational sport and 12 in professional sports persons. In the latter category, the associated cardiac lesions were primitive: natural in 6 cases, and, according to inquest findings, induced by anabolic steroids in the other 6. To shed light on the induced lesions, animal experiments were performed, administering Norethandrolone to rabbits which were then sacrificed and subjected to pathologic examination and caspase-3 assay by fluorometry on cardiac fragments.

The natural primitive lesions were classical for such cases. The anabolic steroid-induced lesions comprised coronary thrombosis associated with left ventricle hypertrophy and lesions analogous to toxic or adrenergic myocarditis. The same lesions were found, to varying degrees, in the rabbit models, which showed significantly elevated Caspase-3 activity as compared to controls. Anabolic steroids would seem, to varying degrees, to induce lesions analogous to those found in myocardiopathy and toxic myocarditis. Their elevated Caspase-3 activity makes these lesions apoptotic in nature.

Doping, Cardiac Lesions, Apoptosis

On 3 September 2006 at 5 p.m., a car was discovered in a parking isolated area in the outskirts of Foggia, Italy, far from urban traffic. A dead man was seated in the driving seat, he had seatbelt fastened, and he lay down on the right hip. The deceased, a young adult man, was fully and tidily dressed, and was identified as a 29-year-old local resident. The car engine was turned off. The car keys were in the ignition in the "off" position, the windows were closed and the doors were locked from the inside: no damage was observed inside or outside the car. On the floor of the car near the anterior right seat, there were five empty small packages; a cigarette filter; a syringe full of 1 milliliter of brownish liquid, its needle was smeared with dried blood. Remote from the body, near his head, on the anterior right seat, there were a small metallic spoon, a needle plastic cap, and two other plastic packages full of white powder. The thanatological data recorded by the forensic pathologist called to the scene (5:30 p.m. of 3 September 2006) stated that at the time of discovery, the cadaver showed rigor mortis, and hypostasis that was partly mobile on digital pressure, but congruous with the position.

At the external examination, the left arm showed a round atrophic scar and left forearm an healing ischemic ulcer. The right antecubital fossa had pigmented pop-scars and swelling of the soft tissue with a necrotic area and two needle punctures; the upper one was surrounded by an extensive ecchymosis, the entire area measured cm 7x5.

A complete autopsy was performed 48 h after death. Internal examination revealed that the heart weighed 450 g, measured 14x13.5x5cm. The coronary arteries, the myocardium and the valvular apparatus were normal. All the other organs did not show specific alterations except for an intense vascular congestion.

Routine histological investigations, applying hematoxylin and eosin staining, were performed on all organ samples. Lung sections showed massive pulmonary oedema. Myocardium presented foci of fragmentation of entire myocytes in anomalous cross bands formed by segments of hyper-contracted sarcomeres and myofibrillar rhesis. The histological examination of the skin section, collected in right cubital fossa, showed a loss of the upper epidermal layers and accumulation of leukocytes, in particular polymorphonuclear neutrophils, and erythrocytes in deeper epidermal and dermal layers. All these skin findings suggested for typical necrotizing ulcers. The examination of other organs was unremarkable except for brain edema and generalized haemostasis.

Cocaine was detected in the subject's urine through immunoenzymatic screening. Toxicological analysis by solid-liquid extraction and gas chromatography-mass spectrometry (GC-MS), was carried out to identify and quantify the individual substances present in the biological fluids and organs. Total cocaine concentrations were as follows: blood 4.08 mcg/mL/g, liver 10.19 mcg/mL/g, brain 6.19 mcg/mL/g, urine 57.00 mcg/mL/g, and bile 17.72 mcg/mL/g. No other drugs or alcohol were detected.

The toxicological analysis of empty and full packages demonstrated that the white powder was cocaine and quinine (used as an adulterant), and the brownish liquid in the syringe, collected in the car, was positive only for cocaine. According to the crime scene data, autopsy and histological and toxicological findings, death was attributed to a fatal arrhythmia during cocaine skin inoculation.

In cocaine skin inoculation, cutaneous necrosis and necrotizing ulcers may develop as a result of several combined factors, including "skin popping", toxicity and the irritant properties of the drug and adulterants, vascular thrombosis, and infection. Quinine used as an adulterant has known caustic effects. In addition cocaine has potent vasoconstrictive and thrombotic effects. Various mechanisms such as cocaine-related increase in plasma lipids, direct and indirect increase in endothelial permeability, higher prevalence of mast-cells and other inflammatory cells in plaques may contribute to the lesions. Typical are round atrophic scars, clustered predominantly on the arms and legs, frequently seen in intravenous drug abusers, particularly cocaine abusers. These may represent healed abscesses, healed ischemic ulcers due to vasoconstrictive effect of cocaine, or the direct toxic effects on capillary endothelium.

Cocaine, Skin Popping, Necrotizing Ulcer

G39 Erroneous Diagnosis of Cadmium Poisoning Based on Postmortem Toxicology

Karl E. Williams, MD, MPH*, Office of the Medical Examiner; Allegheny County, 542 Fourth Avenue, Pittsburgh, PA 15219

The goal of this presentation is to investigate the interpretation of cadmium levels in postmortem blood specimens.

This presentation will impact the forensic science community by demonstrating how the observed evaluation of elevated levels of cadmium in postmortem specimens may lead to an interpretation of accidental or intentional poisoning for what is actually a poorly described artifact of cadmium pharmacokinetics. Lack of knowledge of this artifact can lead to various effects ranging from unnecessary exhumations to civil and criminal legal cases.

In 2004, county coroner (County A) in Pennsylvania ordered a heavy metal screen on an autopsy case to investigate a case of suspected poisoning. The only analyte that was abnormal was markedly elevated cadmium. Suspicion of either accidental or intentional poisoning caused the coroner to order 26 additional postmortem heavy metal studies as well as an exhumation. A comparative population study of cadmium levels was performed on a representative living population in the same community, along with a postmortem study of a similar autopsy population. These studies confirmed that the observed elevations of cadmium were postmortem artifact.

The laboratory results of cadmium were compared for the following study groups: (1) twenty seven (27) cases of postmortem cadmium analysis performed for the Coroner of County A as part of his investigation of possible poisoning, (2) nine (9) analyses of a separate autopsy population in a nearby county (County B) that has a similar demographics and incidence of possible industrial cadmium exposure, and (3) forty seven (47) analyses of a living out-patient population at the major medical center in County A.

The average measured cadmium values were as follows:

- Coroner's cases of County A - 110 μ g/L
- Coroner's cases of County B - 66.6 μ g/L
- Control (Out patients County A) - 1.5 μ g/L

Applying a t-test to these results reveals no significant difference between the two autopsy populations. The difference between the postmortem studies in County A and the living control population of the county is significant to a p-value of 0.003.

Cadmium is a well described human toxic agent. Almost one hundred years of research based on industrial exposures has allowed precise and extensive knowledge of toxicology of the compound. Cadmium is associated with renal and pulmonary toxicity and is considered to have carcinogenic effects. Chronic environmental exposure in Japan, in the 1950's, led to the development of *itai-itai* disease. Normal ranges for cadmium are from 0.3-1.2 μ g/L in non-smokers to 0.6-3.9 μ g/L in the smoking population. The 1991 OSHA standard for cadmium defines a blood cadmium value of 5.0 μ g/L as an action limit for exposed workers. Despite its chronic toxicity, cases of acute poisoning due to cadmium are exceedingly rare and occur mostly in the context of acute fume inhalation in industry or suicidal ingestions. Even in these cases measured blood cadmium levels rarely exceed 30 μ g/L. Thus all the evidence suggests that the observed, massive elevation of postmortem cadmium was an artifact. This has been described only once before in the medical literature, in an environmental journal. It is mostly likely due to a postmortem disassociation of cadmium from its *in vivo* transport protein metallothionein.

Forensic practice relies heavily on the interpretation of postmortem chemistry values for the determination of cause and manner of death. Although this can often be a straight forward process, it requires knowledge of numerous artifacts. In the case at hand, an erroneous interpretation of these cadmium values could have easily led to considerations of either intentional or accidental poisonings.

In this particular part of the country, cadmium is still used in industrial processes and the possibility of environmental contamination was considered. A well controlled and efficient population study confirmed that the observed values were a postmortem artifact.

Cadmium, Artifact, Postmortem

G40 The Continued Role of Over the Counter Drugs in Drug Related Deaths

Anna C. Noller, PhD*, and Marcella F. Fierro, MD, Office of the Chief Medical Examiner, 400 East Jackson Street, Richmond, VA 23219

After attending this presentation, attendees will better understand the epidemiological characteristics of over-the-counter (OTC) drug deaths.

This presentation will impact the forensic community and public health agencies by: (1) serving as a reminder of the continued dangers of the publicly-perceived safe OTC drugs, and (2) the epidemiological trends of who is most likely impacted by these drugs which may help in creating public health safety messages and prevention strategies.

All cases from 2001-2005 in which OTC drugs contributed to the decedents' deaths were analyzed. The OTC drugs, in order of prevalence, were diphenhydramine, acetaminophen, dextromethorphan, chlor-pheniramine, salicylate, ethylene glycol (not an OTC drug but included in analysis), ibuprofen, methanol, ephedrine, and naproxen. All 292 cases were investigated by the Virginia Office of the Chief Medical Examiner (OCME). The data extracted from the OCME database included age, sex, race, manner of death, residency, and toxicological results. OTC deaths were categorized into 5 types: OTC alone, OTC with prescription drug(s), OTC with illicit drug(s), OTC with prescription and illicit drugs, and OTC with carbon monoxide. Virginia residents were analyzed separately to obtain rates.

Considering all drug poisonings, males tend to shoulder the burden of drug-related deaths with an overall ratio of 1.8 to 1 compared to females. For accidents the ratio is 2.4:1 for males to females. Males and females have a similar amount of suicides via drug poisonings (1:1.1). These trends change when looking at the role of OTC drugs. The female/male ratio is 1.45:1 and this ratio stays very similar when examining both accidents and suicides.

Suicides accounted for 51.4% of the OTC deaths, accidents for 46.6% and undetermined for 2%. The combination of OTC with prescription drugs accounted for 66.8% of OTC deaths. Interestingly, OTC alone deaths were almost 3 times higher in suicides than accidents while OTC with illicit or OTC with prescription and illicit drugs were 5 and 4.2 times higher, respectively in accidents than in suicides. Ethanol involvement was found to contribute to death in 16.1% of cases, in 50% of the OTC with illicit drug deaths and in 17.2% of the OTC alone deaths.

Virginia residents accounted for 95.2% (N=278) of the OTC drug deaths. The rate of all OTC drug deaths is 7.5 per million Virginia residents with female rates of 8.9 per million compared to 6.1 for males. Whites carried the burden of these deaths with a rate of 9.1 per million, which was 3.4 times that of blacks and 5.2 that of Asians. The highest burden of OTC deaths was in the 35-34 and 45-54 age groups with almost 2 times the rate of any other age group. Remarkably, the rate for the infant age group (<1 year old) was 4 per million.

While most of the OTC drugs were all found in accidents, suicides, and undetermined cases, some OTCs were detected in a higher percentage of a particular manner than the others. Acetaminophen (70.9%), salicylate (77.8%) ethylene glycol (85.7%), and ibuprofen (88.9%) were found more frequently in suicides than accidents. Additionally, women were 3 and 1.8 times more likely to have used ibuprofen or acetaminophen, respectively than males as all or part of their suicidal drug poisoning. However, males were 3 times more likely to use ethylene glycol than women and also accounted for all the suicides due to diphenhydramine, alone or in combination. Chlorpheniramine (70.8% of all usage) and dextromethorphan (66.7%) were more frequently associated with accidents than suicides. Males were two times more likely to accidentally use ephedrine than females.

In conclusion, OTC drugs continue to be a source of both accidental and suicidal deaths. Women are at a higher risk than men of dying from OTC drugs either alone or in combination with other drugs. Whites also have a higher rate of using a lethal amount of OTC drugs than other races.

OTC Drugs, Drug Deaths, Virginia

G41 Exceptional Suicide by Sharp Force During Mefloquine Therapy: A Case of Drug Induced Psychosis?

Clotilde G. Rougé-Maillart, MD*, and A. Tracqui, MD, Service de Médecine Légale, CHU, 4 rue Larrey, Angers, 49000, FRANCE; A. Le Bouil, MD, and A. Turcant, MD, Institut de Médecine Légale, Faculté de Médecine, Strasbourg, France; and M. Penneau, MD, PhD, Service de Médecine Légale, CHU, 4 rue Larrey, Angers, 49000, FRANCE

The goal of this presentation is to present a case report about a special suicide.

This presentation will impact the forensic science community by assisting in the understanding of drug-induced psychosis.

Suicide by stabbing to the head and/or driving sharp objects into the skull is of extreme rarity. This paper reports the case of a 27-year-old man, who committed suicide by multiple knife stabs and cuts to the head, torso and upper limbs.

A 27-year-old man was found dead at home, lying on his bed. Doors were locked from the inside, and there was no evidence of violence in the flat. The deceased was completely naked, with abundant bloodstains on the whole body surface. The 10-cm long handle of a kitchen knife, also stained with blood, was present near the corpse with the blade broken at *ca.* 1 cm from the guard. The rest of the blade was apparently missing. According to cadaveric signs and police findings, death was likely to have occurred the day before. Autopsy showed two superficial cuts at the lower, anterior part of the neck, two stab wounds in the right temple, one stab wound in the precordium area, one cut at the top of right shoulder near the acromion, one cut at the anterior side of right forearm, one deep complex cross-shaped incised wound at the anterior side of left forearm and wrist a perforating wound of the skull, the 10-cm long broken blade of the knife being still embedded in the right temporal lobe of the brain. The deceased had no history of psychiatric illness but was currently treated by mefloquine, a quinine derivative associated with a high rate of psychiatric side-effects. Toxicology confirmed a recent intake of mefloquine together with chloroquine, another antimalarial drug.

Acute psychiatric reactions, in particular depressive disorders, have been reported as a side-effect of a wide array of medications, including non-steroidal anti-inflammatory drugs, antihypertensive drugs, anticonvulsants, steroids, or antimalarials. Among this latter group, Mefloquine distinguishes itself by a high prevalence of various psychiatric side-effects pointed out during the early postmarketing period. In 1989, the World Health Organization commissioned an investigation that confirmed the existence of such complications, with a prevalence estimated at 4.2/1000 treatments. In 60% of reported cases, disorders appeared after the first intake of mefloquine. Serious complications were noticed only for curative treatments with doses equal to or greater than 1000 mg. To the authors knowledge, this is the first report of a completed suicide with very strong evidence of mefloquine implication. In the present observation there is a very strong presumption that mefloquine was a causative, or at least contributive, factor in the victim's suicide. This statement is supported by the extraordinary method used to commit suicide, the absence of psychiatric history in the victim, whereas most suicides par sharp force to the head have been reported in mentally disturbed patients and prison populations, the close temporal relationship between suicide and mefloquine intake, as documented by the detection of the drug in postmortem samples. In the present observation a contributive role of chloroquine coingestion is difficult to assess because psychiatric side-effects encountered with this drug are much more unfrequent than with mefloquine. However it may be noteworthy that at least one severe reaction, including paranoia, hallucinations and suicidal ideation, has been reported in a subject without psychiatric history and successively treated by mefloquine then by chloroquine. Discussion focuses upon mefloquine-induced psychiatric disorders and highlights the importance of performing toxicological investigations in cases of 'unusual' suicides.

Although such events fortunately remain quite infrequent, forensic practitioners should keep in mind the possibility of drug-induced psychoses

and depression, and toxicological analyses should be the rule in 'unusual' suicides especially in subjects with no known psychiatric history.

Mefloquine Psychosis, Suicide, Sharp Force

G42 Determination of β — Phenylethylamine Blood Levels in Carbon Monoxide Intoxicated-Related Fatalities

Wen-Ling Lin*, and Kai-Ping Shaw, MD, PhD*, Institute of Forensic Medicine, Ministry of Justice, 166-1, Sect. 2, Keelung Road, Taipei (106), Taiwan, ROC

The goal of this presentation is to study the β -Phenylethylamine (PEA) blood levels and its metabolic enzyme, an oxygen-dependent monoamine oxidase B (MAOB), during the hypoxic status induced by carbon monoxide intoxication cases with or without oxygen resuscitation.

PEA, a specific substrate of MAOB, is a biogenic amine that acts as a sympathomimetic amine through its release of dopamine. The rate-limiting step of the MAOB activity of monoamine deamination is a highly oxygen-dependent phenomenon. Carbon monoxide (CO) has a high affinity for hemoglobin that is about 200 times greater than oxygen. CO causes a decrease of the oxygen-carrying capacity of the blood and induces a hypoxic, irreversible status even after re-inhalation of oxygen during resuscitation. The hypothesis is that reduction of the activity of MAOB during the hypoxic status could cause an accumulation of PEA and may be associated with the duration of hypoxic and agonal status. Elevation of PEA blood levels in asphyxia-related fatalities may be related and can be reversed after additional oxygen resuscitation.

A retrospective study consisting of 67 cases of carbon monoxide poison-related fatalities and 121 control cases of CO-unrelated asphyxia and cardiogenic fatalities were collected from the Institute of Forensic Medicine, Ministry of Justice during a medicolegal investigation in Taiwan. Gas Chromatography/Mass Spectrometry was performed to determine the PEA concentrations of each victim's blood. Carboxyhemoglobin (COHb) saturation was determined by Oximeter. Data are reported as mean \pm standard error mean (SEM). The statistical analyses were carried out with ANOVA by SPSS and *p* values of less than 0.05 were considered to be statistically significant in this study.

Base on COHb saturation levels, PEA blood levels of groups of COHb 20-50%, 50-70%, and higher than 70% were 140.72 ± 41.81 (*n*= 16), 107.34 ± 25.63 (*n*= 26) and 66.36 ± 18.03 (*n*= 25) ig/ml, respectively. The PEA blood levels of asphyxia cases (including strangulation and suffocation) recognized as non-CO intoxicated-related fatalities with and without resuscitation were 1.6 ± 0.4 ig/ml (*n*= 11) and 31.7 ± 6.3 ig/ml (*n*= 48), respectively. The PEA blood levels of CO poison related fatalities with and without resuscitation were 64.75 ± 32.42 ig/ml (*n*= 9) and 105.49 ± 17.47 ig/ml (*n*= 58), respectively. The mean PEA concentrations in the blood of strangulation and suffocation cases were 83 and 98 fold higher than those of control values, respectively.

In comparison with medical rescue group with decreases in the PEA levels of non-CO intoxicated fatalities during oxygen resuscitation, the CO intoxicated cases with and without resuscitation both have significant elevations in the PEA level. These results reveal that the reversible MAOB activity during oxygen resuscitation can be blocked by the CO saturation of hemoglobin. The high affinity between CO and hemoglobin molecules and the sequential blocking of the oxygenation of hemoglobin can elevate the blood PEA of CO-intoxicated cases without reactivation of the MAOB activity after sequential oxygen re-inhalation. In conclusion, the PEA can play a crucial role of vital reaction in asphyxia-related fatalities. This study strongly supports that the pathological elevation of PEA in the blood during a hypoxic-agonal status can be reversed by oxygen resuscitation but not in CO-intoxicated fatalities.

β -Phenylethylamine, Asphyxia, Biomarker

G43 The Development of a Model to Assess the Effects of Conducted Electrical Weapons in a Stressful State

Amanda O. Esquivel, MS, and Cynthia Bir, PhD, Wayne State University, 818 West Hancock, Detroit, MI 48201*

This presentation will educate attendees on the safety of conducted electrical weapons (CEWs) that are used in a physiologically stressful state by examining their effects on swine that are hyperthermic, tachycardic, hypotensive and have elevated catecholamine levels.

The research findings presented will impact the forensic science community in guiding policy related to the use of CEWs in given operational scenarios. In addition, knowledge related to the physiological effects of CEW use in compromised individuals is useful to emergency medical personnel for determination of proper medical treatment and the development of treatment protocols.

Although the effects of CEWs on healthy, anesthetized swine appear to be transient, persons that are subjected to repeated exposures of a CEW are most likely in an agitated or combative state. This stimulation could lead to a phenomenon known as excited delirium. In order to determine whether severe physiologic stress in combination with the use of a CEW would cause a serious adverse physiological effect a controlled hemorrhage along with external warming was performed. The hemorrhage was conducted to induce tachycardia, hypotension and catecholamine release as a compensatory mechanism. These signs, along with hyperthermia, are associated with excited delirium.

Preliminary data was gathered in order to assess the effectiveness of the proposed methodology to simulate a state of excited delirium. Three male swine (44 kg +/- 0.8 kg) were included in the study and one additional "sham" (43.4 kg) to observe the effects of the stress only. Under a surgical plane of anesthesia (2%-3% isoflurane) the animals were instrumented and subjected to hemorrhage and hyperthermia. Hemorrhage was induced using the Wiggers model in which blood is removed from the pig until a predetermined mean arterial pressure (MAP) is reached. The average baseline pressure prior to hemorrhage was 70 mmHg. For the proposed effort, it was determined that a MAP of 45 mmHg was sufficient in causing a stress from the blood loss. The swine were covered in a warming blanket to bring their core temperature up to 108°F. The normal temperature for the swine is 101° - 103°F (2.4° - 4.4° higher than humans). This increase in core body temperature is consistent with the sign of hyperthermia often observed in the field and previously described. Exposures to a CEW were given 20 times (4 sets of 5 exposures) in 30 minutes. Cardiac and pulmonary parameters were continuously monitored and blood samples were collected before and after each set of exposures and at one hour intervals for four hours.

The MAP decreased from its baseline value to 39.8, 43.7 and 44.3 mmHg for each of the three animals subjected to exposures. Heart rate increased on average from 112 to 185 beats per minute after the hemorrhage for the three animals subjected to exposures while the sham increased from 100 to 168 beats per minute. As expected, the heart rate remained elevated for the entire study for all animals. The baseline pH (7.44), PCO₂ (41.4 mmHg) and lactate (0.79 mM/L) values recorded were within the normal average values previously reported for swine. The pH decreased slightly after hemorrhage for all in the exposed group to 7.38 and all three in the exposed group became acidotic during the exposures (average 7.25). Blood lactate increased above normal after the hemorrhage to 3.78 and increased further after each set of exposures to 8.93 mM/L. Compared to a previous study in which the same device was applied on healthy, anesthetized swine, these animals were more acidotic and had a greater increase in blood lactate.

This model successfully created a physiologically stressful state similar to excited delirium. The warming blanket induced an increase in core body temperature and the hemorrhage induced tachycardia, hypotension and dehydration. Epinephrine and norepinephrine were not directly measured in this preliminary study however, a compensatory mechanism of hypovolemic shock is a rise in these levels.

Electrical Weapons, Tasers, Less-Lethal Weapons

G44 Exsanguination Due to Disruption of the Left Popliteal Artery and Vein Due to Posterior Dislocation of the Left Knee Prosthesis: A Case Report and Review of the Literature

Wieslawa Tłomak, MD, Milwaukee County Medical Examiner Office, 933 West Highland Avenue, Milwaukee, WI 53233*

The goal of this presentation is to report a case of a 75-year-old woman who died from an exsanguination due to disruption of the left popliteal artery and vein secondary to posterior dislocation of the left knee prosthesis.

This presentation will impact the forensic community because it is a unique case of unexpected death due to posterior dislocation of the knee prosthesis.

Dislocation after primary total knee arthroplasty is a rare but serious complication. Knee prosthesis dislocation results in disruption of soft tissue, palsy of the sciatic or common peroneal nerve and rarely disruption of the popliteal artery causing ischemia. Reported here is a case of a 75-year-old woman who received bilateral knee arthroplasty. Posterior dislocation of the left knee prosthesis occurred seven years after operation. Dislocation resulted in disruption of soft tissue and left popliteal artery and vein. She died from exsanguinations due to disruption of the left popliteal artery and vein.

Exsanguination, Total Knee Arthroplasty, Knee Prosthesis Dislocation

G45 What Lies Beneath: An Unusual Congenital Anomaly in an Assault Victim

Kathryn H. Haden-Pinneri, MD, Jason M. Wiersema, PhD, and Jennifer C. Love, PhD, Harris County, Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054-2098*

This goal of this presentation is to describe an unusual and unexpected cervical vertebrae anomaly in a victim of assault and discuss its significance in the setting of a homicide.

This presentation will impact the forensic community by reviewing the importance of a posterior neck dissection in blunt trauma victims and by illustrating the importance of on-site forensic anthropology services.

A 22-year-old black male was physically assaulted by another male after an incident on a roadway. The victim became unresponsive immediately after the assault in which he was struck multiple times on the head and torso by the suspect's fists. No other weapon was utilized and the fight was witnessed. The incident lasted only a few minutes and the suspect left the scene, unaware that his victim had collapsed. Emergency personnel responded to the scene within minutes and despite aggressive cardiopulmonary resuscitative measures, the victim was pronounced dead at the hospital shortly after arrival.

The victim was obese, weighing 309 pounds with a body length of 71 inches (body mass index of 43.1). External examination revealed a few facial and extremity abrasions and contusions. Internal examination revealed a 3½ inch subscalpular hemorrhage over the left parietal bone and no other traumatic injuries, specifically, no subarachnoid hemorrhage. Incidentally, the decedent was found to have a urogenital anomaly comprised of fusion of the kidneys which were located in the pelvis. The heart weighed 475 grams and was mildly dilated. The coronary arteries had a normal distribution and no atherosclerosis. A complete back dissection performed to delineate any subcutaneous hemorrhage that may have been obscured by lividity was negative. A posterior neck dissection was performed which revealed focal hemorrhage around the upper cervical spinal cord between the first and second vertebral bodies, which were abnormal due to the presence of lateral foramina at the level of the first vertebral pedicles. Further dissection ensued with the assistance and guidance of our on-site forensic anthropologist.

The first through third cervical vertebrae were completely excised in order to examine and document the course of the vertebral artery. A small

amount of adventitial hemorrhage was noted at the level of the second cervical vertebrae; however the artery wall was intact throughout. A small epidural hemorrhage was identified over the posterior aspect of the cervical spinal cord at the level of the first cervical vertebra. The vertebral arteries were removed and submitted for microscopic examination by the pathologist and the forensic anthropologist cleaned and examined the cervical vertebrae.

An atypical bilateral vertebral artery course was observed in the vertebrae. The vertebral arteries passed superiorly through the second vertebral transverse foramina, turned nearly 90 degrees and took a posterior course, doubled back at the level of the first vertebral laminae, then took a second 90 degree turn to pass through the first vertebral transverse foramina and continued superiorly into the cranium. The associated anomalous skeletal characteristics together result in an acutely angled course through which the vertebral arteries pass into the skull.

Microscopic examination of the vertebral arteries revealed fragmentation and degeneration of the elastic laminae, which was confirmed with an elastin stain.

This degeneration is felt to be a ‘wear-and-tear’ type phenomenon due to the abnormal course of the arteries through the vertebrae. Microscopic sections of the heart revealed myocyte hypertrophy and patchy interstitial fibrosis. Toxicology was negative.

Concomitant renal and cervical vertebrae anomalies are not uncommon and are seen in syndromes such as Klippel-Feil in which there are fused vertebrae and varying kidney abnormalities. The association between the urogenital system and the skeletal system occurs during the early embryonic stages of development. During the 4th and 5th weeks of development, the start of renal development occurs in the cervical region of the embryo and then extends caudally. Any interruption in this stage of development can result in anomalies involving the spine, kidneys and/or scapulae.

The vertebral artery course and microscopic appearance are quite abnormal; however are insufficient to account for the sudden death of this young man. Given the circumstances of the witnessed collapse following the physical altercation, the manner of death was ruled a homicide and the cause of death was determined to be sudden death following physical altercation.

Congenital Anomaly, Vertebral Artery, Cervical Vertebrae

G46 Forensic Pathology of the Rupture of an Enlarged Spleen

Maurice G. Rogev, MBChB*, 11/1 Zamenhof Street, Tel Aviv, Jaffo 64373, ISRAEL

The goal of this presentation is to demonstrate the importance of the complete autopsy examination of bodies in whom death resulted from the rupture of an enlarged spleen. The causes of the splenomegaly can be determined. The mechanism causing the rupture can be determined i.e., if the rupture was spontaneous or resulted from violence. The “thin skull” legal concept is relevant in these cases.

This presentation will impact the forensic community by drawing the attention of medical examiners to the various forensic medical aspects of deaths that can result from the rupture of enlarged spleens. The importance of complete autopsies in these cases will be clear. The autopsy will reveal the many different circumstances in which ruptures of the spleen are likely to occur.

Rupture of the spleen causes profuse intra-abdominal hemorrhage leading to hypovolemic shock, which, if undiagnosed and untreated, can be fatal. A medical examiner may occasionally be confronted by an autopsy finding of death due to complications following rupture of an enlarged spleen (splenomegaly). In such cases it is important to bear in mind that rupture of the spleen can occur spontaneously with no history or external signs of trauma to the left side of the chest or to the upper left abdomen.

It is however, vitally important to examine for signs of external injury which may have been caused by violence because, when splenomegaly is present, even light violence suffered by a victim, can be the cause of rupture

of the spleen. The nature, site and extent of the external injury will indicate the severity of the violence inflicted on the body.

There is a clear analogy to the legal concept of the “paper-thin” skull, in which injury to an abnormally vulnerable part of the body can produce disastrous consequences, disproportionate to the results that would have resulted if the violence had been inflicted on an individual who did not suffer from the particular abnormality. The name of the concept derives from the classic example of a “paper-thin” skull in which a modest blow can produce permanent brain damage.

The importance of forensic medical evaluation is evident in cases where rupture of the spleen can be connected to an act of violence inflicted on the victim. In the presence of splenomegaly the severity of the act of violence must be assessed using the results of a complete autopsy and the special investigations to be recommended in this presentation.

The presentation will discuss diagnostic procedures that will facilitate the evaluation of the etiology of the splenomegaly and the pathological changes that predispose to rupture. The causes of splenomegaly are diverse, but they may be conveniently grouped into the following categories:

- Inflammatory splenomegaly: acute or chronic enlargement of the spleen that develops in association with various infections or inflammatory processes. e.g., infectious mononucleosis.
- Hyper plastic splenomegaly: due to work hypertrophy resulting from the removal of abnormal blood cells from the circulation or as the result of extramedullary hematopoiesis e.g., leukemia.
- Congestive splenomegaly: resulting from cirrhosis with portal hypertension, splenic vein occlusion (thrombosis), or congestive heart failure (CHF) with increased venous pressure e.g., bilharzia, chronic alcoholism, cirrhosis caused by aflatoxin (from fungus *Aspergillus flavus* and *Aspergillus parasiticus*).
- infiltrative splenomegaly: caused by the engorgement of macrophages with indigestible materials (e.g., Gaucher’s disease or amyloidosis,) or by the infiltration by malignancy e.g., Lymphoma.

Splenic filtering of blood-borne pathogens, such as parasites or encapsulated organisms, may also lead to splenic enlargement (e.g., parasites causing malaria or kala azar (Leishmania).

A complete autopsy including a detailed description of the macroscopic appearance of all organs is essential. Special examinations must include:

- Histo-pathological examination of samples taken from the organs and selected soft tissue and bone.
- Toxicological examination to isolate toxic organic substances.
- Microbiological examination including isolation and identification of bacteria, viruses, or parasites.

Forensic, Splenomegaly, Rupture

G47 Clinical and Pathological Spectrum of Fatty Cardiomyopathy in Sudden Cardiac Death

Lise A.M. Matzke, MSc*, Michael Allard, MD, and Bruce M. McManus, James Hogg iCapture Centre for Cardiovascular and Pulmonary Research, St. Paul’s Hospital, 1081 Burrard Street, Vancouver, BC V6H 1P9, CANADA; Carol K. Lee, MD, New Mexico Office of the Medical Investigator, MSC11 6030, 1 University of New Mexico, Albuquerque, NM 87131-0001; and Charles Lee, MD, Vancouver General Hospital, Department of Forensic Pathology, 855 West 12th Avenue, Room 1352, Vancouver, BC V5Z 1M9, CANADA

After attending this presentation, attendees will recognize the pattern of pathology findings as correlated to clinical information from cases within the spectrum of fat cardiomyopathy including arrhythmogenic right ventricular cardiomyopathy.

This presentation will impact the forensic community by reviewing clinical and pathological data for sudden cardiac death cases from the spectrum of fat cardiomyopathy. Forensic and cardiovascular pathologists, as well as

other forensic scientists, may find this information useful for comparison with observations from their home institutions and practices.

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a primary heart muscle disease characterized by fibrofatty replacement of the right ventricle (RV) that is commonly associated with sudden death. Infiltration of the RV by fat alone is also believed to be associated with sudden death. However, it is not yet fully known if both conditions are different or similar disease processes in the spectrum of fatty cardiomyopathy and to what extent fatty infiltration of the RV to contribute to sudden cardiac death. In this study, the authors set to characterize the clinical and pathological characteristics of thirteen necropsy hearts collected by the iCAPTURE Cardiovascular (CV) Biobank at St. Paul's Hospital/University of British Columbia and diagnosed with ARVC or right ventricular fatty infiltration from patients that died suddenly and unexpectedly. Each case was referred to a cardiovascular pathologist at the CV Biobank for consultation and patient data were obtained from medical records or the referring pathologist. The CV Biobank, established in 1993, is comprised of cardiovascular tissue specimens from surgery and autopsy (routine hospital and forensic) as well as accompanying annotated data which are securely stored in a database. This unique collection encompasses a wide array of cardiovascular diseases and is a powerful research and educational tool.

These thirteen cases were collected by the CV Biobank during the years 1993 to 2006 and represent approximately 14% of our sudden death cases over this time period. Each of the thirteen cases were assessed in terms of their macroscopic and microscopic features and were found to fit into one of two patterns. Nearly two-thirds demonstrated fibrofatty (six male, two female; age = 17-36 years) replacement of the right ventricular myocardium, while slightly more than 1/3 showed a pattern of predominantly fatty replacement (2 male, 3 female; age = 15-64 years). Within the fatty replacement group, 80% of individuals died following non-strenuous activity and 20% died at rest. Patient histories for this group included one individual with history of fainting and clinical intervention for arrhythmia and one patient with a history of anorexia and bulimia. Within the fibrofatty replacement group, over 57% of individuals died following non-strenuous activity; 28% during strenuous activity and 14% at rest. Patient histories for this group include one individual with documented familial ventricular tachycardia for which he received treatment; one history of dilated cardiomyopathy and mitral valve regurgitation; and one individual with sudden death of a brother due to an unspecified aneurysm. Quantitative computer-assisted morphometric analysis in a subset of seven of the thirteen cases confirmed these two patterns. Of interest, the distribution and extent of involvement differed substantially between fibrofatty and fatty patterns with changes being more extreme and widely distributed in the fibrofatty pattern and localized to the anterolateral apex and lateral base in the fatty pattern.

Thus, fibrofatty replacement of the RV, characteristic of ARVC, and fatty infiltration of the RV alone are both significant findings in cases of sudden cardiac death evaluated at a regional cardiovascular pathology referral centre. The distinctly differing extent and distribution of involvement between the two morphological patterns supports the concept that they represent two different disease processes.

Fat Cardiomyopathy/ARVC, Cardiovascular Pathology, Sudden Cardiac Death

G48 Sudden Death and Fatty Liver Disease

Michael E. Archer, MA, New York Forensics, Inc., 1039 Main Street, PO Box 28, Fishkill, NY 12524-0028; and Dennis J. Chute, MD, and Kari B. Reiber, MD, Office of the Medical Examiner, Dutchess County Department of Health, 387 Main Street, Poughkeepsie, NY 12601*

The objective of this presentation is to draw attention to the alarming prevalence of non-alcoholic fatty liver disease in the obese population and to a potential increase in sudden fatty liver deaths. The need for a thorough medicolegal investigation and autopsy will be emphasized, since a better understanding of the mechanism of death in such cases may have clinical consequences for both alcoholics and non-alcoholics with fatty liver disease.

* Presenting Author

The prevalence of non-alcoholic fatty liver disease in the general population may signal an increase in the number of sudden deaths in which fatty liver disease is the sole pathologic finding at autopsy. This presentation will impact the forensic community by. The forensic pathologist should be prepared to carefully investigate these deaths, since the opportunity to better understand the mechanism of death in such cases may induce clinicians to recommend routine EKG studies in obese patients and alcohol abusers.

The sudden death of a teenager with non-alcoholic fatty liver disease (NAFLD) prompted us to question the mechanism of death in individuals whose sole pathologic observation at autopsy is fatty liver disease. From a clinical stand point, NAFLD is recognized as a leading cause of chronic liver disease, and has been associated with obesity and insulin resistance. According to recent studies, the prevalence of NAFLD in the United States now exceeds 30% and probably mirrors the prevalence of obesity in the general population. One would therefore expect forensic pathologists to see a surge of NAFLD cases at autopsy, regardless of the cause and manner of death.

A 17-year-old morbidly obese female non-drinker with an unsubstantiated history of mild mental retardation, sleep apnea, and insulin resistance died suddenly and unexpectedly. She was found face down on her futon-style bed, clad in shorts and a tee-shirt. She was 5'5" tall and weighed more than 240 lbs. The only abnormal finding at autopsy was a 2490 g pale yellow-tan liver with greasy consistency. Microscopy showed marked fatty change with focal bridging fibrosis and spotty lobular inflammation. A toxicology therapeutic and abused drug screen was negative, and vitreous glucose was less than 20 mg/dl. In the absence of any other findings of significance, the mechanism of death was assumed to be a cardiac arrhythmia, and the cause of death was certified as "Sudden Death Associated with Non-alcoholic Fatty Liver Disease and Morbid Obesity".

Forensic pathologists have long been familiar with cases of sudden, unexpected, non-violent deaths in alcoholics with autopsy findings limited solely to fatty liver. The mechanism of death in such cases is not well understood. In a review of the literature, one current theory proposes that a prolonged QT interval may be triggered by alcohol withdrawal induced hypoglycemia complicated by low potassium and magnesium concentrations.

The anatomic pathology of alcohol-related fatty liver disease and non-alcoholic fatty liver disease is the same. Absent any other factor contributing to death, the mechanism of death may also be the same.

A thorough medicolegal investigation of the circumstances of death and medical history, a careful autopsy, and of standardized histologic grading systems for fatty liver are recommended in all cases of sudden death with fatty liver disease as sole pathologic finding in order to better understand the mechanism of death. An increase in NAFLD deaths may justify the need for routine electrocardiograms in obese individuals and alcohol abusers of all ages.

Fatty Liver Disease, Prolonged QT Syndrome, Sudden Death

G49 Hypertensive Heart Disease May Compound the Risk of Death From Medication and Contrast Media-Induced Anaphylactic Shock

Ariel Goldschmidt, MD, and Jane W. Turner, MD, St. Louis City Medical Examiner's Office, 1300 Clark Street, St. Louis, MO 63103*

After attending this presentation, attendees will understand some principles of the pathophysiology and epidemiology of lethal anaphylactic shock. Additionally, specific forensic autopsy findings related to anaphylactic shock will be reviewed.

This presentation will impact the forensic community because in this retrospective case review, all autopsied cases of individuals with medication or contrast media-induced anaphylactic shock included findings of cardiac abnormalities and, specifically, left ventricular hypertrophy was found in seven of eight cases.

The pathophysiology of anaphylactic shock is complex, involving cross-linking of IgE receptors on the surface of mast cells, causing massive

degranulation and subsequent adverse effects on the cardiovascular and respiratory systems. Circulatory collapse results from impaired venous tone and venous return, as well as decreased cardiac output. Respiratory failure results from reactive airway changes as well as upper airway swelling and obstruction and pulmonary edema.

A review of several case series in the recent literature shows that deaths from medication and contrast media-induced anaphylaxis occur more often in elderly individuals, especially those with comorbid diseases, and are more common than deaths from anaphylaxis caused by Hymenoptera stings and food allergies. Postmortem measurement of serum tryptase, a marker for mast cell activation, has been found in several studies to be a sensitive and specific test that can support a diagnosis of death from anaphylactic shock. The purpose of this study was to determine whether a retrospective review of medical examiner cases in the greater St. Louis region would corroborate the findings of previous case series reported in the literature.

A computer search was utilized to find all cases in St. Louis City and surrounding counties in the past twenty years in which the sole immediate cause of death was listed as anaphylactic shock. Twenty-two such cases were found. In eleven cases, a complete autopsy was performed at the Medical Examiner's office; in one case, a complete hospital autopsy was performed; in one case, an external examination only was performed; and in nine cases, the body was released after review of the medical investigator's report.

Among the seventeen individuals with anaphylaxis induced by medication or contrast media, thirteen were over the age of fifty. By contrast, of the five individuals with "idiopathic" anaphylaxis or anaphylaxis related to Hymenoptera stings or food allergies, four were under the age of fifty. Of the twelve cases in which a complete autopsy was performed, three cases included individuals with a swollen tongue or lips; eight included findings of laryngeal edema; ten had cardiac abnormalities; seven had pulmonary abnormalities; and two had mild cerebral edema. In the five cases in which postmortem serum tryptase levels were measured, four showed levels above the upper limit of the normal reference range (13.5 ug/ml) and all five showed levels above 10 ug/ml.

Many of the individuals who died as a result of medication or contrast media-induced anaphylactic shock suffered from comorbid diseases including obesity, diabetes, and atherosclerosis. Significantly, cardiac abnormalities were found in all of these cases in which a complete autopsy was performed. Specifically, the finding of left ventricular hypertrophy, which is strongly associated with hypertensive heart disease, was found in seven of eight cases.

The findings of this study corroborated those of previous case series, which reported that death from medication or contrast media-induced anaphylactic shock most commonly occurs in elderly individuals, many with comorbid diseases. Interestingly, in this case review, all of these autopsied cases included findings of cardiac abnormalities and, specifically, left ventricular hypertrophy was found in seven of eight cases. The association of hypertensive heart disease with death from anaphylactic shock merits further investigation and could have broad implications for the medical community if confirmed in larger studies.

Anaphylaxis, Hypertension, Hypertrophy

G50 Diffuse Axonal Injury in Medico-Legal Practice

Djordje Alempijevic, MD, PhD, Dragan Jecmenica, MD, PhD, Vladimir Zivkovic, MD, Snezana Pavlekic, MD, PhD, and Slobodan Savic, MD, PhD, University of Belgrade, School of Medicine, Institute of Forensic Medicine, 31a Deligradska Street, Belgrade, 11000, SERBIA AND MONTENEGRO*

The goal of this presentation is to present data that will provide attendees with the important medicolegal and clinical characteristics of diffuse axonal injury in closed head trauma that may contribute ultimately to fatal outcome.

The presentation will impact the forensic community by the fact that in cases of closed head trauma, diffuse axonal injury (DAI) may contribute to overall brain damage and treatment outcome. On the other hand, these results indicate that in the cases of closed head injury, fatal outcome occurs over a shorter period if DIA is present without contusions of the brain.

Diffuse axonal injury (DAI) is a form of neural damage in close head trauma that may contribute to overall trauma severity as well as the prognosis and course. For that reason, an autopsy study was performed to analyze the extent and other important forensic and clinical characteristics of DAI.

The study was carried out prospectively during two years period when 3,012 autopsies were performed. According to defined criteria, 30 autopsy cases of closed head trauma were selected (study group), while a corresponding number of cases formed control group. Whole brain samples were fixed in formaldehyde and subsequently studied macroscopically and microscopically.

Data were obtained from medical records and autopsy findings. A contusion index (CI) was used for assessment of brain contusions. Tissue density, as a measure of myelin sheet damage, was analyzed on luxol fast blue (LFB) stained sections of corpus callosum (CC) by laser scan densitometry. The obtained results were analyzed by means of appropriate statistical methods.

Optic density of LFB stained CC slices depends on myelin quantity. Optic density of CC in controls was 1.02 ± 0.05 , while in studied subjects it was 0.96 ± 0.08 . Observed difference in optic density of CC histological slices was proved to be of statistical significance ($t=4.0035$; $p<0.05$). In cases with higher CI, i.e., where contusion injuries were more severe, optical density of CC was slightly lower in comparison to the cases of less severe contusions, and cases where brain contusions were absent. Optical density of CC is significantly lower in cases with survival period up to 24 hours.

Medico-Legal Aspects, Diffuse Axonal Injury, Trauma

G51 Placental Site Trophoblastic Tumor (PSTT) With Lung Metastases as Cause of Death in a Young Patient: Autopsy Findings and Medico-Legal Implications

Catia Colecchi, MD, Catholic University, Institute of Forensic Medicine, Rome, ITALY; Ezio Fulcheri, MD, University of Genova, Department of Pathology, Genova, ITALY; Sara Partemi, MD, and Fabio De Giorgio MD, Catholic University, School of Medicine, Institute of Forensic Medicine, Largo Francesco Vito 1, Rome, ITALY; Giovanna Battista Serra, MD, Catholic University, Department of Obstetrics and Gynecology, Rome, ITALY; and Vincenzo L. Pascale, MD, PhD, and Antonio Oliva, MD, PhD, Catholic University, School of Medicine, Institute of Forensic Medicine, Largo Francesco Vito 1, Rome, ITALY*

The goal of this presentation is to present the autopsy and histological findings of placental trophoblastic tumor, which are very rarely described in the literature.

This presentation will impact the forensic community by demonstrating how medico-legal implications are related to the difficulties of the doctor who faced this rare condition.

Placental site trophoblastic tumor (PSTT) is a rare form of gestational trophoblastic disease (GTD) with unpredictable biological behaviour. It arises from the transformation of intermediate trophoblastic cells that normally play a critical role in implantation. PSTT was originally termed “atypical chorioepithelioma” by Marchand in 1895. In 1976, under the title “trophoblastic pseudotumor of the uterus”, Kurman et al. recognized the entity as a form of trophoblastic disease, distinct from choriocarcinoma. Five years later, Scully and Young introduced the term “placental site trophoblastic tumor” to indicate possible malignant behaviour. Since the first report, approximately 90 cases of PSTT have been reported, formerly termed atypical choriocarcinoma, chorio-epitheliosis or syncytoma. PSTT can occur after a normal pregnancy, abortion, term delivery, ectopic pregnancy or molar pregnancy. It displays a wide clinical spectrum, and when metastatic, can be difficult to control even with surgery and chemotherapy. Unlike other forms of GTD, PSTT is characterized by low beta-hCG levels because it is a neoplastic proliferation of intermediate trophoblastic cells. Expression, however, of human placental lactogen (hPL) is increased on histologic section as well as in the serum. The most common presenting symptoms of PSTT are vaginal bleeding and amenorrhoea. Diagnosis is confirmed by dilatation and curettage and hysterectomy but meticulous evaluation of metastasis is mandatory.

A 21-year-old woman, (gravida 1, para 0) at 25 weeks of amenorrhea was admitted to the hospital for hyperemesis, hepatic problems, and important weight loss registered during the last few months. Routine laboratory tests such as liver function, haemastics and coagulations markers were abnormal, whereas all fetal parameters were unremarkable. On examination, the patient was cachectic looking. The per-abdominal examination was unremarkable. Few days after the admission the patient suddenly died before the doctors can reach a diagnosis. A forensic investigation for medical malpractice was initiated. Microscopic examination of the samples collected from uterus revealed the presence of large trophoblastic cells with eosinophilic cytoplasm. Deposition of fibrinoid material was noticed between trophoblastic cells. Tumor cells dissected through the myometrium and invaded into the vascular spaces. Specimens of the lungs revealed numerous small neoplastic emboli into the vessels.

Placental site trophoblastic tumor is an uncommon member of GTD, with less than 100 cases having been reported in the English language literature. PSTTs behave in a benign fashion, whereas approximately 10–15% were clinically malignant. Predicting which patients will develop metastases is difficult. The outcome is usually excellent after the simple hysterectomy. Unfortunately at the time of diagnosis our patient presented metastasis beyond the uterus. The management of disease with metastasis can be very difficult, for the relative insensitivity to chemotherapy. Other important adverse prognostic factors are age >40 years and mitotic count >5 mf/10 HPF. Gross autopsy and histological findings, which are very rarely described in the literature, are demonstrated. The medico-legal implications related to the great difficulties of the gynecologist who faced this rare condition in term of diagnosis and prediction of the biological behavior and outlining effective therapeutic approaches are discussed.

Placental Site Trophoblastic Tumor, Lung Metastas, Medico-Legal Implications

G52 Identification of Human Body Fluids: Comparison Between Two Commercial Kits for Detection of Semen

Simona Ricci, MD, Department of Legal Medicine, Viale Regina Elena 336, Rome, ITALY; Fabio Verginelli, Department of Oncology and Neuroscience University “G.d’Annunzio” and Center of Excellence on Aging (Ce.S.I.), D.d’Annunzio Foundation, Chieti, ITALY; Andrea Mele, MD, Department of Legal Medicine University “Sapienza” Viale Regina Elena 336, Rome, ITALY; and Manuela Rosini, and Carla Vecchiotti, MD, PhD, Laboratory Genetic of the Department of Legal Medicine University “Sapienza”, Viale Regina Elena 336 00161 Rome, ITALY*

The aim of our presentation is to show the results making a parallel study to detect human semen on old and recent traces with these two different commercial kits.

This presentation will impact the forensic science community by showing how it is possible to improve the knowledge about identification methods using new approach to detect traces.

The examination of living victims of sexual assaults is very important; the necessity to have markers to detect the presence of semen on clothes or body fluids could be helpful in forensic science. Semen is the most common form of body fluid evidence encountered in these cases; in screening or examining sexual assault evidence, semen or other body fluids can be present on a variety of surfaces including sample collection swabs, pieces of clothes, bed sheets, towel, flooring, condoms, and feminine products. The samples can also be stored for many years: testing for body fluid identification and DNA profiling should be able to reliably, and with high sensitivity detect semen from a variety of sources. In countries with sophisticated forensic science or laboratories, the pathologist will not be called upon to carry out actual techniques for detection of seminal fluids: he has to be a careful collector of samples and to be able to make an interpretation of the results, but sometimes even the pathologist has to be well informed and has to be able to make these tests by himself. The detection of semen depends upon many different methods as naked-eye and lens recognition; examination under ultraviolet light, enzyme reactions (acid phosphatase activity), immunological methods, FISH method.

Particularly the immunological methods are recently used in many laboratories and they detect the presence of some antigens that normally can be found also in seminal fluid: for example PSA and Semenogelin.

PSA or prostate-specific antigen is a glycoprotein produced by the prostatic gland and it is found in seminal plasma, male urine, and blood, it could be present also in tissue or fluid of the female body but the concentrations are very low. A positive PSA test is a reliable indicator of semen regardless the presence of spermatozoa or elevated acid phosphatase level.

The other test detect a different protein that is present on semen, Semenogelin: it is the major component of human semen and together with fibronectin, gives rise to the gel-like coagulum of newly ejaculated semen.

Both of them are immunochromatographic assay tests that use monoclonal antibodies specific for the antigen and they use a strip test that can be manipulate easily.

The aim of our presentation is to show the results we had in our Laboratory making a parallel study to detect human semen on old and recent traces with these two different commercial kits. This study has the purpose to test also the sensitivity of these new methods because of the importance they could have in forensic cases.

Identification, Human Semen, Immunological Kits

G53 A Brush With Death: Suicidal Ingestion of Toothpaste

Rebecca Irvine, MD*, 808 Shire Street, South West, Albuquerque, NM 87121; and Susan Kunkle, PharmD, New Mexico Poison and Drug Information Center, MSC11 3060, 1 University of New Mexico, Albuquerque, NM 87131-0001

The goal of this presentation is to describe the gross findings and the physiologic derangement resulting in death in toothpaste/flouride toxicity.

This presentation will impact the forensic community by making medical examiners aware of the potential acute toxicity of [widely-available] fluoridated toothpaste, its recognition and the high national incidence of non-fatal toothpaste poisonings.

This poster presentation will permit the attendee to brush up on the toxic effects that accompany the ingestion of toothpaste with fluoride, an extremely common, if rarely fatal, poisoning event. After attending this presentation, the attendee will be able to describe the gross findings in acute fluoride poisoning, the circumstances in which toothpaste poisoning may occur and the physiologic derangement that results in injury or death.

A 51-year-old man was found unresponsive on his bed, by his wife, when she came home from work. The bedroom door was locked from the inside. There was a history of domestic abuse, and reportedly the wife had assaulted him three days earlier, resulting in visible contusions on the right eye and upper arm. Resuscitative attempts were unsuccessful and he was pronounced dead at the scene. There was no investigative evidence of acute trauma or foul play.

Past medical history was significant for bipolar disorder, hypertension and chronic back pain. The decedent was known to abuse cocaine and multiple burnt copper pad fragments were identified throughout the house.

Two weeks earlier, the decedent, who was noted by his wife to be depressed for several months, had uttered an isolated suicidal statement to the effect that when his medications arrived by mail he should "take them all". His medications (Depakote, bupropion and olanzapine) were irregularly out of count and some were in a pile on the bedside table, along with a Thermos. No note was found.

Autopsy revealed an overweight male (BMI 28.5 kg/m²) with cardiomegaly (600 grams), organized anterior infarct, marked concentric left ventricular hypertrophy and chronic lung disease with pulmonary hypertension. There was florid hemorrhagic necrosis of the entire gastric mucosa. The stomach contained frank blood (300 ml) and a 230-gram conglomerate of translucent blue-green paste (with a minty odor).

Follow-up investigation located an almost empty 119-gram tube of toothpaste as well as multiple partially full tubes of toothpaste in the outdoor trash. The wife indicated that the decedent had some level of sophistication regarding medications, had a sibling who was a pharmacist, and would be aware of the dangers of toothpaste ingestion, especially with the warning on the package.

Toxicological evaluation revealed the presence of cocaine and benzoylcegonine as well as bupropion and citalopram. A biochemical vitreous screen was unremarkable. Fluoride was not detected in femoral blood.

The cause of death was: gastrointestinal hemorrhage due to massive ingestion of fluoridated toothpaste, hypertensive heart disease, and cocaine intoxication were significant contributing factors.

Given the history of suicidal intent, the concealment of the toothpaste tubes and the noxiousness of ingestion, the manner of death was certified as suicide.

Gastrointestinal signs and symptoms usually predominate upon ingestion of toothpaste. Other observed effects have included headache, numbness, and electrolyte disturbances, especially hypocalcemia. Hypotension and dysrhythmias are evident in severe poisonings. Toothpaste often contains up to 5 mg of fluoride per teaspoon. The fluoride is the component of toothpaste associated with toxicity. In many cases, 3 to 5 milligrams per kilogram of elemental fluoride is a toxic dose. The mechanism for toxicity following the ingestion fluoride-containing substances is thought to be a reaction between the sodium fluoride in the toothpaste gastric acid, resulting in the production of highly corrosive

hydrogen fluoride (HF). The HF causes adverse effects reported in large ingestions, including nausea, vomiting, diarrhea, abdominal pain, and acute hemorrhagic gastroenteritis.

According to Annual Reports of the American Association of Poison Control Centers, over 118 thousand poisoning exposures were reported to poison centers nationally during the five-year period ending in 2005. Of these, 91 percent were unintentional exposures; roughly 90 percent involved children less than six years old. This case is unique in the respect that it was the sole fatality attributed to toothpaste ingestion during this period.

Toothpaste, Fluoride, Poisoning

G54 Toxicological Implications in Heat Related Deaths in Phoenix, Arizona: Case Reports From the Office of the Medical Examiner

Kimberly McCall-Tackett, BS*, Maricopa County, Forensic Science Center, 701 West Jefferson Street, Phoenix, AZ 85050; Ann L. Bucholtz, MD, 6643 East Sweetwater Avenue, Scottsdale, AZ 85254; Amy L. Lais, BS, Maricopa County Forensic Science Center, 701 West Jefferson Street, Phoenix, AZ 85007; and Norman A. Wade, MS, Office of the Medical Examiner, Forensic Science Center, 701 West Jefferson Street, Phoenix, AZ 85007

After attending this presentation, attendees will be afforded a three year review of the statistics, toxicology, and pertinent scene findings associated with heat related deaths in the metropolitan Phoenix area.

This presentation will impact the forensic community by raising awareness of this public health issue.

The diagnosis of a heat related death rests on the importance of considering all factors involved for certifying the death when a person is found dead in a hot environment that can routinely be greater than 105 degrees during summer months. In recent years, media scrutiny of the number of deaths related to hyperthermia has reached headline proportions in our area, which has prompted much public awareness and activism. Although these headlines are accurate in reporting deaths have occurred, they do not typically reflect the true circumstances surrounding the deaths. This paper will discuss the headlines versus factual findings, retrospectively demonstrate the statistics, and discuss an algorithmic approach to unify the certification for more accurate compilation of county health statistics. Data was collected from May 1st to September 30th for years 2005 and 2006 (2007 data is still being collected). During this 2 year period, 168 deaths were certified as heat related. Of these deaths, 52% (87) had negative toxicology findings and were attributed to heat only. Of the remaining 48% (81 cases): 14% (24) had positive toxicology screens for ethanol, 16% (25) had positive screens for stimulants (cocaine or methamphetamine), 5% (8) were positive for psychotropic drugs, and 14% (24) had positive results for more than one of these categories. Toxicology also plays a vital role in electrolyte determinations. The levels of sodium, creatinine, and urea nitrogen must be considered, if possible, when evaluating potential heat related deaths. In conclusion, vitreous analysis, scene variables, and decomposition all affect the ability to evaluate results. The relevance of these findings in conjunction with other variables used to make the diagnosis will be discussed. The proposed algorithm will assist with the information gathering process and aid the forensic investigation by promoting categories for the deaths to be cataloged, so more accurate statistical, epidemiological and community prevention measures can be instituted. This retrospective analysis will demonstrate the multiple factors used to make a diagnosis of a heat related death and elicit common problems encountered in evaluating a decomposed body in a potentially hot environment. From these findings, an algorithmic approach will be proposed to further define the cause and manner of death in future investigations and improve public health reporting. It is hypothesized that the cause and manner of death could be more definitively diagnosed by using a more uniform information gathering process at the scene, during the autopsy examination and from the toxicology findings. Specific case findings and circumstances will be discussed.

Hyperthermia, Toxicology, Death

G55 Firearm Deaths by Law Enforcement in New York City

James R. Gill, MD, Office of Chief Medical Examiner's Office, 520 First Avenue, New York, NY 10016; and Melissa Pasquale-Styles, MD*, New York City, Office of Chief Medical Examiner's Office, 599 Winthrop Street, Brooklyn, NY 11203

Upon completion of this presentation, participants should obtain an overview of the circumstances and injury patterns seen with 42 police shootings.

This presentation will impact the forensic science community by demonstrating how although police shootings in which the decedent was unarmed and/or sustained numerous gunshot wounds are widely reported by the lay press, these types of shootings were not typical in our study.

The use of deadly force during law enforcement is a matter that compels public scrutiny. There were 42 gunshot deaths caused by police over a 4-year period in New York City. The decedents' average age was 31 years and ranged from 17 to 64 years. There were 41 males and 1 female; and 26 Black, 9 Hispanic, and 7 White decedents. The majority (90%) of the decedents possessed a weapon. There were 26 handguns, 6 knives, 1 axe, 1 metal pipe, and 1 toy gun (carried by an adult impersonating a police officer). Vehicles were used as weapons in two incidents. Ethanol and/or drugs of abuse were detected in 78% (31/40) of the decedents. The detected drugs of abuse included: 15 cannabinoids, 14 ethanol, 10 cocaine/BE, and 1 amphetamine. Seven decedents had a history of psychiatric illness.

The most common reason for the police presence was a response to a crime and for the shooting was the decedent's possession/use of a weapon. All but one of the decedents had injuries caused by handguns (one involved a handgun and rifle). A total of 177 bullets struck the 42 decedents. Fourteen decedents sustained single gunshot wounds, and the remainder had multiple gunshot wounds ranging from 2 to 21. In the majority of the cases in this study, the number of gunshot wounds of the body was 3 or fewer. There were 112 penetrating, 55 perforating, and 8 graze wounds. Thirteen decedents had at least one gunshot wound of the back or buttocks, accounting for 25 of the total 177 wounds, and four of the twelve had gunshot wounds of *only* the back. With the exception of the upper extremities, gunshot wounds of all locations were more likely to penetrate than perforate.

The location of the entrance wound is sometimes used as evidence to support or dispute the justification for the use of force. A shooting is a dynamic process with split second decisions and movements. It has been demonstrated that a person can turn the torso completely in the milliseconds that it takes for one to decide to fire a gun and pull the trigger. Our data show a wide range of entrance wound locations which would reflect this dynamic process.

Although these deaths may be high profile, the certification is typically straight forward and the cause (i.e., gunshot wound) and manner of death (homicide) are readily apparent. Since the medicolegal definition of homicide is death at the hand of another, the forensic pathologist is absolved of considering intent or the appropriateness of the use of force. Typically, those issues are left to the legal investigation (e.g., grand jury investigation). During this time, the medical examiner may play an important role in the corroboration of witness statements and other evidence by providing information on the direction of the wound tracks, range of fire, and opining on how the injuries may have affected the victim during the course of the event.

Although police shootings in which the decedent was unarmed and/or sustained numerous gunshot wounds are widely reported by the lay press, these types of shootings were not typical in our study. The vast majority of police-shootings occurred with the police responding to a crime in which the decedent was armed. In addition, most of the decedents had 3 or fewer gunshot wounds.

Forensic Pathology, Firearm, Police

G56 Postmortem Genital Examinations With Colposcopy in the Evaluation of Fatal Sexual Violence Against Women

Sharon R. Crowley, RN, MN*, 122 Emeline Avenue, Santa Cruz, CA 95060

The goals of this presentation are: to help attendees better understand the nature and appearance of the anogenital tissues at various postmortem intervals; to compare the results from photocolposcopy at various magnifications vs. single lens reflex (SLR) photography; and to determine if toluidine blue dye is a reliable and/or useful adjunct in the postmortem genital examination.

This presentation will impact the forensic science community by improving the diagnostic acumen of the forensic examiner; avoiding ambiguity of interpretation of clinical findings in postmortem genital examinations; and providing a framework for the medical evaluation of fatal sexual violence against women.

This paper proposes to describe ongoing research on postmortem genital anatomy. These cases comprise a significant portion of a baseline study of postmortem genital examinations, to better study fatal sexual violence against women. To this end, a detailed analysis of anogenital anatomy at various postmortem intervals is being conducted.

The focus of the present discussion is to describe the initial results of cases drawn from the Donated Body Program, at University of California, Davis, California. A total of 30 cases will come from this population and will form a subset of the final, larger project sample. Analysis of results from these baseline studies will allow eventual comparison to genital injuries sustained by both sexual homicide victims and living sexual assault victims. Data accumulated during this project will provide the core information for a *Sexual Homicide Database* (Crowley, AAFS/1998;2000; JFS/2004).

The operations base of the Donated Body Program at the University of California, Davis, California, is at the Sacramento County Coroner's Office Morgue. Most donors are received by the Program \leq 24 hours of death. All cases selected for this baseline study are fresh, or fresh-frozen, vs. embalmed. Cases are examined based upon availability, i.e., female gender, and received by the Program in a time frame compatible with examination by the primary investigator.

A paucity of data exists on the "normal" appearance of the genital anatomy during the postmortem interval. We lack data from scrutiny and photodocumentation of the postmortem anogenital tissues. In living sexual assault victims, specific anogenital sites have been well-studied (Slaughter, Brown, Crowley, and Peck, 1997). The use of colposcopy is well established for both adult and child *living* victims. During the autopsy, gross visualization alone may not allow the detection of the more subtle findings that usually constitute genital trauma in sexual assault. Crowley described a mobile system for postmortem genital examinations with colposcopy (JFS, 2004).

Previously, the use of 1% toluidine blue as an adjunctive tool in fatal abuse cases was limited to select case examples. This nuclear stain has been incorporated as a practice standard by many programs, for the medical legal evaluation of living sexual assault victims. A review of the original methodologies was presented earlier (Crowley, AAFS/2005; 2007). Toluidine blue is specific for zones of parakeratosis and results can be due to inflammatory, benign, or malignant vulvovaginal diseases. Following application of toluidine blue dye *in vivo*, false positive results may be caused by 23 benign vulvovaginal conditions, in addition to cervical mucous. In nongenital sites, toluidine blue dye has been shown to yield positive results in granulation tissue (Crowley, 2007).

Using Crowley's mobile system of technology, the clinical phase of this research project began in March, 2007, at the Donated Body Program at the University of California, Davis, California. The research project is an observational study, with a cross-sectional design. The examination methodology employs photocolposcopy at 7.5X, 15X magnification, or both, plus 35 mm photography via the colposcope. Additional photographs are taken with a 35mm single lens reflex (SLR) digital camera, for comparison. Inspection and photodocumentation of specific anogenital sites is employed, prior to manipulation of the genital tissues. On select cases, concomitant application

of a 1% solution of toluidine blue dye has also been incorporated, in order to evaluate the reliability of this general nuclear stain as an adjunct to the postmortem examination.

Available demographic data is collected on each case, which is assigned a unique identifier, for entry into a modified version of the *Sexual Homicide Database*. Eleven anatomic sites are routinely evaluated and documented on the postmortem worksheet. Inspection, labial separation, and labial traction are used to maximize visualization, in addition to speculum insertion and anoscopy. The nature and pattern of postmortem genital findings are described in a manner consistent with the proposed taxonomy for postmortem anatomy previously described by Crowley and Peterson (AAFS/2004).

Currently, a wide variation exists in the methodology for the examination of antemortem sexual assault victims. Protocols and procedures vary, especially with regards to adjunctive methods, e.g., application, timing, and interpretation of toluidine blue dye. Postmortem challenges are multifaceted; they may pose even greater significance than in living victims. Postmortem deposition of the victim's remains usually precludes the opportunity for a follow-up examination/re-evaluation. Moreover, when experts whose sole expertise is with the antemortem victim are asked to collaborate in a sexual homicide case, even greater challenges arise. The expert *must* consider working as a team member, not in a vacuum; their frame of reference cannot solely reside in the antemortem arena.

The higher magnification potential of the colposcope affords greater opportunity for careful scrutiny and photodocumentation. This improves both the diagnostic acumen of the examiner and the quality of the postmortem genital examination. Colposcopy facilitates peer review, salient to the scientific process and eventual applicability of the research endeavor.

It is certainly true that in equivocal cases, the Forensic Pathologist can simply remove en bloc, for dissection and microscopic evaluation, the tissues germane to genital findings. However, it may prove to be beneficial to have an initial *in situ* examination of the anogenital anatomy via colposcopy.

The ultimate goal is to better visualize, in order to improve our understanding of what is normal in the anogenital anatomy during the postmortem interval.

Forensic Clinical Nurse Specialist, Colposcopy, Donated Body Program

G57 The Serial Killer of Elderly Women: Analysis of a Multi-Victim Homicide Investigation

Carlo P. Campobasso, MD, PhD, University of Molise, via De Sanctis, snc, Campobasso, 86100, ITALY; and Massimo F. Colonna, MD, Felice Carabellese, MD, Ignazio Grattagliano, PsyD, Chiara Candelli, MD, and Roberto Catanesi, MD, University of Bari, Section of Forensic Psychiatry, Piazza Giulio Cesare, Bari, 70124, ITALY*

After attending this presentation, the participants will learn: (1) the practical issues involved in investigating and analyzing the actions of a serial murderer, and (2) the motives, methods of operation, victim selection, injuries and body disposal scenarios highlighted through case examples never presented before.

This presentation will impact the forensic community by showing a little-known but noteworthy case of a serial killer murder of an elderly women occurring in Southern Italy ten years ago.

Ben Mohamed Ezzedine Sebai, is a convicted Italian serial killer. Originally from Kairouan (Tunisia), he immigrated illegally to Italy in 1990. In 1991 he was charged of attempted murder and rape and the police headquarters of Bolzano issued an expulsion order. He fled and took refuge in the province of Foggia (Southern Italy), where he worked as farm laborer. He begged for money and relied on voluntary organizations managed by religious institutions for food and shelter. Between 1994 and 1997, in the territories of Southern Italy, fifteen women aged over 70 were murdered. One victim in 1994, two victims in 1995, three in 1996, nine in 1997, but not

all attributed to Sebai. Most of the victims were stabbed multiple times on the neck (min. 1, max. 20) with the exception of three cases in which the cause of death was manual strangulation. The assailant had sex with only one victim and sperm traces were recovered on the body. All the victims were found in their own apartments with no sign of break-in. However, the murders were connected to the theft of money and/or jewelry. The press alerted the public to the inability of the local police to seize the guilty party. In the meantime a criminal profiling was requested to aid the local police in refining their suspect list. The results showed that the murder pattern was completely inconsistent with the local criminal patterns, suggesting that the perpetrator could be an illegal immigrant sexually motivated or prior arrested for sex-related incidents. On the 15th of September, 1997, Sebai was arrested while attempting to catch a train after his last murder. Sebai was recognized by an 8-year-old child next-door neighbor of the victim while he was casting off his blood-stained clothing. He was convicted of four murders and given life sentence.

For the remaining homicides, other people were convicted; in most cases they were relatives of the victims spurred by economical reasons. In 2006, after nine years, Sebai admitted responsibility for the murders of four more elderly women, for which nine other people had already been convicted, among whom one had committed suicide in jail in 2005. The reasons of this posthumous confession are to be found in his willingness to clear these people of a groundless charge and hand over the crime weapon never found before. One year later, in 2007, he confessed to seven more murders,,with all 15 deaths occurring between 1994 and 1997. After first interviews with Sebai, a story of difficulty during childhood involving his grandmother; apparently she allowed his uncles to abuse him. His father was violent too. He hit Sebai on his feet after hanging him face down. Sebai's techniques were quite simple; once he studied the elderly women's habits, he made sure that nobody was in and he intruded under the pretext of a salesman of holy pictures then burst into the house. He deliberately chose the victims, having no prior personal connection with them at all. The neck was his favourite target because there the stab wounds can produce rapid death by exsanguination. With profuse bleeding, physical activity of the victim is also limited or lost rapidly preventing victims from screaming. He also confessed that at the end of each murder he used to ejaculate confirming the previous hypothesis of homicides sexually motivated. Sebai's criminal profiling is still going on and further developments of this case cannot be excluded.

Serial Killer, Multi-Victim Homicide Investigation, Criminal Profiling

G58 One Entrance Wound, Three Bullets, and Four Pulls of the Trigger: An Unusual Case of a Suicidal Gunshot Wound of the Head

Todd M. Luckasevic, DO, Allegheny County, Office of the Medical Examiner, 542 Fourth Avenue, Pittsburgh, PA 15219; Kenneth Clark, MD, University of Pittsburgh Medical Center, 200 Lothrop Street, Pittsburgh, PA 15213; and Abdulrezak M. Shakir, MD, and Karl E. Williams, MD, MPH, Allegheny County, Office of the Medical Examiner, 542 Fourth Avenue, Pittsburgh, PA 15219*

The goal of this presentation is to illustrate an unusual case of suicide with a revolver and multiple squib bullets.

This presentation will impact the forensic community by illustrating the need for close collaboration between the forensic pathologist and the firearm examiner when dealing with cases of unusual gunshot wounds.

Suicide is one of the most important public health issues in the United States. Suicide represents the eleventh leading cause of death in the United States. Suicides comprise approximately 12% of the caseload of the Allegheny County Medical Examiner's Office in Pittsburgh, Pennsylvania. Suicide rates for this country have been relatively stable over the past decade averaging approximately 10 per 100,000 populations. The most common method of suicide in the United States is the use of a firearm.

An elderly Caucasian male with a history of prostate cancer recently

* Presenting Author

learned that his prostate cancer had metastasized to his pancreas. Family members relayed that he made comments that he did not want to go through radiation and chemotherapy treatment again. On the morning of his demise, the decedent told his wife that "It just ain't worth it anymore." Later that morning his elderly wife heard a thump in the adjacent room. The decedent was found in the fetal position on top of his overturned walker. The wife called her brother-in-law to help, at which time they found blood coming from his head and a revolver in his right hand.

The external examination revealed an elderly Caucasian male with a single contact penetrating gunshot wound of entrance to the right temple region of the head. Dense soot deposits were present on the skin and within the wound track. A faint muzzle abrasion was identified surrounding the entrance wound. Gunpowder residue was grossly visible on the left index finger. Radiographs of the head revealed three separate bullets. Autopsy revealed a single entrance with internal beveling of the right temple bone. The path of the bullets was leftward through the bilateral temporal lobes of the brain. One .38 caliber slug was recovered from the left temporal lobe and the other two slugs were recovered from the subcutaneous tissue of the left temporal scalp.

The firearms report found the Colt .38 special caliber revolver to be in good working order. The six shot cylinder of the revolver contained three spent cartridges and three live cartridges. Interestingly, the three spent cartridges were in positions 1, 2, and 4. In position 3 was a live round with its primer struck. The three slugs recovered from the decedent's head were .38 caliber lead wad cutter-type bullets that were found to be fired by the above Colt revolver.

Collaboration between the pathologist and firearms examiner concluded that the decedent used his right thumb to pull the trigger four times and his left hand was used to steady the revolver. The first two cartridges were squibs that lodged in the barrel of the revolver. The third cartridge was a dud; the primer was struck with the revolver's firing pin but it did not discharge. The fourth cartridge was live and when struck by the firing pin discharged forcing itself and the two lodged squib bullets out of the barrel of the revolver and through the skull and brain of the decedent creating one classic entrance wound and bullet path. The bases of the two squib bullets confirm this scenario along with the deformation of the nose of the first squib slug and the relative pristine nature of the fourth live round.

Suicide, Handgun, Squib Bullets

G59 Suicidal Shotgun Wound Using a Shotgun Barrel, a Shotgun Shell, and a BB

Brian S. Linert, BS*, 2102 North Meridian Street, Apartment 9, Indianapolis, IN 46202; Janis Regnier, Portage Police Department, Portage, IN; Barrett W. Doyle, Porter County Coroner's Office, Valparaiso, IN; and Joseph A. Prahlow, MD, South Bend Medical Foundation, 530 North Lafayette Boulevard, South Bend, IN 46601

After viewing this presentation individuals will be better able to recognize unusual patterns of suicide. These patterns include: homemade or improvised firearms, unusual firing positions, and disguise of the suicide as a murder.

This presentation will impact the forensic science community by providing another unusual example of the use of a firearm for suicidal purposes. It also stresses the importance of good investigative technique as well as maintaining an open mind throughout the duration of an investigation.

Suicidal gunshot wounds are common in the United States. Many of these cases involve handguns; however, the use of long guns such as rifles or shotguns is also prevalent. Occasionally, an individual will employ the use of a homemade firearm or 'zip gun'. Creative or elaborate mechanisms for pulling the trigger are sometimes devised. Some individuals go to great lengths to conceal the weapon, confusing the issue and making the suicide appear as a homicide. In this report, we describe an unusual suicidal shotgun wound, in which the victim used a shotgun barrel (without the rest of the gun), a shotgun shell, and a BB.

A 54-year-old man was found dead in the basement of his home by

* Presenting Author

friends who were helping him move out of his home. He was lying on the concrete floor with an obvious wound to his lower left chest. Emergency medical personnel responded, as did police. He was pronounced dead at the scene. The coroner was notified. The police and coroner believed that the chest wound was the probable cause of death, and their initial impression was that it represented some sort of impaling wound. The basement was relatively empty, as the man and his friends had been moving his belongings out of the home. An old shotgun barrel was seen lying on the floor near the body, but it was not initially considered significant. Examination of the body at autopsy revealed the true nature of the wound: a non-contact shotgun wound with wad-petal abrasions and stippling. Close inspection of the shotgun barrel and scene disclosed a spent shotgun shell within the barrel, multiple small indentations on the base of the shell, including one on the primer, and a BB pellet on the floor near where the man and the shotgun barrel were discovered. It was surmised that the man, while bending at the waist and leaning over, held the barrel in a vertical position, with the muzzle end directed upward toward his chest and the opposite end, containing a loaded shell, toward the floor. By slamming the base of the shotgun shell on a BB on the floor, the man eventually hit the BB with the primer, causing the weapon to discharge.

The present case serves to remind death investigators of the importance of a thorough scene investigation as well as the importance of maintaining an open mind regarding the cause and manner of death. In this case, the initial concern was for a homicide with an impaling wound. Autopsy and subsequent investigation revealed the truth—a suicide employing a shotgun fired in a very unique manner. The case provides another example of how suicidal individuals can be very creative when it comes to discharging a weapon.

Suicide, Shotgun, Barrel

G60 Characteristics of Suicidal Gunshot Wounds to the Mouth in Women

Lakshmanan Sathyavagiswaran, MD*, Christopher B. Rogers, MD, Frances Hicks, and Donald Boger, MD, Los Angeles County Medical Examiner's Office, 1104 North Mission Road, Los Angeles, CA 90033

After attending this presentation, attendees will become familiar with the characteristics of suicidal gunshot wounds to the mouth in women, particularly relating to the circumstances in which the decedent shot herself.

This presentation will impact the forensic community by drawing attention to an unusual case and reviewing factors which may be used to distinguish homicide from suicide in female victims of oral gunshot wounds.

In 2003, an unusual case occurred in which the decedent, a 40-year-old woman, sustained a gunshot wound of the mouth in another person's residence, and in his presence. Her skirt had been removed and folded in her purse, and the crowns of her central incisors were chipped. An important forensic issue in this case was whether the mode of death was homicide or suicide.

In calendar years 2004-2006, the Los Angeles County Department of Coroner examined 755 victims of suicidal gunshot wounds. Of these, 80 (11%) were female. Of the female victims, 72 (90%) used handguns and 8 (10%) used rifles or shotguns.

The gunshot entry wound was located in the mouth in 24 individuals. The ages of these 24 victims ranged from 34 to 90. A suicide note or equivalent (telephone call, estate documents left out) was present in 14 cases (58%).

In virtually every case, the decedent was fully clothed (23/23 cases; one case where amount of clothing was unknown) and the gunshot wound was inflicted at the decedent's home (21/24 cases, 88%). The shooting was unwitnessed in 22 cases (92%).

In 20 cases, the decedent did not sustain chip fractures of the tips of the incisors by x-ray. In two cases the decedent was edentulous, and in two cases the presence of fractures could not be ascertained because of extensive destruction of the mouth by the firearm wound.

The caliber of the gun varied widely. There were two injuries with .22

caliber weapons, one with a .25 caliber weapon, one with a .32 caliber weapon, three with 9 mm weapons, five with .357 caliber weapons, nine with .38 caliber weapons, and one with a .45 caliber weapon. One decedent used a 12 gauge shotgun, and one used a 20 gauge shotgun.

Suicidal gunshot wounds of the mouth are unusual in women, occurring in 24/755 of our suicidal gunshot wounds in this series (3%). In the large majority of cases, the female victims of suicidal gunshot wounds to the mouth were fully clothed and committed suicide unobserved in their own residences. Chip fractures of the tips of the incisors were not seen in our cases. Most victims in this case used handguns rather than rifles or shotguns. On the other hand, presence of a suicide note and caliber of the gun were not distinctive features of this group of cases.

In determining the mode of death in a gunshot wound of the mouth in a female victim, it may be valuable to note the circumstances in which the injury occurred; particularly whether the decedent was clothed, whether the injury was observed, and whether the decedent was in her own residence.

Gunshot Wound, Suicide, Female

G61 Victimization of Children, Adolescents, and Young Adults by Physical and/or Sexual Abuse in Northwestern Greece: A Three Year Study

Vasilios S. Stoukas, Telamonos 25, Anthoupoli, Peristeri, Athens, 12135, GREECE; Angeliki Tsiola, MD, Patras, GREECE; and Anastasia Varvarigou, MD, University of Patras, Medical School, GREECE*

After attending this presentation, attendees will become familiar with the epidemiologic, demographic, social and medical features of child, adolescent and young adult victims of physical and/or sexual abuse in Northwestern Greece.

This presentation will impact the forensic community by demonstrating the value of data collection and interdisciplinary research work as an important initial step in facing child abuse (either physical or sexual) effectively.

Child abuse is a worldwide problem, although its manifestations and extent in specific regions may vary. It is far more prevalent and detrimental than is generally recognized, having both short and long-term physical, psychological, and social consequences. In Greece mild physical punishment of children is considered to be a normal aspect of child rearing. Compared to other countries (e.g., USA, United Kingdom or Japan) the reported incidence of child abuse in Greece is minimal. It is probable, however, that the rate is underestimated because of the lack of mandatory reporting of child abuse, and also because of inadequate awareness among health care providers. *A priori*, these circumstances make any effort of estimating the true extent of child abuse in Greece even harder.

The incidence, gravity and the social and medical characteristics of the reported cases of child, adolescent and young adult abuse in Northwestern Greece were the parameters chosen to be investigated. A comparison was also done to the characteristics found in other areas of Greece and foreign countries. Data survey was performed through the retrospective analysis of child, adolescent and young adult abuse cases, for the period November 2004 to December 2006, based on the archive files (forensic reports) of the Patras Medical Examiner Office, which serves the entire region of North-western Greece.

Twenty-six (26) cases of child, adolescent and young adult abuse were reported. The age of the victims ranged between 1 and 20 years old for both sexes. From these 26 cases, 18 were identified as physical and/or sexual abuse. At the rest 8 cases neither physical nor sexual abuse findings were established. Six (6) cases concerned rape or sexual abuse, and the victims' age ranged between 5 and 15 years old. Four (4) victims were males and 4 were females respectively. The 18 established cases of physical and/or sexual abuse included 4 victims of rape (3 were females), and 14 children and adolescents physically abused. The significance of the injuries (see table 2)

of 3 out of the 14 physically abused victims was characterized as dangerous (2 females, 1 male) and 11 as simple or light (9 females, 2 males). The families of 15 victims resided in urban centres and the rest 3 in the country, respectively. As far as the nationality of the victims is concerned, one family was Eastern European while the rest (17 families) were Greek. The above categorization of physical and sexual abuse was performed according to the Greek legal system (Greek Criminal Law).

Demographic and social characteristics of the victims included:

- Delay in Seeking Help: 38 (70%)
- "Difficult Child": 24 (44.4%)
- Unwanted Pregnancy: 21 (39%)
- Illegitimate Child: 7 (13%)
- Difficult Pregnancy and Delivery: 19 (35%)
- Premature Child: 8 (14%)
- Problem during the Neonatal Period: 15 (28%)
- Illness during the first months of life: 12 (22%)

Summarized medical findings in 18 cases of abused children, adolescents and young adults included:

- Blunt Force Injuries: 23 (42.5%)
- Craniocerebral Injuries (including fractures): 19 (35.2%)
- Fractures of Long Bones: 8 (15%)
- Burns and Scalds: 7 (13%)
- Sharp Force Injuries: 5 (9.2%)
- Developmental Disorders: 15 (28%)
- Psychomotor Retardation: 7 (13%)
- Congenital Malformations: 1 (1.8%)
- Other: 4 (7.4%)

* Several victims were diagnosed with more than one finding.

There is no doubt that child abuse and neglect is manifested in Northwestern Greece with characteristics similar to those described in other areas of Greece and in foreign countries. Nevertheless, in our study there was a high prevalence of females among the victims, an argument that comes in controversy with the standing esteem medical examiners have in Greece. The relatively low number of reported cases (26 cases, less than 9 per year) is primarily a result of lack of the Greek National Health System's organization, but may be also attributed to the nature of the Greek family which precludes the maltreatment of children. Indisputably, there is wide denial of a child abuse problem among professionals in Greece, especially in the medical profession. Notwithstanding, Greece is just making its initial steps in identifying and facing the phenomenon of child abuse and neglect, and we are very optimistic that the situation will be ameliorated in the near future.

Forensic Medicine, Child Abuse, Northwestern Greece

G62 Aneurysms and Old Lace: A Ruptured Splenic Artery Mycotic Aneurysm Masquerading as Arsenic Poisoning

Sam Simmons, MD, and Gregory J. Davis, MD, University of Kentucky, Medical Center, MS 117, 800 Rose Street, Lexington, KY 40536-0298*

After attending this presentation, attendees will gain a better understanding of the clinical presentations of patients with abdominal mycotic aneurysm and understand the usual clinical findings associated with arsenic poisoning and its differential diagnosis.

This case study discussion will impact the forensic community and the general medical community by highlighting the clinical signs and symptoms of a patient with a fatal ruptured splenic artery mycotic aneurysm, expanding clinicians' and investigators' knowledge bases to heighten pre-mortem suspicion of such cases, thus decreasing the mortality of mycotic aneurysms and decreasing unfounded accusations of poisoning.

The term *mycotic aneurysm* is often used to describe infected aneurysms within the vascular system. These lesions are classically caused by bacterial endocarditis when multiple downstream vessels are showered with and

seeded by bacterial emboli. In recent times, these aneurysms are seldom attributed to fungal organisms, and may also be referred to as infected aneurysms.

A high level of clinical suspicion is often required, augmented by blood cultures, echocardiograms to identify endocardial vegetations, and additional imaging studies such as MRI or CT scans to identify specific emboli, aneurysms, or downstream infarcts. Treatment includes antibiotic therapy, and often surgical removal of the aneurysm. Symptoms vary, depending on the vessels or organs involved by the aneurysm. Mycotic aneurysms in the splenic or mesenteric arteries may present with nonspecific abdominal pain, or no pain at all. Due to the usual concurrent bacteremia, these patients often complain of headaches, and demonstrate confusion or drowsiness.

Similarly, victims of arsenic poisoning can have varying levels of clinical symptoms, depending on the amount of arsenic ingested. The baseline health status of the patient will also affect his or her reaction to the poison. Low levels of arsenic can cause headaches and confusion. Diarrhea, vomiting, and stomach pain are more common with higher levels of poison. Because arsenic is a frequent component of daily household cleaning products and some food items, a low level of arsenic may be detected in many individuals. Individuals who are poisoned, either through accidental exposure/ingestion or due to purposeful poisoning by another person usually exhibit higher levels of detectable arsenic. Arsenic levels are generally detected by chemical analysis of hair or urine. Hair samples may show falsely elevated levels of arsenic, due to environmental accumulation of arsenic on the hair. However, hair follicles retain arsenic for much longer periods than it can be detected in the urine. Nails and skin can also harbor arsenic for long periods of time.

An elderly gentleman lived in a nursing home and was the suspected victim of arsenic poisoning at the hands of one of his children with whom there had been a recent property dispute. The patient initially complained of nondescript but at times severe abdominal pain. Clinical specimens (hair samples) taken shortly before his death revealed no toxic levels of arsenic. Shortly thereafter, he died secondary to a ruptured splenic artery mycotic aneurysm.

At autopsy, the gentleman was found to have a hemoperitoneum and a large retroperitoneal hematoma in the area of the splenic artery, due to an apparent ruptured aneurysm. No endocardial vegetations were identified. There was evidence of pyelonephritis in the kidneys. Pre-mortem arsenic levels were measured clinically via hair analysis, and were found to be within normal limits.

Further discussion will outline the incidence and various clinical presentations of mycotic aneurysms, methods by which these aneurysms have been detected in other cases, and ensuing successful clinical interventions. For the purposes of comparison, the typical findings of arsenic poisoning and their overlap with this case will be discussed.

Aneurysm, Mycotic, Arsenic

G63 Lymphocytic Hypophysitis Associated With Sudden Unexpected Death in a Young Woman

Rudy J. Castellani, MD, and Luis F. Gonzalez-Cuyar, MD, University of Maryland, Baltimore, Department of Pathology, 22 South Greene Street, Baltimore, MD 21201; Fabio Tavora, MD, Johns Hopkins Hospital, 600 North Wolfe Street, Baltimore, MD 21205 ; Kyle Shaw, MD, University of Maryland, Baltimore, Department of Pathology, 22 South Greene Street, Baltimore, MD 21201; and Joyce L. deJong, DO, Sparrow Forensic Pathology, 1215 East Michigan Avenue, Lansing, MI 48909*

The goals of this presentation are to recognize clinical setting and pathological changes in lymphocytic hypophysitis, and to recognize importance of sampling the pituitary for histopathology in young women with sudden unexpected death.

Lymphocytic hypophysitis causes endocrine dysfunction that could

potentially lead to sudden unexpected death. Moreover, the definitive diagnosis requires histopathological examination of the pituitary gland. Given the inconsistent practice of pituitary sampling, this presentation will impact the forensic science community by presenting how lymphocytic hypophysitis may be an underrecognized cause of sudden death.

Lymphocytic hypophysitis is an unusual inflammatory condition of the pituitary gland, classically seen in females during the peripartum periods. The clinical presentation is varied and depends on hormonal deficiencies and pathophysiological effects on the target organs. While involvement of the neurohypophysis and secondary diabetes insipidus are rare, progression to multiple organ endocrinopathies is common. Pathologically the condition is characterized by lymphocytic infiltration of the hypophysis with occasional involvement of the thyroid and adrenal glands. In this report, we present the case of a 23-year-old woman diagnosed at autopsy with lymphocytic hypophysitis, with concomitant infiltrates in the thyroid gland and adrenal medulla, who died suddenly and unexpectedly, with no other apparent cause of death. While the precise mechanism of death is unclear, this case raises the possibility of endocrine dysfunction as a contributing factor to sudden death and emphasizes the need for greater awareness of the entity and routinely sampling the pituitary gland in cases of sudden unexpected death.

Lymphocytic Hypophysitis, Pituitary, Sudden Death

G64 Medico-Legal Aspects of Posttraumatic Gastroduodenal Ulcers

Slobodan Savic, MD, PhD, School of Medicine, University of Belgrade, Institute of Forensic Medicine, Deligradska 31a, Belgrade, YT 11000, SERBIA AND MONTENEGRO; Radmila Stevanovic, MD, MSc, Institute of Pathology, School of Medicine, University of Belgrade, 8 Dr Subotica Street, Belgrade, 11000, SERBIA AND MONTENEGRO; Djordje Alempijevic, MD, PhD, Institute of Forensic Medicine, 31a Deligradska Street, Belgrade, Serbia 11000, SERBIA AND MONTENEGRO; and Stojan Petkovic, MD, MSc, Clinical Center of Vojvodina, Institute of Forensic Medicine, 5 Hajduk Veljkova Street, Novi Sad, 21000, SERBIA AND MONTENEGRO*

On the basis of presented data attendees will be well acquainted with the important medicolegal and clinical characteristics of posttraumatic gastroduodenal ulcers that can be very serious and even fatal complications of various types of injuries.

The presentation will impact the forensic community by the fact that in cases with development of posttraumatic stress ulcers medicolegal expertise of injuries may be very complicated, especially if fatal complications of stress ulcers occur (hemorrhage, perforation), since in such cases the causative relationship between the primary injuries and fatal outcome should be explained. On the other hand, the important influence on humanity may have data that indicate the most risky injuries concerning development of stress ulcers, as well as the importance of their adequate prevention during the treatment of injured individuals.

The posttraumatic gastroduodenal ulcers (PGDU), so called stress ulcers, represent very important, sometimes life threatening or even fatal complication of various types of injuries. Therefore, a broad autopsy study was performed in order to analyze frequency and other important forensic and clinical characteristics of PGDU.

The study was divided in a retrospective part (period 1996-2000, 5197 autopsies), and a prospective part (period 2004-2005, 2356 autopsies). In the retrospective part of the study 157 autopsy cases with posttraumatic gastroduodenal ulcers were observed (experimental group), and 730 cases without posttraumatic ulcers (control group). In the prospective part of the study 45 autopsy cases with posttraumatic ulcers were analyzed (experimental group), and 212 cases without posttraumatic ulcers (control group).

Data were obtained from autopsy protocols, anamnestic data from the deceased's family members and accessible medical records. Degree of the injury severity was presented by ISS value. Furthermore, in the prospective

part of the study histological examination of small vessels of the abdominal organs was performed in order to investigate influence of atherosclerosis on development of PGDU. The obtained results were analyzed by means of appropriate statistical methods.

In both retrospective and prospective part of the study, the percentage of occurrence of PGDU was approximately 17% among all cases with potentially risky injuries. Posttraumatic ulcers are more common in males (around 77% of all individuals with stress ulcers), as well as in older age (over 50 years). The outliving period ranged between 24 hours and 25 days, but it was often no longer than 12 days (76%). From the preventive point of view, it is important to point out that 16.5% out of all PGDU in the retrospective part, and 15.5% in the prospective part of the study, was found at autopsy in the injured individuals who outlived trauma less than 48 hours.

The manner of trauma was mostly accidental with the vast majority of traffic accidents (66%), and with the highest absolute number of pedestrians (66). The main causes of death in the experimental group were as following: damage to the vital brain centers (64%), chest injuries (13%), spinal cord injuries (6%), burns (6%) and complications of injuries. The most of injured persons with posttraumatic ulcers sustained multiple injuries, that is polytrauma. Isolated craniocerebral injury was found in 25% cases with posttraumatic ulcers. In majority of cases with mechanical injuries, the calculated ISS value was ≥ 16 .

The most risky injuries for development of PGDU appeared to be isolated spinal cord injuries. Namely, among all cases with isolated spinal cord injuries, PGDU were diagnosed in 50% in the retrospective part, and in 25% in the prospective part of this study. The other types of injuries with high risk for development of PGDU were burns and scalds, isolated mechanical craniocerebral trauma, and mechanical polytrauma. This investigation shows that small vessels changes of the stomach and other abdominal organs are not very important factor in pathogenesis of posttraumatic ulcers, while the most important suppose to be functional disturbances of microcirculation caused by the primary injuries.

The stomach was the most frequent localization of PGDU, mostly with numerous lesions (so called erosive gastritis). Duodenum was the most frequent site of solitary ulcers, as well as exacerbated chronic peptic ulcers.

Complications of PGDU were found at autopsy in 40% of all cases with stress ulcers, mostly in form of hemorrhage, and rarely as perforation, and penetration. In 20% out of all 157 cases with PGDU in the retrospective part of the study, the postmortem diagnosed complications of PGDU were proclaimed to be a cause of violent death in the autopsy protocols (mostly mutually with primary injuries).

In the medicolegal expertise of cases with PGDU, three main problems usually appear: (1) estimation of severity of primary injuries, (2) establishing of causative relationship between the primary injuries and lethal outcome in cases with fatal complications of PGDU (mostly hemorrhage with resultant exsanguination), and (3) possible accusation of treating physicians for medical negligence.

Medico-Legal Aspects, Stress Ulcer, Trauma

G65 Death Caused by Cardioinhibitory Reflex: Myth or Reality?

Bettina Schrag, MD*, Béat Horisberger, MD, and Patrice Margin, MD, PhD, University Lausanne, Institute of Legal Medicine, Rue du Bugnon 21, Lausanne, SWITZERLAND

The goal of this presentation is to inform the medicolegal community about the different practices in using the cardioinhibitory reflex.

This presentation will impact the forensic science community by informing the medicolegal community about the mainstream opinion.

It has been known for hundreds years that pressure applied to the carotid sinus region may result in unconsciousness and convulsions. Hering and Heymans demonstrated that stimulation of the carotid sinus region results in a number of reflexes, with effects on the cardiac rhythm, vascular tonus, and respiratory function. Ever since, a number of reports dealing with cases of

death after mechanical pressure (such as strangulation, short-termed neck trauma and/or other traumatic injuries) against the carotid sinus region were published in the literature. The autopsy signs were the lack of local vital signs (such as absence of congestion, cyanosis, petechiae), indicating a very short agony possibly due a reflex mechanism.

In recent times, there has been an observed increase in numbers of clinical forensic cases in which the victim have suffered neck compression. Some victims show suggestive signs (e.g., petechiae, bruises). Other victims do not show any objective signs but anamnestic subjective symptoms are consistent with neck compression. The role of the forensic expert is to evaluate if there was life endangerment subsequent to compression based on objective and subjective findings.

The question whether ‘violence against the neck may cause life endangerment by cardio-inhibitory reflex’ is often the subject of discussion in medicolegal practice. The answer to this question may have important consequences in penal jurisprudence, particularly in cases in clinical forensic medicine.

In order to evaluate this question we mailed six questions in the framework of a qualitative and quantitative study to the members of different organisations of legal medicine: IALM, AAFS (International listing), NAME, French Society of Legal Medicine, German Society of Legal Medicine, and the Swiss Society of Legal Medicine.

The survey was conducted by E-Questionnaire based on the opinion, experience, and collaboration of several experts from about thirty countries.

The two principle questions were: (1) can cardioinhibitory reflex subsequent to neck injury cause death (forensic pathology)? And (2) can cardioinhibitory reflex subsequent to neck injury cause life endangerment (clinical forensic medicine)?

The questions required the participants to specify how often they made this kind of diagnosis and on which criteria they based their conclusions. Criteria for forensic pathology included the following: provided information, postmortem examination (macroscopic), histological examination, complementary investigations (such as medical imaging), or by elimination.

Criteria for clinical forensic medicine included the following: provided information, subjective findings (such as spots before the eyes, loss of consciousness), objective findings on the victim, complementary investigations (such as medical imaging), or by elimination. Other variables concerning the forensic experts were the following: active - emeritus, years of experience in forensic pathology and/or clinical forensic medicine, principal discipline of activity: forensic pathology, clinical forensic medicine, genetics, and toxicology.

The preliminary analysis indicates that over two-thirds of the participants believe that neck injury can induce a cardioinhibitory reflex and therefore life endangerment is possible. About a third of the experts use the cardioinhibitory reflex in their medicolegal opinions to confirm life endangerment in clinical forensic medicine or as a cause of death. They base their diagnosis on different criteria.

Cardioinhibitory Reflex, Neck Compression, Life Endangerment

G66 Ehlers-Danlos Syndrome Type IV (Vascular): An Atypical Presentation and Unexpected Diagnosis in a Medical Examiner Setting

James L. Caruso, MD*, Armed Forces Medical Examiner System, U.S. Naval Hospital, Okinawa, Japan, PSC 482 Box 2560, FPO, AP 96362

After attending this presentation, attendees will have a basic knowledge of the pathophysiology of the Ehlers-Danlos Syndrome, particularly the most severe form, Ehlers-Danlos Syndrome Type IV. They will also learn some of the basics of the genetic testing performed and be made aware of resources available should this diagnosis be suspected.

Because Ehlers-Danlos Syndrome can result in premature death, which

* Presenting Author

may be related to trauma or even mistakenly thought to be due to trauma, this presentation will impact the forensic science community by demonstrating how it is important for medical examiners and forensic investigators to be aware of this clinical entity and have a basic understanding of the pathophysiology.

Ehlers-Danlos Syndrome is a group of genetically inherited defects in collagen synthesis characterized by a wide array of clinical manifestations and with diverse clinical presentations. Because Ehlers-Danlos Syndrome can result in premature death, which may be related to trauma or even mistakenly thought to be due to trauma, it is important for medical examiners and forensic investigators to be aware of this clinical entity and have a basic understanding of the pathophysiology. This presentation will accomplish those goals using a recent case as an example.

There are six recognized major types of Ehlers-Danlos Syndrome, all of which vary somewhat in biosynthetic defect, mode of inheritance, and clinical presentation. The common feature among the subtypes is decreased tissue tensile strength, particularly tissues rich in collagen. Ehlers-Danlos Syndrome type IV is the most severe form because the defect involves type III collagen and may result in the rupture of large blood vessels or organs. Complications include arterial and bowel rupture and, in pregnancy, rupture of the uterus at delivery.

A recent case at the Office of the Armed Forces Medical Examiner-Pacific Region demonstrated the importance of considering diseases like Ehlers-Danlos Syndrome in the differential diagnosis. An adolescent female developed right flank pain and was treated presumptively for a urinary tract infection. After a week of both outpatient and inpatient management her condition did not improve. The patient collapsed while getting out of a vehicle and sustained a large scalp laceration. She subsequently went into cardiac arrest in the Emergency Department and died in the operating room of the local medical treatment facility.

During the autopsy the medical examiner was struck by the friability of the patient's connective tissue, particularly the mesentery. Multiple vascular defects and complete avulsion of one kidney with partial avulsion of the vascular pedicle of the other kidney were noted. A connective tissue abnormality, such as Ehlers-Danlos Syndrome, was suspected based on the gross anatomic findings. A microscopic examination demonstrated organizing hemorrhage outside of the adventitia of the right renal artery, indicating that the rupture had evolved over a period of time.

The medical examiner consulted with a research laboratory that specializes in the Ehlers-Danlos Syndromes. Frozen tissue specimens were provided and spleen was used to extract DNA for analysis. The researchers identified a mutation in one allele of the COL3A1 gene that is located on chromosome two. The effect on the gene product was deletion of 18 amino acids from the protein, accounting for the clinical presentation and autopsy findings.

In retrospect the family related that their daughter had always bruised easily and sustained unusually severe lacerations for seemingly minor trauma as a child. She also had some of the characteristic facial and skin features of Ehlers-Danlos Syndrome as well as the classic finding of joint laxity. Routine laboratory studies performed years earlier to evaluate the problem of easy bruising were all within normal limits.

An accurate diagnosis was extremely important to provide closure for a family that was attempting to understand how their daughter could be diagnosed with a urinary tract infection and die one week later. Establishing a diagnosis was critical for the clinicians who took care of this patient, all of whom were initially left wondering if there was anything they could have done to change the outcome. It was also essential to recommend genetic counseling for the parents and siblings of the deceased, particularly since Ehlers-Danlos Syndrome Type IV is typically inherited in an autosomal dominant mode.

Special acknowledgement to Peter Byers, MD, Ulrike Schwartz, MD, and Melanie Pipin, MS, in the Department of Pathology, University of Washington, Seattle, Washington, for performing the genetic testing and providing technical information and support.

G67 Mechanisms of Delayed Splenic Rupture: A New Hypothesis

Sarathchandra Kodikara, MBBS, MD, DLM, NIL, Department of Forensic Medicine, Faculty of Medici, Peradeniya, SRI LANKA; and Murugapillai Sivasubramanium, MBBS, MD, DLM, Teaching Hospital, Kegalle, Sri Lanka*

After attending this presentation, attendees will understand a new hypothesis which describes a potential mechanism of delayed splenic rupture.

This presentation will impact the forensic community by introducing a new mechanism of delayed splenic rupture. Also it impacts the medical and surgical communities as it guides to reduce the high mortality rate in delayed splenic rupture.

A 46-year-old man was assaulted with a club to the face and chest and sustained multiple contusions. On admission there were no signs of circulatory shock. The abdominal examination was unremarkable. During his stay in hospital he had light diets due to pain and loss of appetite. He was managed symptomatically and discharged five days after the incident.

Two hours after discharge he was admitted again with a complain of severe abdominal pain. He claimed that soon after his return to home, he ate two full plates of rice and curry, three mangos, and drank two glasses of water as he was so hungry and developed appetite for home made food. Immediately after the diet he experienced this abdominal pain.

On admission, he was pale with a pulse rate of 116 beats per minute and a blood pressure of 60/30 mmHg. There was a marked tenderness with rigidity and guarding on abdominal palpation. Bowel sounds were attenuated. Hemoglobin level had dropped to 7.2 g/ dl from a level of 10.5 g/dl within five hours. Two pints of blood were transfused. Although it was planned to do an ultrasound scan of abdomen the patient was pronounced dead thirteen hours after admission.

Autopsy revealed a generalized pallor. The abdomen was distended. A contusion of 8x3.5 cm was seen on left lower chest laterally. There were no rib fractures. A hemoperitoneum of 2300 ml was noted. The spleen was within the normal range. A hematoma of 2.5x3x1.5 cm was seen overlying a splenic laceration on the gastric area of the visceral surface. The laceration was 1.25 cm in length with a depth of 0.25 cm, involving splenic capsule and parenchyma. The body of the empty stomach was in contact with this hematoma. Histological examination confirmed the perisplenic haematoma of otherwise normal spleen.

The mechanism of this serious and possible life threatening complication is still not fully understood. There are a number of potential mechanisms for delayed splenic rupture.

Intrasplenic hematomas, pseudoaneurysms of intraparenchymal splenic artery branches, and asymptomatic splenic pseudocysts all of which develop following abdominal trauma and rupture, possibly days, months or years later are three mechanisms suggested in this context. Also bleeding from a splenic rupture could be tamponaded by surrounding organs and /or peri-splenic haematoma formed at the time of injury, delaying its rupture at a later date.

The visceral surface of the spleen consists of gastric, colic and renal surfaces. The gastric surface is directly in contact with the body of the stomach. Therefore a perisplenic hematoma which plugs the splenic laceration on the gastric surface temporarily, may easily be dislodged by the mechanical forces exerted by distending stomach, causing fatal intraperitoneal hemorrhage. Such risk is imminent during the early period of regeneration of splenic laceration where wound breaking strength is relatively low.

In this case, the laceration occurred at the time of assault was plugged temporarily by the hematoma. On day five, pressure exerted by full stomach after the heavy solid meal, dislodged the hematoma causing hemorrhage from the site of laceration.

The pressure exerted by full stomach after heavy solid meals may disturb perisplenic hematoma overlying a laceration on the gastric surface of the spleen causing delayed splenic rupture leading to sudden fatal intraperitoneal hemorrhage.

It is advisable to maintain a light liquid/ semisolid diet instead of a

heavy solid meal during the period of recovery of the patients who are having perisplenic haematomas due to lacerations on the gastric surface of the site of laceration.

Delayed Rupture, Spleen, Mechanisms

G68 Death of a Vampire?: Case of Exhumation and Mutilation of a Corpse in Rural Romania

William C. Rodriguez III, Ph.D. *, Office of the Armed Forces Medical Examiners Office, Armed Forces Institute of Pathology, 1413 Research Blvd. Building 102, Rockville, MD 20850

After attending this presentation, attendees will have a better understanding on how the mis-interpretation of decompositional artifacts have contributed to beliefs, superstitions and the myth about the existence of vampires. Attendees will be shown a video clip of the actual forensic grave side examination of a reported "vampire" who was put to his final death by family members.

Even before the famous classic tale of horror "Dracula", written by Bram Stoker in 1897, the belief of vampires can be traced back as far as the fifteenth century to various parts of Europe. Of all the various countries and regions steeped in the belief of vampires and the undead, none run so deep as in the country of Romania. The belief in vampires is rooted in many cultural beliefs regarding the after life such as the acknowledgement of Satan and his monstrous minions. Another important aspect of the belief in vampires is based on the mis-understanding of the changes that occur to the body as the result of the decompositional process. Misunderstood changes include the postmortem purging of bloody fluids from mouth and nose which were thought to be evidence of recent feeding, and the appearance that the hair and nails continue to grow after death. Other examples of mis-conception include the presence of guttural sounds from the deceased as the result of expelled post mortem gases, and the postmortem pink and reddish discolorization of the skin which gave the appearance that a corpse had returned to life.

A prime example of the deep seated cultural belief in vampires in parts of rural Romania is demonstrated in a recent case which involves the exhumation, and mutilation of a corpse. In December of 2003 a seventy-six year old retired school teacher in the rural Romanian village of Marotinul de Sus died. At his death, the elderly male was placed in a simple wooden coffin, which was then buried in a shallow grave located below a make shift stone vault. Later in time various relatives of the deceased begin to fall ill and claimed to have had dreams in which the deceased had risen from the dead as a vampire to drink their blood. As a result of the unexplained illnesses, and terrifying dreams, several family members made the decision to follow the ancient cultural tradition, and destroy their now believed undead family member.

In July of 2005 six family members traveled to the cemetery under darkness, and exhumed the body of their deceased relative. Waiting to the stroke of midnight a member of the group drove a pitchfork into the chest of the corpse, and then opened the chest cavity with a large knife, and removed the heart. The corpse was then repeatedly stabbed in various locations with wooden stakes, and garlic sprinkled over the body. The group departed the cemetery with the heart impaled on the pitchfork, and proceeded to a near by crossroads. At the crossroads, the family members burned the heart, then mixed the ashes with peppermint schnapps, and drank the concoction. As a result of their actions, they no longer felt ill, and their terrible dreams of their vampire relative were no repeated.

Later in time, word of this macabre ritualistic act made its way to the daughter of the deceased, and local authorities. A second exhumation of the corpse was ordered by authorities investigating the horrific act, in which a grave side forensic examination was conducted by a forensic pathology team. The grave side examination by the forensic pathology team corroborated the story of the mutilation, including the removal of the heart. A video clip of the actual grave side examination will be presented.

As a result of the seemingly indignant and horrid act, the six family

members who had participated in the mutilation of the corpse were arrested and sentenced to six months in jail. The arrest of the family members, greatly angered local villagers who indicated that this was a practice that been conducted by locals for many centuries. Many villagers praised the action carried out by the six, noting that it was a great thing to take out his heart as the people were in danger. Other villagers confessed to have taken the hearts from the dead many times before, and to have drunk a solution containing the ashes of the heart. In their own defense, the leader of the six family members pleaded innocent, having done nothing wrong. The leader informed the police that when they exhumed the corpse he had blood surrounding his mouth, and that he moaned when they stabbed him with the pitch fork. Pleading with authorities the head family member stated that if he hadn't conducted the ritual, that his son, wife, and daughter-in-law would have died.

Decomposition, Postmortem Mutilation, Ritual

G69 Sickle Cell Disease and Sudden Death

Michelle A. Jorden, MD*, Jennifer A. McReynolds, PhD, and Adrienne E. Segovia, MD, Cook County Medical Examiner, 2121 West Harrison Street, Chicago, IL 60612

The goal of this presentation is to educate and alert the forensic community to the common causes of death in sickle cell patients.

This presentation will impact the forensic community by demonstrating the importance of recognizing pulmonary complications at autopsy that are frequently seen in the sickle cell population and which are responsible for causing sudden death. Lastly, the possibility of sickle cell disease should be entertained in any young African-American person who dies suddenly and unexpectedly without a known history of sickle cell disease.

Sickle cell disease afflicts one of every 650 African Americans and an estimated 8% of African Americans are heterozygous for the sickle cell gene. Sickle cell anemia is attributed to profound morbidity as well as mortality to those afflicted with the disease. In the clinical setting, sickle cell anemia can present as recurrent infection especially in the younger population and as sickle cell pain crisis, stroke, and sudden death in the adult population. In 1949, the discovery that sickle hemoglobin exhibited an abnormal electrophoretic mobility has pioneered our current understanding that sickle cell disease is a molecular disease/diagnosis. With the advent of immunizations and vaccinations, antibiotic therapy and the implementation of newborn screening programs, the mortality rate of individuals with sickle cell disease has declined.

Although morbidity and mortality from sickle cell disease has declined in recent years, a subset of patients die from sudden and unexpected deaths. The most common causes of sudden death in individuals succumbing to sickle cell disease are acute and chronic pulmonary complications that encompass pulmonary edema, pulmonary thromboembolism/thrombosis, and pulmonary hypertension. Although the literature comments on the presence of pulmonary thromboembolism as a frequent autopsy finding, the literature is unclear as to whether these patients also exhibited deep venous thrombosis. Therefore, sickle cell patients may not share the same risk factors for development of pulmonary thromboembolism as the rest of the population (i.e., recent surgery, obesity, and immobilization). Instead, sickle cell patients may undergo pulmonary thrombosis as a consequence of in-situ sickling of red blood cells within blood vessels during hypoxic episodes. For forensic pathologists who perform autopsies on all cases of sudden death, the history of sickle cell disease may be absent or may never have been diagnosed, especially in athletic adolescents. Therefore, in those individuals who are of African American race, younger age, and presenting with pulmonary thromboembolism/thrombosis in the absence of known associated risk factors, the importance of a thorough autopsy examination including a detailed gross and microscopic examination of the heart and lungs, and dissection of the lower extremity veins, in conjunction with postmortem hemoglobin solubility/electrophoresis tests are underscored.

During the past year at the Cook County Medical Examiner's Office in Chicago, IL the authors have encountered two (2) cases of young African

* Presenting Author

American individuals (one female at 31 years old and one male at 38 years old) who carried a diagnosis of sickle cell disease and who were found unresponsive with no known antecedent symptoms. After a complete autopsy, the cause of death in both cases was pulmonary thromboembolism/thrombosis in the absence of deep venous thrombosis. In both cases, the microscopic sections displayed acute and organizing pulmonary thrombi. In addition, both cases displayed severe pulmonary hypertensive changes characterized by thickened pulmonary arterioles and plexiform arteriopathy.

Given these findings, the decision was made to pull all cases of young African American individuals who died suddenly from pulmonary thromboembolism/thrombosis without a known history of sickle cell disease over a two year period. Three (3) additional cases were identified and consisted of two females and one male (ages 20-40s). Hemoglobin solubility tests were performed on the postmortem blood of these individuals. The hemoglobin solubility tests were negative in all three cases. Although the tests were negative, we eliminated the possibility of sickle cell disease as a contributory factor and upon further review of these cases, all these cases demonstrated deep venous thrombosis, and an identifiable risk factor was observed in one case.

Sickle cell disease is a common disease that afflicts the African American population. For forensic pathologists, the findings of pulmonary thrombosis in the absence of deep venous thrombosis and associated risk factors in the young African American population should alert the forensic pathologist to the possibility of sickle cell disease and further laboratory testing of postmortem blood for hemoglobin solubility.

Sickle Cell Disease, Sudden Death, Pulmonary Complications

G70 The Biochemical Alteration of Soil by Decomposition Products

Shari L. Forbes, PhD, University of Ontario Institute of Technology, 2000 Simcoe Street North, Oshawa, Ontario, L1H 7K4, CANADA; David O. Carter, PhD, University of Nebraska, Department of Entomology, 202 Plant Industry Building, Lincoln, NE 68583-0816; and Laura A. Benninger, BSc, University of Ontario Institute of Technology, 2000 Simcoe Street North, Oshawa, Ontario, L1H 7K4, CANADA*

After attending this presentation, attendees will understand the importance of soil analysis in cases involving decomposed remains, and the correlation of soil composition changes with the decomposition period.

This presentation will impact the forensic community by serving as a potential tool for estimating the postmortem period and may have implications for both forensic and human rights investigations.

Decomposition chemistry refers to the chemical degradation processes which occur in soft tissue as decomposition proceeds. These processes involve the breakdown of the body's main constituents including proteins, carbohydrates and lipids. Lipids represent an important biomarker of decomposition as they are not easily degraded and can be retained in the soil environment for extended periods. Currently, there are few techniques which can provide an accurate estimation of the postmortem period. When a body decomposes in a soil environment the currently available techniques become even less accurate.

The aim of this study was to investigate the relationship between the release of decomposition fluids into a soil environment and their potential correlation with the decomposition period. The study was conducted in the southern region of Ontario, Canada during the summer months of July and August. Pig carcasses were used as acceptable models for human decomposition and were allowed to decompose on the surface of the soil until skeletonization occurred after approximately 100 days. Soil samples were collected from the region directly beneath the carcass at varying decomposition intervals. The total microbial biomass was determined by measuring the extractable lipid phosphate and the fatty acid content. Samples were analyzed by chromatography and spectroscopy techniques. The soils were characterized using particle size analysis and variations in total carbon, nitrogen, phosphorous, pH and moisture content were also investigated.

The study identified a significant increase in the amount of total nitrogen and soil extractable phosphorous released into the soil. However, the total available carbon did not increase significantly with time. Lipid-phosphate and fatty acid concentrations also increased with time confirming that there was a flux in the microbial biomass present in the soil. The pilot study was able to highlight the forensic potential of these techniques for estimating the postmortem period and promoted ongoing studies in this area. The results have the potential to be used in a forensic investigation involving remains which have decomposed for an extended period in a soil environment.

Decomposition, Soil, Postmortem Period

G71 A Cadaver Encased Within Concrete: A Case Report

Gilles Tournel, MD, PhD, Anne Becart-Robert, DDS, Benoît Bourel, PhD, Axelle Balgairies, Cédric Houssaye, Valéry Hedouin, PhD, and Didier Gosset, MD, PhD, Institut de Médecine Légale de Lille, 1, place de Verdun, Faculté de Médecine, Lille, 59045, FRANCE*

The goal of this presentation is to present an amazing case report on a cadaver encased within concrete.

This presentation will impact the forensic science community by showing the particularities of the crime scene and the autopsy of this deceased person.

Encasings within concrete are relatively rare forms of hiding or disposing of a body. At first, these cases are often treated as "matters involving a missing person". In this case report, the circumstances and findings are described in which a body was encased within concrete. It is of importance to note that the body may be preserved quite well in concrete, which allows not only the identification of the victim but also the determination of the cause of death, even after a prolonged postmortem interval.

A male cadaver aged 65 is discovered in reinforced concrete in a cellar. Circumstances of his death, circumstances of his burial, identification, autopsy findings, and the perpetrator's behavior are described. In March 2003, Mr P's brother goes to the Police Department and says he hasn't seen his brother for five years. The police investigations lead to his wife. She says her husband was very violent physically with herself and their son. Five years ago, during summer, her husband fell on the floor in their house. Because she was afraid of his reactions, she went away from the house, came back three weeks later and discovered her husband dead, still at the same place. She decided alone to remove the body. With the help of her son, she put her husband in her car, enveloped in several layers of tissues, and deposited him in a cellar of another house. She said she built a wall alone and placed the body under 70 centimeters of reinforced concrete.

Crime scene and autopsy findings are described. The body was found dressed like on the day of his death. His wife had put a plastic bag on his head and pins on his nose. She said it was to avoid a putrid flow. She wrapped the body into several blankets. The body was putrefied (three weeks of putrefaction) and conserved in the same state. Identification was easy, rapid, and completed odontologically. No traumatic lesions were discovered during the autopsy. Several hypotheses were proposed for the manner of the death: toxic, natural or asphyxia by plastic bag. Anthropological analysis is detailed to determine the origin of the lesions. On the body, in the blankets, *Calliphora vicinae* larvae and *Calliphora vomitoria* pupae were discovered. An entomologist expert tried to precisely determine the postmortem delay since it was crucial for the investigations to conclude the delay between the death and the encasing in the cellar. These findings are compared to police investigations. These findings are compared to literature on bodies disposed in reinforced concrete, on the behavior of this woman. The body conservation is detailed according to different methods of burial. Moreover, after denunciation, selenium intoxication was suspected. The investigation and findings on selenium are described.

This case is amazing, and has required a multidisciplinary approach to be elucidated. The authors underline, one more time, the importance of the description of the death scene associated with the autopsy findings to

understand and to conclude on the cause and the manner of death.

Anthropology, Concrete, Entomology

G72 A Degloving Experiment to Suggest Postmortem Interval: Give the Anthropologist Some Hands From Freshwater

Turhon A. Murad, PhD, California State University, Department of Anthropology, 400 West First Street, Chico, CA 95929-0400*

Following the presentation, the attendee will know the results of a unique experiment to determine the minimum length of time necessary for a pair of human hands to be degloved after being submerged in freshwater at 21°C.

This presentation will impact the forensic science community by using the degloving of human hands to suggest the postmortem interval.

A unique experiment was performed during spring 2007 in response to an unusual request from a defense attorney. In late March 2007 an attorney inquired if human hands could be "degloved" after being submerged in freshwater for a period of 36 hours at a water temperature of approximately 70°F. Of particular interest was the minimum length of time necessary for human hands to be "degloved" under the specified conditions. "Degloving," or the removal of the entire epidermal skin surface of human hands has been well documented as resulting from both: (1) some types of accident, and (2) natural phenomena occurring after hands have been submerged for an extended period.

In this particular instance specific aqueous parameters needed to be addressed, such as the type of water (freshwater over that of a marine environment), complete submergence of the hands, and a water temperature of approximately 21°C (70°F). Following a preliminary literature review it was determined that most information on degloving was anecdotal (Aggrawa 2005, Anderson and Hobischak 2004, Boyle, Galloway and Mason 1997, Kovarik, Stewart and Cockerell 2005, Rodriguez, 1997). Therefore, a unique experiment was proposed, and ultimately agreed upon.

Over the next few weeks the University of California Davis Donated Body Program (UCD-DBP) in central California was contacted. Specifically, arrangements were made to acquire two freshly harvested human forearms with the intent of soaking them in freshwater, and to the best degree possible, emulating the conditions of a canal described by the attorney and documented by the relevant county's Water Quality Control Board. It seems the canal, which is used for agricultural irrigation and thus well monitored, passes through a county in which a decedent had previously been recovered. At issue was the postmortem interval and thereby a possible alibi for the attorney's client. Water temperature and speed of water flow for the central California canal were recorded throughout the period relevant to the investigation.

Thus, to determine the length of time necessary for degloving to occur a controlled degloving experiment was initiated. By May 18, 2007 arrangements had been made to pick-up two forearms on that date from the UCD-DBP. A left (UCD-07-048-UL-FL) and a right (UCD-07-048-UL-FR) forearm was acquired from an 89 year-old female who had died from cardiopulmonary arrest shortly before becoming a part of the experiment. Both forearms had been removed from the decedent during the morning of their acquisition. They had been refrigerated until approximately 1400 hours when they were then transported to the CSU, Chico Human Identification Laboratory for the experiment. By 1800 hours on May 18, both the forearms had been prepared for being submerged in a stainless steel water bath maintained at a near constant water temperature of 21°C (70° F) for the next ten days. Preparation included: initial photographs of both the arms and hands, sealing the disarticulated proximal ends with rubber seals and additionally covered with waxed polyseal, preparing the stainless water bath with a thermometer, and filling the bath with un-chlorinated, room temperature, fresh water. The proximal ends of both arms were sealed to prevent water from entering beneath the skin from the disarticulated ends. Additionally, both

arms were submerged to slightly below the seals for the same reason.

The arms were then monitored every six (6) to twelve (12) hours for changes in color, odor, and general appearance, including the degree of skin-slippage. Additionally, the water temperature was carefully monitored on each occasion the forearms and hands were checked. The observational process was maintained throughout the first 42 hours of the experiment, after which the arms and hands were checked only twice a day, in the early morning and early evening (i.e., at 600 and 1800 hrs.).

During the entire experimental period the highest and lowest water bath temperature achieved was 24°C and 18°C, (75.2°F and 64.4°F, respectively) while the average water temperature was 20.5°C (68.9°F). Periodically water was removed from the bath and replaced with fresh, unchlorinated water of an appropriate temperature to more accurately reflect the conditions described by the Water Quality Control Board for the canal's condition. Thus, every day from three to four liters, or approximately three to four quarts, of water were removed and replaced.

Both hands acquired the classic "washer women's appearance" during the first six hours and continued to worsen over the first 36 hour period. By the end of the second day (i.e., 42 to 48 hours) deep wrinkles appeared and very minor skin-slippage began to appear. Photos were taken, and neither hand was capable of being "degloved" at the end of 36 hours, nor at the end of 48 hours. By day four both hands had begun to become discolored (dark pink), as gases and odor became apparent. During the fifth day (96-120 hrs.) marbling of black and blue colors was acquired, odor increased, and marked bloat of gases was found at the proximal ends beneath the rubber seals (i.e., the ends where the disarticulation had occurred). During day six (by 141 hrs.) both hands had become increasing marbled black and blue as skin-slippage also increased. During the seventh day (between 160 and 168 hrs.) an attempt to deglove the right hand failed but resulted in tearing the skin on the dorsal surface. The left hand had developed a large blister at the anterior wrist where putrid fluid had accumulated. Gases continued to be produced at the proximal ends of both arms but to a greater extent on the right than the left. Simply, the skin on the left hand was generally more firmly attached than that of the right. Photos were taken of the tear and the blister as well as the general deteriorating condition of both hands. On day eight (182 to 190 hrs.) the degree of skin-slippage increased on the dorsal and anterior surfaces but the skin of all the fingers remained moderately attached. There was a marked difference between slippage on the right versus the left hand, with the right hand proceeding more rapidly. During day nine (at 204 hrs. into the experiment) the right hand was "degloved," although the skin of some of the fingers and all the fingernails remained attached. The left hand was still not ready to be "degloved" on day ten. However, at 256 hours into the experiment, or after 10.5 days, the left hand was "degloved," although once again, the skin of some of the fingers and all the fingernails remained attached.

It was concluded that freshly acquired fleshed human hands submerged in freshwater at a temperature of 20.5°C could be "degloved" after a minimum period of nearly 200 hours. However, additionally, it was concluded that because the skin of the fingers as well as the nails never became completely detach during the experiment (as they had in the questioned case) it would very likely take much longer for such degloving to occur. Since all chemical and decomposition processes are temperature dependant the temperature of the water can be expected to play a critical role in the length of time necessary degloving to occur. Also of note, because the experimental hands were acquired from an 89-year-old decedent (i.e., one much older than the decedent prompting the experiment) a decedent's age or health status needs be considered in affecting the experimental result – the attachment and elasticity of connective tissue between the epidermis and dermas in younger versus older persons could be expected to play a role. If that were the case the length of time for degloving to occur in a young healthy male should be expected well after the 36 hour period in question.

Degloving, Postmortem Interval, Freshwater Death

G73 Parasitic Wasps: Succession, Development, and Forensic Importance as PMI Indicators

Sasha C. Voss, BSc*, and Ian Dadour, PhD, Centre for Forensic Science, University of Western Australia, 35 Stirling Highway, Nedlands, Western Australia 6009, AUSTRALIA

After attending this presentation, attendees will understand the potential forensic value of parasitic wasps associated with decomposing remains in determining time since death. Aspects of parasitoid biology and behavior in regard to carcass attendance and insect development will also be discussed for use in the estimation of a postmortem interval (PMI).

This presentation will impact the forensic science community by. These results provide biological and developmental data for forensically relevant species of parasitic wasp for use in determining time since death in forensic investigations. Data gathered will improve the accuracy of PMI estimations in cases where decomposition has advanced beyond the life cycle of flies, the traditional indicators of time since death. Discussion of the relevance of the results presented here to forensic cases will establish the importance of parasitic wasps as forensic indicators of time since death and our findings provide reference data required for accurate PMI estimation.

Knowledge of the predictable pattern of insect succession onto a carcass and the relationship between temperature and larval development has proved invaluable in estimating PMI. To date forensic entomologists have focused on the use of synanthropic flies, particularly Calliphorids as forensic indicators of time since death. However, where time since death extends beyond the larval development time of these commonly used species, only a minimum PMI can be estimated. For instance, where only empty fly pupae cases are recovered from a crime scene the time lapse between the emergence of adult flies from the pupae cases and the discovery of the body is unknown. In such cases, the presence of parasitic wasp larvae within insect hosts such as fly pupae can be used to estimate an extended PMI.

The order Hymenoptera contains an extremely diverse range of insects, including numerous parasitic wasps or more accurately “parasitoids.” The term “parasitoid” encompasses those arthropod species whose larvae feed exclusively on the body of an arthropod host, eventually killing it. Parasitoids use a broad spectrum of hosts including necrophagous insects found in association with decomposing remains (Archer & Elgar, 2003).

Use of parasitoids as tools in criminal investigations requires; baseline data on the temperature-dependant development of both the host and parasitoid species; knowledge of the development stage at which the female wasp parasitizes the host; and an understanding of the factors involved in host location within a decomposition habitat. Currently, there is a paucity of relevant reference data and the research that is available is either geographically specific or is focused on parasitoid species used as biological control agents of filth flies rather than in a forensic context.

In this study, the species and biology of parasitic wasps associated with decomposing remains in Western Australia and their relevant host species were investigated. A monthly survey of relevant insect fauna frequenting decomposing remains was conducted. Domestic guinea pig carcasses (*Cavia porcellus*) were used as an attractant. The stage of decomposition at which the observed parasitoid species attended carcasses, species seasonality and rates of parasitization in the field were identified. Predominant species identified included *Tachinaephagus zealandicus* Ashmead (Hymenoptera, Encyrtidae) and *Nasonia vitripennis* Walker (Hymenoptera, Pteromalidae). Base-line reference data on the temperature-dependant development of both of these parasitoid species were also established under laboratory conditions.

These results provide biological and developmental data for forensically relevant species of parasitic wasp for use in determining time since death in forensic investigations. Data gathered will improve the accuracy of PMI estimations in cases where decomposition has advanced beyond the life cycle of flies, the traditional indicators of time since death. Discussion of the relevance of the results presented here to forensic cases will establish the importance of parasitic wasps as forensic indicators of time since death and our findings provide reference data required for accurate PMI estimation.

Entomology, Parasitic Wasp, Postmortem Interval

G74 Difficulties in Determining Sex From the Skull: Considering Conflicting Lines of Evidence

Krista E. Latham, MS, MA*, Temple University, Anthropology Department, Philadelphia, PA 19122; Carlos J. Zambrano, MS, C.A. Pound Human ID Lab, 5231 North West 56th Court, Gainesville, FL 32653; and Laurel E. Freas, MA, 3425 South West 2nd Avenue, #246, Gainesville, FL 32607

The goal of this presentation is to demonstrate that forensic scientists should understand and employ all available scientific techniques when analyzing human remains, as well as to emphasize that individuals performing forensic osteological analysis must possess a firm understanding both of modern human variation and of the theoretical subtleties of the methods employed to study such variation.

This presentation will impact the forensic community by emphasizing the importance of: (1) a firm foundation in patterns of modern human biological variation, (2) an equally firm understanding of the theoretical and practical strengths and limitations of the methods employed in sex determination, (3) an education in statistics in order to realize that misclassification is not random and can usually be traced to some morphological idiosyncrasy of the remains in question, and (4) a demonstration of the value of using all available scientific methods to determine biological sex from the human skeleton.

A common misconception held by non-anthropologists is that the determination of biological sex from human skeletal remains is relatively easy and/or straightforward because there is a 50% chance of just “guessing” the correct sex assignment. While it is true that forensic anthropologists are extremely accurate at sex determination, they are also aware of the potential sources of error within their assessments, as well as the potential error associated with the external interpretation of their analyses.

Determining sex from gross skeletal morphology can be accomplished via both non-metric and metric techniques. Non-metric techniques examine sexually-dimorphic patterns of discrete skeletal trait expression to distinguish between males and females. Metric techniques rely on the quantification of size and shape differences between males and females, as measured from several diagnostic skeletal elements. The determination of sex using metric methods is most frequently accomplished via the discriminant functions calculated by the FORDISC software (Ousley and Jantz, 1996). Both non-metric and metric approaches to sex determination rely heavily on the os coxa and cranium, which are the two most reliably-diagnostic skeletal elements. Though the os coxa is the preferred element for sex assessment, unfortunately this element is not always present in the remains available to forensic anthropologists for analysis. Indeed, many forensic anthropology cases consist solely of isolated skulls or crania. Not surprisingly, accurate sex determination becomes increasingly difficult in instances of heavily fragmented or largely incomplete skeletons.

Regardless of the techniques or skeletal elements used in the analysis, the forensic anthropologist’s ability to accurately assess the sex of unidentified skeletal remains may be stymied by individuals who are atypically skeletally robust or gracile, or by individuals who originate from populations which are outside the forensic anthropologist’s sphere of experience. The possibility of encountering such individuals therefore places several critical demands on the forensic anthropologist, including: 1) a firm foundation in patterns of modern human biological variation, and 2) an equally firm understanding of the theoretical and practical strengths and limitations of the methods employed in sex determination. Additionally, the forensic anthropologist should be well educated in statistics in order to realize that misclassification is not random, and can usually be traced to some morphological idiosyncrasy of the remains in question. Collectively, these considerations caution against the hasty interpretation of the results of anthropological analyses, as they may not always be as clear-cut as a cursory examination of the conclusions may suggest.

This presentation will impact the forensic community by demonstra-

ting the value of using all available scientific methods to determine biological sex from the human skeleton. Two cases will be presented in which the only skeletal element available for analysis was the skull. In the first example the non-metric analysis was suggestive of a female and was supported by FORDISC's sex-only function; however, when ancestry was considered, the specimen was classified as a male. In the second example, both the metric and non-metric analyses suggested female. However, the individual's ancestry was questionable and the skull may have represented a male from a population of small, gracile individuals. The atypicality of both specimens alerted the forensic anthropologist to possible interpretational issues which warranted further investigation. In order to supplement the osteological analysis, samples from each individual were sent for genetic sex determination. While it is understood that there are also errors associated with genetic sex determination, this reemphasizes the forensic anthropologist's need to understand modern human variation and the available scientific methods to study variation. Each case will be discussed with an emphasis on sex determination by both osteological and genetic means, as well as a critical assessment of the interpretational error associated with each.

Sex Determination, FORDISC, DNA

G75 Molecular Genetic Testing in 323 Cases of Fatal Pulmonary Thromboembolism in the City of New York Revealed Racial Stratification

Yingying Tang, MD, PhD, Erik T. Bieschke, MS, Stacey Sainte-Marie, MSFS, Jean Jeudy, Yoonhee A. Kim, Stephanie Pack, Barbara A. Sampson, and Mechthild Prinz, PhD, Office of Chief Medical Examiner, Department of Forensic Biology, 421 East 26th Street, New York, NY 10016*

The goal of this presentation is to investigate the frequency of these genetic risk factors in fatal PE and to understand the genotype and phenotype correlation.

This presentation will impact the forensic science community by presenting detailed characterization of the mutation spectrum in fatal PE is vital for providing accurate diagnosis of cause of death and efficient preventative treatment to the high-risk family members.

Fatal pulmonary thromboembolism (PE) is a common cause of death encountered in the forensic pathology setting and usually presents as a complication of deep venous thrombosis (DVT). The pathogenesis of venous thrombosis is multifactorial and requires interaction between both inherited and acquired risk factors. Heterozygous or homozygous Factor V Leiden (G1691A) or prothrombin (G20210A) mutations, and homozygous MTHFR (C677T) variant have been recognized as common independent genetic risk factors in DVT. In order to investigate the frequency of these genetic risk factors in fatal PE and to understand the genotype and phenotype correlation, we have validated a genetic testing method to detect the three common mutations.

Testing was conducted using multiplex PCR-SNaPshot technologies on postmortem tissue and blood samples. Between March 2005 and May 2007, we tested 323 fatal PE cases from the New York City Office of Chief Medical Examiner. The authors found that 48 of the 323 cases were positive for at least one mutation. The genetic testing results were categorized by the demographic data and acquired contributing factors. The overall frequency of three mutations in PE cases was found highest in Whites (34.15 %), followed by Hispanics (28%), very low in Blacks (3%), and zero in Asians. In contrast, the number of fatal PE instances in our study is highest in Blacks (54.8%), followed by Whites (25.4%), and Hispanics (15.5%), and very rare in Asians (1.5%). Blacks were also associated with a high percentage of idiopathic PE with unknown acquired contributing factors. This study suggests that there are racial disparities in genetic risks contributing to fatal PE. In addition, comparing the incidences of PE in different races to the racial composition in New York City residents (44.7% Whites, 26.6% Blacks, and

9.8% of Asians), Blacks showed the highest incidences of fatal PE. Further research focused on delineating the genetic risks in black populations is warranted. Detailed characterization of the mutation spectrum in fatal PE is vital for providing accurate diagnosis of cause of death and efficient preventative treatment to the high-risk family members.

Molecular Genetic Testing, Fatal Pulmonary Thromboembolism, Racial Stratification

G76 The Pathologist's Role in Preserving Implanted Pacemakers and Cardiac Defibrillators or How Not to Get Shocked!

Suzanne D. Parisian, MD, Medical Device Assistance, Inc., 7117 North 3rd Street, Phoenix, AZ 85020; and Bruce H. Barkalow, PhD*, and William E. Grant, MA, B.H. Barkalow, P.C., 490 Quarterline Road, Newaygo, MI 49337-9125*

After attending this presentation, attendees will understand the standardization of techniques for safe and effective explantation of implanted electric cardiac devices such as pacemakers, defibrillators, and leadwire systems.

This presentation will impact the forensic science community by demonstrating how careful adherence to recommended procedures by medical examiners will minimize damage to retrieved implanted cardiac devices (pacemaker, ICD, CRT-D and leads), and will facilitate postmortem device analysis and cause of death determination. In addition, appropriate pre-extraction planning of methods for removing implanted defibrillator leads will reduce risk of electrical shock for personnel.

Permanent implantable electrical cardiac devices such as Pacemakers, Implanted Cardiac Defibrillators (ICDs), and Cardiac Resynchronization Therapy-Defibrillators (CRT-D) are common therapies. On occasion, the function or malfunction of such devices has been suspected in patient deaths, especially in view of recent large recalls. It is possible to determine what role, if any, an implanted cardiac device could have played in a patient's death from postmortem examination of a retrieved device, interrogation of stored memory, and additional testing even several years after death. It is very important that implanted electrical devices and associated leads be considered for retrieval as a system. The goals for removal of pacemakers/ICDs/CRT-Ds are: (1) keep as much of the total system together and intact as possible, (2) identify the components for the device and how it was implanted before retrieval, (3) document throughout the retrieval process, and (4) keep explanting personnel safe.

Before attempting removal of any implanted electrical device system, it is advisable to familiarize yourself with how it is implanted, and possible risks. Whenever possible, review any x-ray or imaging that shows the device and lead(s). Pacemakers, ICDs and CRT-Ds are surgically implanted in a similar manner, in a prominent palpable subcutaneous pocket located usually on the left chest or abdomen. Electrical leadwires (leads) are attached to a pacemaker, ICD, CRT-D by screws in a "header." Leads are usually tunneled together upwards through the left chest and into the medial left subclavian vein and then to the appropriate areas of the atrium and ventricles.

The lead carries electric current to the electrode attached to the patient's heart and carries sensed electrical information to the pacemaker/ICD/CRT-D. These signals are processed by an on-board computer and software for interpretation and delivered therapy. The treating physician has prescribed desired device performance by programming the device. An electrical lead is made of an outer layer of plastic insulation, an often intricate inner metal wire core for carrying current, a terminal electrode attached to the heart's surface, and an attachment to the device's header. Lead failures are known to account for approximately 50% or more of implanted electrical system failures. Therefore, it is vital that we attempt to optimize lead retrieval during postmortem examinations. Also of note, additional unattached leads may be found because when leads are replaced in patients often times original leads are simply abandoned—and often it is the abandoned leads that are of interest. Therefore, whenever possible both the pacemaker/ICD/CRT-D

and the attached lead should be extracted as a single device system, along with careful extraction of any abandoned leads.

The pacemaker/ICD/CRT-D subcutaneous pouch should be documented by sketches or photographs looking for pre-mortem burns or charring of the walls, type and amount of fluid present, or evidence of fluid ingress into the plastic header or metal pacemaker/ICD/CRT-D case. All findings and clinical impressions about explanted lead(s) and attachment to pacemaker/ICD/CRT-D header should be documented for the record and photographed.

ICDs and CRT-Ds are about the same size as pacemakers and are implanted in a similar manner, but because defibrillators use high energy, they represent a significant safety issue. ICD/CRT-D leads have a special terminal electrode attachment for defibrillation. For retrieval of ICD or CRT-Ds which remain switched on, personnel must be aware to avoid inadvertent contact with the lead's terminal defibrillation electrode. The ICD/CRT-D terminal electrodes resemble springs or coils and are attached to the end of the lead attached to the heart, and must be assumed to be "hot" even after a patient's death. Retrieval procedures can induce electrical signals in to the ICD/CRT-D that, while artifact, may set the device up to deliver a shock. If an ICD/CRT-D is known to be implanted in a patient, prior to starting an autopsy or retrieval, identification of the make and model of the device and consultation with a cardiologist can help ensure the unit is switched to "off" to reduce the risk of shock. A patient's chart can also be examined to determine if the unit was switched to "off" prior to death. However, it is always best to handle a retrieved terminal electrode from a defibrillator as if it is still "hot" and capable of delivering an electrical shock.

Brief background information on pacemakers and ICDs with appropriate references will be presented, along with a detailed suggested extraction protocol.

Implantable Cardioverter Defibrillator, Cardiac Resynchronization Therapy Defibrillator, Pacemaker

G77 Postmortem Angiography in Support of Radiologic Assisted Autopsy

H. Theodore Harcke, MD, Armed Forces Institute of Pathology, 3205 Coachman Road, Wilmington, DE 19803; and Carol Solomon, MD, and Scott Luzi, MD, Office of the Chief Medical Examiner, 1413 Research Boulevard, Building 102, Rockville, MD 20850*

Upon completion of this presentation, participants will be able to recognize the usefulness of digital radiography and computed tomography in the assessment of vascular injury. Postmortem studies may be performed with antegrade or retrograde injection of contrast medium into the vessels under investigation, in conjunction with the standard forensic autopsy.

This presentation will impact the forensic science community by demonstrating the value of Radiologic Assisted Autopsy.

Radiologic Assisted Autopsy (RAA) performed with digital radiographs (DR) and multidetector computed tomography (MDCT) is limited in its ability to assess vascular integrity. Postmortem angiography has been proposed as a technique to overcome this limitation, a variety of contrast agents and techniques are being evaluated. This report outlines a method for performing postmortem peripheral vascular assessment in conjunction with the standard forensic autopsy.

During autopsy the vessel of interest was isolated at its source or a convenient location distal to the area of interest. Lower extremity arteries were cannulated with embalming trocars where they exited the open abdominal cavity. Vertebral arteries were isolated in the posterior fossa after brain removal and cannulated with a 5F angiocatheter. Hand injection of contrast was performed during MDCT imaging of the area of interest. Satisfactory visualization of peripheral arteries was achieved with a mixture of embalming fluid and radiographic contrast [Omnipaque 320]; undiluted contrast was injected retrograde into the vertebral arteries. Arteries can be injected postmortem in either antegrade or retrograde direction.

Successful demonstration of a lacerated femoral artery (2 cases), lacerated iliac artery and vein (1 case), intact vertebral artery (2 cases) and a lacerated vertebral artery (1 case) were accomplished. When performed in conjunction with RAA postmortem angiography has the potential to: (1) allow the investigator to avoid unwanted dissections, and (2) optimization of autopsy resources.

Angiography, Radiologic Assisted Autopsy, MDCT Virtual Autopsy

G78 CSI Halifax in Miami: The Importance of Practical Courses in the Forensic Sciences

Tanya R. Peckmann, PhD, Saint Mary's University, Department of Anthropology, McNally South 208, 923 Robie Street, Halifax, Nova Scotia B3H 3C3, CANADA; and Dr. Bruce A. Hyma, MD, Miami-Dade County Medical Examiner's Office, 1 Bob Hope Road, Miami, FL 33136*

Upon completion of this workshop, participants will gain insight into the importance of providing practical experiential learning opportunities for students in the forensic sciences and gain a better understanding of the collaborative effort involved with forensic investigations.

This presentation will impact the forensic science community by illustrating the need to develop hands-on courses as students, who want to pursue careers in forensic science, need to understand the realities of the training required and the job tasks as well as illustrating the desire for students to experience practical hands-on courses in the forensic sciences and therefore the importance for educators and practitioners to create such courses. In addition, this presentation will illustrate the importance and need for international collaboration in the forensic sciences – students were unable to gain this experience in Nova Scotia but were able to experience it in Miami-Dade County.

Student interest in forensic science has grown tremendously over the past few years; however, a practical approach to the topic is very rare. Within North America and Europe, forensic cases are highly guarded and treated as 'top secret' by police departments and coroner's offices; only a select few individuals receive security clearance to examine and analyse human remains, therefore making it almost impossible for a novice to gain this very necessary 'realistic' forensic experience.

However, in May 2007, a unique and groundbreaking practical hands-on internship was created by the collaboration of Saint Mary's University and the Miami-Dade County Medical Examiner's Office. During this course, students gained a rare and comprehensive knowledge of applied forensics; they were exposed to the multidisciplinary nature of forensic investigation and mentored by experts in the field of forensic science.

Education, Experiential Learning, International Collaboration

G79 Can Renal Acute Tubular Necrosis Be Differentiated From Autolysis at Autopsy?

Johan A. Duflou, MBChB, MMed, and Linda Kocovski, BSc, Department of Forensic Medicine, PO Box 90, Glebe, 2037, AUSTRALIA*

After attending this presentation, attendees will have an understanding of the morphological characteristics used to define acute tubular necrosis (ATN) and how certain characteristics may be used to differentiate between ischemic ATN and autolysis in postmortem samples.

This presentation will impact on the forensic community by providing morphological characteristics to be used in the microscopic examination of postmortem renal tissue to determine and/or confirm analyses of ATN as contributing to cause of death. The use of diagnostic criteria will augment the identification of ischemic ATN as distinct from the process of autolysis.

Acute tubular necrosis is the most common cause of acute renal failure and accounts for 50% of all cases of acute renal failure in hospitalised patients and greater than 75% of critical care/intensive care unit cases. Acute renal

failure affects about 5% of hospitalized patients and has a high mortality rate of 50%. It is a commonly held view amongst autopsy pathologists that it is generally not possible to diagnose ATN at autopsy because of the presence of autolysis, and that the only way the condition can be diagnosed is by identifying mitotic figures in the tubular epithelium. This belief may lead to the under-reporting of the condition as a finding upon microscopic analysis of renal tissue.

The Department of Forensic Medicine, Glebe, Sydney autopsy database was queried for cases where an antemortem diagnosis of ATN was made. Antemortem hospital medical charts for each case were searched for a diagnosis of ATN based on clinical and biochemical parameters. A total of 57 cases over a 5 year period were found. These cases were compared to a similar number of age and sex matched controls, who died suddenly as a result of self-inflicted hanging but were otherwise healthy.

A total of 114 deidentified and randomized kidney sections were examined. Serial tissue sections from each case were stained with H&E, Martius Scarlet Blue (MSB), Masson's Trichrome and anti-human Ki-67 immunoperoxidase. Morphological characteristics compared were proliferating epithelial cells (as visualized by Ki-67 positivity); fibrin thrombi in glomeruli; tubular epithelial whorls; mitoses in tubular epithelium; presence of tubular casts; degree of autolysis; tubulorrhexis; tubular epithelial flattening; interstitial inflammation, and interstitial edema.

All results were expressed as mean \pm standard deviation. Differences between groups were determined by two sample t-test. A *p* value < 0.05 was considered to be statistically significant.

Statistically significant differences were between the cases exhibiting ATN and the controls in the following morphological characteristics: number of tubular epithelial whorls, proliferating cells, tubulorrhexis, and interstitial edema. The mean number of tubular epithelial whorls in ATN cases was 1.93 ± 5.15 ; no whorls were found in any control cases (*p* < 0.001). The mean number of proliferating cells in ATN cases was 19.5 ± 29 and in control cases was 5 ± 9.2 (*p* = 0.0001). The mean number of tubules exhibiting tubulorrhexis in ATN cases was 0.0309 ± 0.0826 and in control cases was 0.007 ± 0.0258 (*p* = 0.041). The mean degree of interstitial edema (as determined by proportion of fields exhibiting the condition) in ATN cases was 0.533 ± 0.412 and in control cases was 0.195 ± 0.312 (*p* < 0.001).

The remaining morphological characteristics (fibrin thrombi, tubular casts, degree of autolysis, mitotic figures, tubular epithelial flattening and interstitial inflammation) were analysed and showed no statistically significant differences between the two groups.

Acute tubular necrosis can be reliably differentiated from autolysis at autopsy. The presence of characteristic tubular epithelial whorls is highly diagnostic of ATN. When taken together with tubulorrhexis, interstitial edema and epithelial proliferation, a diagnosis of ATN can be reliably made at autopsy.

Autopsy, Acute Tubular Necrosis, Renal Pathology

G80 The Effects of a New Level 1 Trauma Center on the Local Medical Examiner Office

Martha J. Burt, MD, District 8, Medical Examiner Office, 606 South West 3rd Avenue, Gainesville, FL 32601; and Charlotte J. Stevens, BA, 6417 South West 9th Avenue, Apartment A, Gainesville, FL 32607*

The goal of this presentation is to describe the changes in the medical examiner non-natural case load in relation to the establishment of a level 1 trauma center.

This presentation will impact the forensic community and humanity by providing insight into the effects of a level 1 trauma center on regional medical examiner, which in turn affects law enforcement, families, funeral homes and regional funding.

The goal of this study is to look at the change, if any, to the medical examiner case load and distribution following the opening of a new level 1 trauma center. Factors evaluated included the increase or decrease in the total number of medical examiner cases per year, the medical examiner districts from which these cases are originating and what types of cases the trauma center is bringing into the district.

On October 1, 2004, the University of Florida & Shands Hospital in Gainesville, Florida became a Level 1 Trauma Center. For a patient to be given trauma alert status, they must meet very specific criteria, such as two or more long bone fractures, ventilation beyond passive oxygen administration, or 15% or more of body involved in second or third degree burns.

This new trauma center covers nine whole counties and seven partial counties. The counties with partial coverage are relatively equidistant between two level 1 trauma centers, such that patients in these counties may go to one of two trauma centers for treatment. Of these sixteen counties covered by the new trauma center, only seven are within the District 8 Medical Examiner's jurisdiction. Even though the injury(s) may have occurred outside the jurisdiction of District 8 Medical Examiner Office, when a trauma patient dies at the trauma center, the time and place of death is in Alachua County. Because medical examiner jurisdiction in Florida is defined by place of death, not place of injury, such cases fall under the auspices of the District 8 Medical Examiner Office.

The District 8 Medical Examiner Office case files were retrospectively reviewed from January 1, 2002 to June 30, 2007. Only non-natural deaths were included in the study population as natural deaths would not be affected by the presence or absence of a level 1 trauma center. The trauma center began operating at level 1 status October 1, 2004, and this is the date used to demarcate "before" and "after" data sets. During this time, 3156 total cases were investigated by the MEO and 2388 were autopsied. The annual case load has been steadily increasing, with the largest increase in 2005 (a 10% increase in total cases and a 22% increase in autopsies). Since October 1, 2004, 312 cases have been investigated that came through the trauma center as a trauma alert, with 275 investigated by the District 8 MEO. Roughly 58% of the deaths coming through the trauma center were a result of motor vehicle crashes, by far the largest mechanism, followed by falls of all types (20%). Only 33% of the trauma center deaths had their corresponding injuries within the District 8 medical examiner jurisdiction. Before the trauma center opened, approximately 15% of all non-natural investigations were outside of the District 8 MEO, whereas afterwards, 26% were outside the jurisdiction.

This study has found that a much larger percent of the District 8 Medical Examiners case load is now coming from outside of the current jurisdiction since the opening of the trauma center, which is associated with an increase in the over all number of cases each year and an increase in the complexity of the cases. Patients from the trauma center tend to have more complex injuries resulting in longer autopsies and more time spent determining causes of death. Additionally, a large percentage of the trauma cases are coming from surrounding districts, cases that originally would have gone to that outside district or a different one with a level 1 trauma center, such that trauma deaths are being redistributed throughout the region. The larger implication being that the opening of a Level 1 Trauma Center not only affects the medical examiner district in which it resides, but also the surrounding medical examiner offices by reducing their case load.

Medical Examiner, Trauma, Non-Natural Death

G81 Mapping the Literature in Forensic Pathology and Legal Medicine: A Bibliometric Study of North-American Journals From 1980 to 2005

Anny Sauvageau, MD*, A. Godin, S. Desnoyers, C. Kremer, MSc, and S. Racette, BSc, Lab de Sciences Judiciaires, et de Medecine Legale, 1701, Parthenais Street, 12th Floor, Montreal, PQ H2K 3S7, CANADA

The goal of this presentation is to describe the evolution of the literature in forensic pathology and legal medicine for North-American journals over more than twenty-five years. More precisely, it will draw a picture of our literature and describe developments and trends regarding numbers of author(s) per article, represented countries and international collaborations, types of articles and use of the scientific method.

This presentation will impact the forensic community by providing new insight in the forensic pathology literature. A better knowledge of this body of literature could help us assess our strengths and weaknesses, and better position ourselves on literature ethical issues.

Bibliometric studies have increasingly been used over the last years. Those studies are useful to understand the evolution of literature or trends in particular fields or within a geographical area. However, in forensic sciences, bibliometry has barely been used yet and the few studies that have been performed mainly focused on most highly cited articles, most prolific authors and impact factors. Thus, the present study specifically aims at mapping the literature in the field of forensic pathology and legal medicine.

The two North-American leading journals in forensic sciences were selected: the Journal of Forensic Sciences and the American Journal of Forensic Medicine and Pathology. All articles in the field of forensic pathology and legal medicine published in those journals in 1980, 1985, 1990, 1995, 2000, and 2005 were retrospectively analysed, excluding editorials, guest editorials, tributes, and book reviews. For each article, the following features were compiled: number of author(s), author's country and international collaboration and type of article. Furthermore, it was assessed if the article was using or not the scientific method, with testing of hypotheses by statistical analysis. A total of 522 articles were examined from 1980 to 2005 at a 5-year interval: 215 articles from the Journal of Forensic Sciences and 307 articles from the American Journal of Forensic Medicine and Pathology. The SPSS 15.0 software was used to perform statistical analyses at a threshold of significance of 5%. Mean values were compared using analysis of variance, while proportions were compared through Chi-square tests.

Overall, the number of articles per year has passed from 55 articles in 1980 to 89 in 2005. Meanwhile, the average number of author(s) per article has significantly increased ($p=0.000$, $p<0.05$), passing from 1.8 to 3.5. The relative contribution of other countries in comparison to the United States has significantly increased from 9.3% to 57.3% ($p=0.000$, $p<0.05$). Articles from international collaboration were absent in 1980, passing to 5.62% of articles in 2005. As for the types of articles, the review article was the only type of article significantly decreasing ($p<0.05$). No significant differences was revealed for the remaining types of articles, although letters to the editor showed a tendency to decrease ($p=0.069$), while original studies showed a tendency to increase ($p=0.088$). Finally, the number of studies using the scientific method did not significantly progressed from 1980 to 2005 ($p=0.416$, $p>0.05$), passing from 10.9% to 15.7%.

The literature in forensic pathology and legal medicine in North-American journals has expanded in number of articles per year from 1980 to 2005. However, the relative proportion of pathology and legal medicine in the forensic literature as a whole has stayed about the same. The significant increase in the average number of author(s) per article follows a similar trend in the forensic literature. Finally, it is surprising to see that while the use of the scientific method has significantly progressed in the forensic literature over the last twenty-five years, pathology and legal medicine literature has stayed behind on this aspect. This observation is a warning sign that researchers and authors in our field should notice.

G82 Purtscher Retinopathy Detected by Postmortem Monocular Indirect Ophthalmoscopy

Patrick E. Lantz, MD*, Department of Pathology, Wake Forest University, SOM, Medical Center Boulevard, Winston-Salem, NC 27157-1072; Constance A. Stanton, MD, Department of Pathology, Wake Forest University of Health Sciences, Medical Center Boulevard, Winston Salem, NC 27157; and Marshall E. Tyler, Department of Ophthalmology, Wake Forest University of Health Sciences, Medical Center Boulevard, Winston Salem, NC 27157

The goals of this presentation are to: (1) describe the retinal features of the Purtscher retinopathy, (2) list conditions and disorders associated with Purtscher retinopathy, and (3) describe the histological features of Purtscher-flecken.

After attending this presentation, attendees will gain insight into the value of postmortem monocular indirect ophthalmoscopy (PMIO) in detecting Purtscher retinopathy and subsequent histopathological description of the observed retinal lesions. This presentation will impact the forensic community by providing an introduction to non-hemorrhagic retinopathies detectable by PMIO and consequent histopathological characterization.

In 1910, Dr. Otmar Purtscher described a patient with severe head trauma who had a hemorrhagic and vaso-occlusive retinopathy characterized by multiple variably sized cotton-wool spots (Purtscher-flecken) plus retinal hemorrhages around the optic nerve head. Two years later he designated the condition angiopathia retinae traumatica. Since then the term Purtscher retinopathy has been used to describe a clinical picture of angiopathia retinae traumatica even in the absence of known head trauma. Purtscher-like retinopathy has been observed in a variety of conditions including compressive chest injuries, long bone fractures, retrobulbar anesthesia, connective tissue and vasculitic diseases, orthopedic surgery, acute pancreatitis, strenuous childbirth, and battered child syndrome. The exact pathophysiological mechanism causing Purtscher or Purtscher-like retinopathy remains controversial and published supportive histological descriptions are rare. Two cases are described of Purtscher retinopathy detected by postmortem monocular indirect ophthalmoscopy plus the histological features and immunohistochemical staining for β -amyloid precursor protein of observed Purtscher-flecken.

Case 1: A 36-year-old man sustained a traumatic brain injury with immediate loss of consciousness following an assault in a parking lot. Cranial computed tomography revealed subdural and subarachnoid hemorrhages. He remained comatose and died thirteen days after the injury. Neuropathological examination revealed traumatic axonal injury, a cerebral contre-coup contusion plus organizing subdural and subarachnoid hemorrhages. Prior to autopsy PMIO identified retinal hemorrhages and multiple posterior, peri-papillary, polygonal foci of retinal whitening (Purtscher-flecken) distributed between retinal arterioles and veins. Histologically, these areas were collections of swollen, contracted axons (cytoid bodies) in the nerve fiber layer highlighted by immunohistochemical staining for β -amyloid precursor protein.

Case 2: A 27-year-old man had experienced nausea and vomiting for a number of days. While at his girlfriend's residence he collapsed following an episode of vomiting. Resuscitative efforts were unsuccessful and he was pronounced dead in the emergency department. Hepatosplenomegaly was present at autopsy and his hypercellular bone marrow contained > 20% myeloid blasts with Auer rods. The leukemic cells stained positively for CD68 and myeloperoxidase. Prior to autopsy PMIO revealed multiple bilateral retinal hemorrhages, many white-centered, plus posterior foci of small Purtscher-flecken. Histologically, these foci were cytoid bodies in the nerve fiber layer that stained positively for β -amyloid precursor protein.

No published reports of Purtscher retinopathy detected initially at autopsy are in the medical and scientific literature. Previous articles on the histopathology of Purtscher retinopathy have been two case reports from patients with acute pancreatitis who died 6 and 23 days after the onset of their illness. Both had focal areas of retinal edema and loss of architecture

in the inner retinal layers with abrupt transition to normal retina. In the author's reported cases the detected Purtscher-flecken were cytid bodies that stained positively for β -amyloid precursor protein. These inner retinal collections of swollen, contracted axons are relatively nonspecific and histopathologically similar to retinal cotton-wool spots and foci of axonal injury observed throughout the nervous system commonly associated with a variety of traumatic and non-traumatic conditions.

Purtscher Retinopathy, Traumatic Brain Injury, β -Amyloid Precursor Protein

G83 Sudden Death Due to a Cardiac Sarcoidosis: Histopathological Helping Evidences

Irene Riezzo, MD*, and Stefano D'Errico, MD, University of Foggia, Department of Forensic Pathology, via Luigi Pinto, 1, Foggia, 71100, ITALY; and Francesco Ventura, MD, University of Genova, Department of Forensic Pathology, Via de'Toni, 12, Genova, 16132, ITALY

The goal of this presentation is to present an uncommon case of sudden cardiac death in a 34-year-old. A complete methodological forensic approach by means of autopsy, histological, and immunohistochemical examinations led us to conclusion of a systemic sarcoidosis with massive cardiac involvement.

This presentation will impact the forensic science community by demonstrating how the rarity of cardiac sarcoidosis makes the case peculiar; in addition to clinical and lab tests, a complete forensic methodological approach by means of autopsy, histopathological examination and immunohistochemical stain led us to confirm the diagnosis of cardiac sarcoidosis as the cause of death.

Sarcoidosis is a multisystem disorder of unknown aetiology, characterized by noncaseating epithelioid cell granulomas. The aetiology and pathogenesis are unclear, although many infectious, environmental and genetic factors have been implicated. Prognosis and clinical manifestations are dependent on the location and extend of granulomatous infiltrates. The cardiac involvement is uncommon (at autopsy, cardiac involvement has been reported in 20-30% of patients with sarcoidosis, although most studies indicate that <5% of patients with sarcoidosis have symptoms related to cardiac involvement) and has a wide range of clinical manifestations (conduction disorder, ventricular arrhythmias, atrial arrhythmias, pericarditis, valvular dysfunction, congestive heart failure). It is unusual for sarcoidosis to present with isolated cardiac involvement. In autopsy study, cardiac involvement proved to be the cause of death in 37% of the patients with sarcoidosis. Cardiac involvement associated with poorer prognosis and the mortality rate may exceed 40% at 5 years and 55% within 10 years. The presence of pulmonary involvement was associated with better survival. Sudden death due ventricular tachyarrhythmia or conduction block accounts for 25 to 65% of the deaths due to cardiac sarcoidosis.

A 34-year-old woman was found lifeless at home from by her parents. Death scene investigation was unremarkable. The extended family hadn't a history of sudden death. In her history a visit to the Emergency Room three months before death was recorded. She complained chest pain, non-sustained ventricular tachycardia and loss of consciousness. Body temperature was normal. Subsequent cardiological evaluation with ECG showed sinus rhythm with ventricular premature beat and intraventricular conduction abnormalities. Echocardiography showed normal chamber dimensions, no wall motion abnormalities. The research for viruses was negative. The laboratory findings were normal. During hospitalization she presented some episodes of supraventricular paroxysmal tachycardia (160 bpm) and non-sustained ventricular tachycardia. No other symptoms or apparatus failure were present. Family history was reportedly negative for cardiac disease. An anti-arrhythmic treatment was prescribed.

A complete postmortem examination was performed two days after death. External examination was unremarkable. The internal examination revealed only a polivisceral congestion and pulmonary edema. All internal organs were macroscopically normal. The heart had a normal shape and was

normal in size and weight. The left and right coronary arteries arose normally. No significant stenosis or thrombotic occlusion of the coronary segment were detected. The atrio-ventricular and semilunar valves were normal. The myocardium showed an extensive fibrotic scarring, particularly in the supero-anterior wall of the LV and the posteroseptal wall. The histological examination of the heart, performed with routine haematoxylin-eosin revealed diffuse and extensive fibrosis with non-caseating granulomas composed mainly of an aggregate of epithelioid cells and multinucleated giant cells in the centre surrounded by lymphocytes, plasmacells and mastcells. The lungs and kidneys also showed the same non-caseating granulomas. An immunohistochemical examination of heart samples was performed to confirm diagnosis. Mycobacterium tuberculosis and fungal infections were excluded on special stains. The remainder of the histological examination was unremarkable. The diagnosis of sarcoidosis with massive and extensive cardiac involvement was established as cause of death.

Cardiac Sarcoidosis, Sudden Death, Ventricular Arrhythmias

G84 A Diagnosis of Chagas Disease at Autopsy

Ana E. Lopez, MD*, Harris County Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054; L. Maximilian Buja, MD, University of Texas-Houston Health Science Center, 7000 Fannin, Suite 1715, Houston, TX 77030; and Luis A. Sanchez, MD, Harris County Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054

The goal of this presentation is to become familiar with Chagas disease and to consider it as a diagnosis in the setting of chronic myocarditis and sudden death.

The forensic community will be presented with an interesting case of chronic myocarditis related to Chagas disease, raising awareness of the presence of this disease in the United States, and its relation to sudden death.

Chagas disease is caused by the parasite *Trypanosoma cruzi*, which is a blood-dwelling and tissue-dwelling protozoan. The disease occurs in the Americas, primarily in Central and South America. It is transmitted to humans through the bite of the reduviid bug. The disease is commonly seen in children younger than five years who develop a skin lesion known as a chagoma at the site of infection where the organisms proliferate in the skin. The trypomastigotes (flagellate forms) may then spread via hematogenous or lymphatic routes and cause an acute illness characterized by lymphadenopathy, fever, anorexia, and fatigue. After the acute phase, recovery may occur, or the disease may progress into a chronic phase, which is usually seen in adults and older children. Chronic carriers of *Trypanosoma cruzi* may develop chronic myocarditis and a cardiomyopathy or dilatation of the digestive tract, characterized by dysphagia and megacolon.

Chagas disease is diagnosed at autopsy in a 66-year-old Hispanic male originally from El Salvador who died in Houston while at work in the construction of a residential apartment complex. He was found dead by his employer who had arrived at the job site to supervise him. He was found on the floor inside of an apartment that was being renovated, and it appeared he had collapsed as he was preparing to perform some caulking. Per his family, he had no known medical or social history but had been complaining of dizziness and palpitations over the past two weeks. At autopsy, he had an enlarged, 515-gram heart with left ventricular hypertrophy and focal thinning of the left ventricular wall toward the apex. A 1.5-centimeter mural thrombus was in the apex of the left ventricle, and the surrounding myocardium had diffuse scarring. Extensive myocardial fibrosis extended into the lateral and posterior left ventricle towards the base of the heart. The coronary arteries showed mild atherosclerosis with 10% to 20% stenosis in the left anterior descending and right coronary arteries. He also had remote embolic infarcts in the kidneys and brain with 9-centimeter and 3-centimeter cortical scars in the kidneys and a 2-centimeter area of cortical encephalomalacia in the left occipital lobe. Microscopically, sections of the heart showed chronic interstitial inflammation with lymphocytes and eosinophils associated with patches of myocardial fibrosis. Toxicology was negative for drugs and alcohol. Chagas disease was considered in the differential diagnosis of chronic myo-

carditis in an adult male from Central America; therefore, serologic testing was requested through the Centers for Disease Control. An indirect fluorescent assay showed an IgG antibody titer of 1:512, which was positive for Chagas disease.

There are many different causes of myocarditis including infections, immune reactions, drug hypersensitivity, poststreptococcal, giant cell myocarditis, and sarcoidosis. Common infectious causes are typically viral such as coxsackieviruses, echoviruses, influenza, and adenovirus. Additionally, other protozoa such as toxoplasma and helminths can also affect the heart and cause myocarditis. Although typically prevalent in South and Central America, Chagas disease should be considered in individuals in the United States who present with cardiac arrhythmias, congestive heart failure, and sudden death, especially in Texas, California, and throughout the South given the large immigrant population in these states. *Trypanosoma cruzi* can also be transmitted through blood transfusions, organ transplantation, transplacentally, and through breast milk. In 2006, the FDA approved a screening test for Chagas disease in the blood donation population, which is currently being used for screening the donated blood in the Gulf Coast region of Texas.

Chagas Disease, Chronic Myocarditis, Autopsy

G85 Dysplasia of the Atrioventricular Nodal Artery: A Case Report and Review of the Literature

Clarissa Krinsky, MD, 3908 Silver, South East, Albuquerque, NM 87108; Sam W. Andrews, MD, Office of Chief Medical Examiner, 4070 Bowness Road North West, Calgary, Alberta T3B 3R7, CANADA; and Rebecca Irvin, MD, 808 Shire Street, South West, Albuquerque, NM 87121*

After reviewing this presentation, attendees will understand the pathophysiology and epidemiology of conduction system arterial dysplasia, a rarely reported condition. Autopsy findings and the correlation between histopathologic abnormalities and sudden death will be emphasized via a case presentation and a review of the literature on this topic.

It is important that the forensic community be aware of this process, its characteristic histopathology, the distribution and clinical consequences of similar lesions throughout the body, and its implications as a cause of sudden death. Pathologic processes involving the conduction system are often considered in the investigation of otherwise healthy persons, and this presentation will impact the forensic science community by presenting evidence for the systematic examination of conduction system histology.

A case of the investigation of the sudden death of a previously healthy 15-year-old male will be presented. The patient had a history of being overweight (BMI 28.4), mild well-controlled asthma, and Attention Deficit and Hyperactivity Disorder treated in the past with stimulants. Examination revealed an essentially negative autopsy, a negative skeletal survey by radiography, and normal histopathology of the usual microscopic sections taken at autopsy. Postmortem toxicology was significant for the presence of a moderate amount of caffeine. Viral and bacterial cultures grew a likely postmortem contaminant only, and vitreous chemistries were normal. Further examination of the conduction system revealed significant dysplasia of the atrioventricular nodal artery, characterized by irregular fibrointimal thickening of the vessel wall with marked disruption of the elastic lamina, highlighted by special stains.

Dysplasia of the atrioventricular nodal artery is a rare entity, described only in small case reports and series. The morphologic changes are the same as those found with fibromuscular dysplasia, which is most commonly seen in the renal and internal carotid arteries but has been reported in numerous arterial beds and may even be a generalized condition. Fibromuscular dysplasia is a nonatherosclerotic, noninflammatory disease of the arterial wall, the exact cause of which is unknown. The lesions may predominantly alter the intima, media, or the adventitia, and the sequelae are dependent upon the degree of vascular wall thickening or destruction and the location of the affected vessels.

Within the forensic literature, there are scattered case reports of dy-

splasia within the vasculature supplying the conduction system, but the majority of the literature linking fibromuscular dysplasia to a cause of death focuses on the disease process within the small coronary arteries. In fact, some controversy exists as to the presence of apparent dysplasia within the nodal arteries in control subjects dying of other causes and whether the use of special stains can highlight specific alterations of the vessel wall that may lead to an increased association with sudden death.

An example of atrioventricular nodal dysplasia is the cause of sudden death in a relatively healthy adolescent. It is important that the forensic community be aware of this process, its characteristic histopathology, the distribution and clinical consequences of similar lesions throughout the body, and its implications as a cause of sudden death. Pathologic processes involving the conduction system are often considered in the investigation of otherwise healthy persons, and this presentation will present evidence for the systematic examination of conduction system histology.

Atrioventricular Node, Dysplasia, Sudden Death

G86 Subaortic Aneurysm of the Left Ventricle Complicating Staphylococcal Endocarditis

Pauline Saint-Martin, MD, Service de Medecine Legale, Hopital Troussseau, Centre Hospitalier Regional Universitaire de Tours, Tours, 37000, FRANCE; Christopher B. Rogers, MD, and Eugene Carpenter, MD, Los Angeles County, Medical Examiner's Office, 1104 North Mission Road, Los Angeles, CA 90033; Michael C. Fishbein, MD, Department of Pathology and Laboratory Medicine, David Geffen School of Medicine at University of California, Los Angeles, CA 90095; and Lakshmanan Sathyavagiswaran, MD, Los Angeles County Medical Examiner's Office, 1104 North Mission Road, Los Angeles, CA 90033*

After attending this presentation, the audience will learn about an unusual complication of endocarditis, which could lead to sudden death of young people.

This presentation will impact the forensic science community by demonstrating how subaortic aneurysms can complicate staphylococcal aortic valve endocarditis and cause sudden unexpected deaths in young people.

Subaortic aortic aneurysms are rare. Initially thought to be of congenital origin, they may occur as a complication of aortic valve endocarditis. This report describes a subaortic aneurysm in a 21-year-old patient who had a recent history of staphylococcal endocarditis.

A 20-year-old Vietnamese male who worked as a machinist presented to the Emergency Room of a local hospital with a 4-6 days history of fever, chills, and headache. A cardiology evaluation was requested due to a systolic murmur on examination. A transesophageal echocardiography revealed abnormal vegetation of the aortic valve and mild aortic, tricuspid and mitral regurgitation. Blood cultures drawn at the time of the admission grew *Staphylococcus aureus*. *Staphylococcus aureus* endocarditis was diagnosed. The patient was treated with Gentamycin for 14 days, and Nafcillin for seven weeks. The patient was followed by a cardiologist for eight months. The patient refused aortic valve replacement surgery. Ten months after the onset of the first episode the patient was found down at home with shortness of breath and an altered level of consciousness. He was transported to the hospital, but suffered cardiac arrest and was pronounced in the Emergency Room. At autopsy, the patient weighed 149 pounds and measured 67 inches. The external examination showed evidence of therapeutic intervention and no external trauma was noted. The pericardial cavity was filled with 200 mL of clotted blood. The heart weighed 430 grams. There was aneurysmal enlargement at the base of the left ventricle, between the aorta and the left atrium, measuring 3.0 cm in diameter. A ruptured snout measuring 1 cm was located on the superior aspect of the aneurysm. The aortic valve was bicuspid. The aneurysm communicated with the left ventricle just below the right commissure of the two cusps by a triangular opening measuring 1.5 x 1.0 cm. Death was attributed to cardiac tamponade from spontaneous rupture

of a subaortic aneurysm.

Subaortic aneurysms can be congenital, infective or traumatic. Congenital weakness of the fibrous annuli could predispose to the development of such aneurysms. A bicuspid aortic valve is another contributing condition. The role of aortic regurgitation as a consequence of infective endocarditis in the aneurysmal formation needs to be considered in our case. It is probable that rupture of the aneurysm resulted from weakness and increased tension of the aneurysmal wall.

Forensic Pathology, Sudden Death, Subaortic Aneurysm

G87 A Rare Case of Cardiac Failure Due to Hypertensive Crisis in Pheochromocytoma: A Methodological Approach for Diagnosis

Stefano Derrico, MD, Irene Riezzo, MD, and Cristoforo Pomara, MD, Department of Forensic Pathology, University of Foggia, via Luigi Pinto, 1, Foggia, Italy 71100, ITALY*

The goal of this presentation is to present a rare case of cardiac failure due to hypertensive crisis in pheochromocytoma in an asymptomatic 25-year-old young man is presented. The rarity of pheochromocytoma makes the case peculiar and the complete pathologic investigation adopted (autopsy performing, immunoistochemical staining, and biochemical screening) is strongly recommended to pathologists to confirm diagnosis.

This presentation will impact the forensic science community by demonstrating how the rarity of pheochromocytoma makes the case peculiar. It is strongly suggest, in these cases, the relevance for pathologists of a complete methodological approach, integrating clinical data by means of autopsy findings, immunoistochemical staining and biochemical screening to confirm diagnosis.

Pheochromocytomas are rare but clinically important tumours of chromaffin cells that produce, store, release and metabolize catecholamines. Pheochromocytomas usually manifest clinically as hypertension which can be sustained or paroxysmal. The diagnosis of pheochromocytoma is based on measuring excessive amounts of catecholamines and their metabolites on blood and urine; more than 90% of patients with pheochromocytoma have elevated levels of catecholamines, metanephrine, and vanillyl-mandelic acid. Sensitivity and specificity of these measurements are 91%. Failure to diagnose the tumours can result in sudden, unexpected and potentially lethal complications; cause of death in these cases is generally a consequence of paroxysmal hypertension as well as cerebral vascular accidents, abrupt haemorrhage into the tumour or acute left ventricular failure.

A 25-year-old man, with a past medical history significant for recurrent episodes of cephalgia, was transported to the local Hospital at 11:44 p.m. complaining of vomiting and headache. A prescription for symptomatic treatment was issued unsuccessfully. He had high blood pressure (180/80) and tachycardia (110 bpm). Neurological examination was unremarkable, abdomen showed no rigidity, peristaltic sounds were normal. Initial laboratory findings showed hyperglycaemia (177 mg/dl) and high level of amylase (125 U/L); further findings showed high levels of myoglobin (153 ng/ml). A 12 lead electrocardiogram on admission was performed showing sinus tachycardia, with right bundle branch block and ventricular bigeminy extra systoles; non specific repolarization change were also described. Few hours later, 8:15 a.m. the patient appeared pale and sweating; blood pressure was unappreciable and hypocontractility of left ventricle with low ejection fraction was observed on echocardiography (EF 25-30%). A state of haemodynamic shock was declared (FC 170, blood pressure was unappreciable). Pulmonary edema was observed on chest Rx examination and oro-tracheal intubation was performed substaining ventilation in intensive care unit. At 9:15 a.m. ECG monitor showed cardiac arrest; resuscitation manoeuvres were attempted unsuccessfully.

A complete postmortem examination was performed two days after death. External examination was unremarkable except for food residuals in the mouth. Internal examination showed cerebral oedema; food residuals were recorded at oesophagus exploration; heavy lungs presenting white foam

on the main bronchi was also detected. Heart was fixed in formalin, cardiac size was normal, with conical shape. Macroscopic study (cut in cross-section 3 mm intervals) of coronary arteries was unremarkable. A well circumscribed encapsulated lobulated reddish and brownish suspected lump measuring 3.5x3x3 was attached to the medial aspect of the left kidney; it was soft on section and presented aspect of necrosis and haemorrhage. Adrenal tissue was attenuated over the upper part of the mass; aspect of minimal haemorrhage was observed on pancreas examination.

Histological examination revealed polyvisceral stasis, mild cerebral edema: massive pulmonary edema was recorded. Cardiac myofibers varied considerably in size with many large fibers and aspect of fibrosis suggesting for hypertension; the pathological myocardial picture included fragmentation of the whole myocyte (pancellular lesion) which ranged from early breakdown in pathological band (intense hyperosinophilia of the hypercontracted myocardial cells with rexis of the myofibrillar apparatus into cross-fiber, anomalous and irregular) to a total granular disruption (myofibrillar degeneration). Histological examination of the suspected lump addressed diagnosis for a benign pheochromocytoma with the presence of well-defined nests (Zellballen) bound by a delicate fibrovascular stroma, which contain amyloid. The cells varied considerably in size and shape and had purely granular basophilic cytoplasm; the nuclei were round with prominent nucleoli.

An immunoistochemical study was performed and it showed a positive reaction for chromogranin and synaptophysin.

Dosage of catecholamines and their metabolites on a blood and urine samples was performed showing high levels of catecholamines, metanephrine and vanillyl-mandelic acid.

Clinical data, autopsy findings, data collected from immunoistochemical staining and biochemical analysis led us to conclude that cardiac failure due to hypertensive crisis in adrenal pheochromocytoma was the cause of death.

In conclusion, the rarity of pheochromocytoma makes the case peculiar. The authors strongly suggest, in these cases, the relevance for pathologists of a complete methodological approach, integrating clinical data by means of autopsy findings, immunoistochemical staining and biochemical screening to confirm diagnosis.

Pheochromocytoma, Cardiac Failure, Hypertensive Crisis

G88 Arrhythmogenic Right Ventricular Dysplasia (ARVD): A Not So Rare Cause of Sudden Death in Young Adults

Frank Braza, MD, PhD, Juan A. Merayo-Rodriguez, MD, and Jeffrey West, Danbury Hospital, 24 Hospital Avenue, 2 Tower Lab, Danbury, CT 06810*

The goal of this presentation is to make the forensic community aware of this entity (ARVD) as a sudden cause of death in the young adult population.

This presentation will impact the forensic science community by demonstrating how routine full autopsies may not detect the subtle pathologic changes that cause Arrhythmogenic Right Ventricular Dysplasia.

Ten (10) cases of ARVD/Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC) autopsied at Danbury Hospital, CT, from June 2002 until June 2007 were reviewed. This number represents 3.75% of the total adult full autopsies performed in our institution during the same period.

Age, sex, and ethnic background were noted. Associated cardiac and non cardiac related diseases were reviewed.

Medications, social and family history (sudden death of a sibling) as well as body habitus (obesity) were tabulated.

Prior symptoms (syncope episodes, palpitations) and pre-terminal circumstances (place of death, physical activity) were examined. Autopsy findings (both cardiovascular and systemic) were correlated.

The ten patients' ages ranged from 34 to 65. Sex ratio was 1:1. 8/10

* Presenting Author

were obese, 5/10 used alcohol frequently, 10/10 were at rest at time of pre-final event, 1/10 had family history of sibling (brother) sudden death, 10/10 had some degree of Coronary Artery Disease (CAD), 7/10 had cardiomegaly (450g to 650g), 1/10 had coexisting myocarditis, 10/10 were Caucasian (only 1 with an Italian background), 4/10 had suffered a significant traumatic injury and 3/10 used medications for depression or anxiety. In patients with ARVD, the most common findings were obesity, CAD. The authors also concluded that Caucasian ethnicity is prevalent, the pre-terminal episode happens at rest, the age group is between 4th and 7th decades, and M:F ratio is ~1.

This report helps to increase awareness regarding this congenital cardiac disease. It is relevant to the forensic community, because of its high incidence in children, and young adults, and it is a frequent cause of (sudden death) in the North East (New England).

Arrhythmogenic right ventricular dysplasia (ARVD, also known as arrhythmogenic right ventricular cardiomyopathy or ARVC) is a type of non-ischemic cardiomyopathy that involves primarily the right ventricle of the heart. It is characterized by hypokinetic areas involving the free wall of the right ventricle, with fibrofatty replacement of the right ventricular myocardium, with associated arrhythmias originating in the right ventricle.

ARVD is an important cause of ventricular arrhythmias in children and young adults. It is seen predominantly in males, and 30-50% of cases have a familial distribution. It is usually inherited in an autosomal dominant pattern, with variable expression. The penetrance is 20-35% in general, but significantly higher in Italy. Seven gene loci have been implicated in ARVD. The incidence of ARVD is about 1/10,000 in the general American population, although some studies have suggested that it may be as common as 1/1,000. It accounts for up to 17% of all sudden cardiac deaths in the young. In Italy, the incidence is 40/10,000, making it the most common cause of sudden cardiac death in the young.

Up to 80% of individuals with ARVD present with syncope or sudden cardiac death. The remainder frequently present with palpitations or other symptoms due to right ventricular outflow tract (RVOT) tachycardia.

Apoptosis (programmed cell death) appears to play a large role in the pathogenesis. It is unclear why the right ventricle is predominantly involved. The disease process starts in the subepicardial region and works its way towards the endocardial surface, leading to transmural involvement. The left ventricle is involved in 50-67% of individuals. If the left ventricle is involved, it is usually late in the course of disease, and confers a poor prognosis.

90% of individuals with ARVD have some EKG abnormality. The most common one seen in ARVD is T wave inversion in leads V1 to V3.

Transvenous biopsy of the right ventricle can be highly specific for ARVD, but it has low sensitivity. A biopsy sample that is consistent with ARVD is found to have > 3% fat, >40% fibrous tissue, and <45% myocytes.

A postmortem histological demonstration of full thickness substitution of the RV myocardium by fatty or fibro-fatty tissue is consistent with ARVD.

There is no pathognomonic feature of ARVD. The diagnosis is based on a combination of major and minor criteria. The diagnosis is based on a combination of major and minor criteria, and requires either 2 major criteria or 1 major plus 2 minor, or 4 minor criteria.

Many of these patients have symptoms associated with ventricular tachycardia, such as palpitations, light-headedness, or syncope. Others may have symptoms and signs related to right ventricular failure, such as lower extremity edema, or liver congestion with elevated hepatic enzymes. Unfortunately, sudden death may be the first and sole manifestation of disease.

The goal of management of ARVD is to decrease the incidence of sudden cardiac death. This raises a clinical dilemma: How to prophylactically treat the asymptomatic patient who was diagnosed during family screening.

Sotalol, a beta blocker and also a class III antiarrhythmic agent, is the most effective antiarrhythmic agent in ARVD. Other antiarrhythmic agents used include Amiodarone and conventional beta blockers (i.e., Metoprolol). If antiarrhythmic agents are used, their efficacy should be guided by series ambulatory Holter monitoring, to show a reduction in arrhythmic events.

Individuals with decreased RV ejection fraction and dyskinetic portions of the right ventricle, may also benefit from long term anticoagulation with

warfarin to prevent thrombus formation and subsequent pulmonary embolism.

Implantable cardioverter-defibrillator devices (ICD's) are the most effective prevention against sudden cardiac death.

Cardiac transplant surgery is only rarely performed in ARVD. It may be indicated if the arrhythmias associated with the disease are uncontrollable or if there is severe bi-ventricular heart failure that is not manageable with routine pharmacological therapy.

All first degree family members of the affected individual should be screened for ARVD. This is used to establish the pattern of inheritance. Screening should begin during the teenage years unless otherwise indicated. Screening tests include: Echocardiogram, EKG, holter monitoring, cardiac MRI, and exercise stress test.

ARVD, Sudden Death, Pre and Postmortem Diagnosis

G89 Cardiac Death in Anabolic Steroid Abuse: A Pathological and Toxicological Study

Claudio Terranova*, and Massimo Montisci, PhD, University of Padova, Section of Legal Medicine, via Falloppio n.50, Padova - Italy; Padova, 35121, ITALY; Cristina Basso, and Gaetano Thiene, via Gabelli 61, Padova, 35121, ITALY; and Santo Davide Ferrara, PhD, University of Padua - Section of Legal Medicine and Forensic Toxicology, Via Falloppio 50, Padua, 35121, ITALY

After this presentation, participants will understand the proposed methodological approach in analysis of cases of doping-related death. The presentation will cover reports in the scientific literature of doping-related deaths due exclusively to the use of anabolic androgenic steroids (AAS).

This presentation will impact the forensic science community by highlighting the importance of a correct methodological approach in such cases, and the possible cause-effect relation between AAS intake and cardiac death.

The true extent of doping is underestimated. The absence of chemico-toxicological findings in biological samples is a limitation in epidemiological studies, conducted as surveys on the living or case histories of the dead. Literature reports of doping-related deaths due exclusively to AAS confirm that the phenomenon is underestimated and that epidemiological data from postmortem and intra vitam studies are contradictory.

The present work describes two cases of the death of young athletes who had taken AAS; cardiopathological evidence is discussed in relation to studies in the relative literature.

The methodological approach is based on the following steps: (1) assessment of circumstances, (2) analysis of medical documentation, (3) external examination and autopsy, (4) microbiological analysis, (5) chemico-toxicological analysis, and (6) interpretation of results.

Case 1 - A body-builder aged 32 was found dead in his home. Medical history: Subject had taken AAS for years. He had recently stopped taking them, due to unidentified side-effects. Postmortem findings: External examination, excessive muscular development. Cadaveric section: cardiomegaly, with concentric hypertrophy of the left ventricle (LV). Histology: focal lymphocytic myocarditis and adipose dystrophy in disarray at the apex of the right ventricle. Microbiological analysis: Molecular study by Polymerase Chain Reaction (PCR): negative for cardiotropic viruses. Toxicological analysis: Screening and confirmatory chromatographic techniques to search for xenobiotics were negative.

Case 2 - A body-builder aged 31, accustomed to practicing martial arts, unexpectedly lost consciousness during training. Hospitalized in intensive care, he died 72 hours later of cardiac failure and acute hepatorenal failure.

The medical history included astenia, dyspnea, and perimalleolar edema. The clinical picture had worsened ten days before death. Also was reported long-term intake of AAS (boldenone, dromostanolone, enanthate methenolone, stanozolol, trenbolone). Postmortem external examination: Excessive muscular development. Cadaveric section, dilatative cardiomyopathy, with endocardial thrombosis. Histology: Marked dysmetria of hypertrophic myocytes, with diameter up to 30 μ ; dyschromic and

dysmetric nuclei, evident interstitial fibrosis, and rare inflammatory infiltrates. The subendocardial trabeculae, especially of the right ventricle (RV), showed extensive areas of colliquative myocytolysis in repair phase. Microbiological analysis: Molecular study by PCR positive for Epstein-Barr Virus (EBV). Toxicological analysis: Screening (GC-MS) and chromatographic (GC-MS/MS) confirmatory techniques to reveal xenobiotics in hair were positive for AAS (stanazolol).

A cause-effect relation between AAS and cardiac death can only be demonstrated by applying rigorous methods of investigation. Further clinical and experimental studies are needed for further in-depth knowledge of the pathogenetic and physiopathological role played by AAS in causing cardiac death. In particular, clarification is needed on the possible effects of AAS on sympathetic control of the cardiac function, related to myocardial contractility and vascularization.

Anabolic Androgenic Steroids, Cardiac Death, Doping

G90 A “Café Coronary” in a 2-Year-Old: Case Report

Jennifer L. Shuttlesworth, MD*, University of Texas Medical Branch, 301 University Boulevard, Route 0743, Galveston, TX 77555; and Stephen M. Pustilnik, MD, Galveston County Medical Examiner’s Office, 6607 Highway 1764, Texas City, TX 77591

After attending this presentation, attendees will understand the history of the term “café coronary” and the mechanisms, genetics, presenting signs and symptoms, and pathologic findings of abnormal cholesterol metabolism involved in familial hypercholesterolemia.

This presentation will impact the forensic community by reviewing the role genetic diseases play in fatal, premature pediatric coronary artery disease. During café coronary events, myocardial ischemia should be considered as a cause of death, even in the pediatric population, and especially if there is a family history of premature coronary artery disease or familial dyslipidemia.

“Café coronary” is a term used to describe a sudden attack resulting in death that occurs during or shortly after eating, often in the elderly, and is secondary to choking; however, the death is erroneously attributed to coronary artery disease. In children and adolescents, the opposite scenario, death in a suspected choking victim having a final diagnosis of myocardial ischemia secondary to coronary artery disease, is extremely rare.

Childhood is a critical period in which dietary and lifestyle patterns have long-term implications for coronary heart disease risk in adult life. Smoking, high intake of dietary total fat and saturated fat, low exercise level, and excessive alcohol consumption are correlated with elevated serum cholesterol, obesity, and hypertension in children, as well as a predisposition to premature death from coronary heart disease.

Children and adolescents can be at an even higher risk of cardiovascular disease if there is a family history of premature coronary artery disease or familial dyslipidemia. Of the primary hyperlipidemias, familial hypercholesterolemia (FH) is the most common and the most documented to have important cardiovascular consequences beginning in childhood. FH is an inherited dominant condition due to a defect in the LDL receptor gene and is usually discovered when there are increases in plasma total and LDL cholesterol in the child and in at least one of the parents. More than 600 different LDL-receptor mutations have been described. Mutations of the LDL-receptor cause significantly elevated LDL levels. This inability for cholesterol uptake leads to premature atherosclerosis and a very high risk of early cardiovascular disease and myocardial infarction. Patients with homozygous FH manifest cardiovascular disease within the first two decades of life, and may present within the first decade of life with physical findings related to cholesterol deposition, such as tendon xanthomata, cutaneous xanthelasma, or corneal arcus. FH heterozygotes usually present with problems in early to mid-adulthood.

A 2-year-old Hispanic male appeared to be suffering from a “café coronary” while eating, but was actually suffering from acute myocardial

ischemia secondary to >90% stenosis of multiple coronary arteries. Initial responders and emergency department personnel proceeded with resuscitative procedures/protocols in response to a presumed choking/asphyxia event. Autopsy revealed extensive cholesterol deposition in the coronary arteries with additional deposits found throughout the aorta and within the skin (xanthomas). The decedent’s family history was significant for a father and 12-year-old sister with hypercholesterolemia. A recent visit to the pediatrician revealed fasting plasma total cholesterol >400 mg/dl. It is recommended that medicolegal death investigators become familiar with the possibility of an acute cardiac death in young children with a family history of abnormal cholesterol metabolism.

Café Coronary, Children, Familial Hypercholesterolemia

G91 Identification of Twenty Charred Victims of a Helicopter Accident, Africa

Laurent Martrille, MS, MD*, Service de Médecine Légale, CHU Lapeyronie, 191 Avenue du Doyen Gaston Giraud, Montpellier, CEDEX 5 34295, FRANCE; Charles Georget, DMD, Stéphane Chapenoire, MD, Jean Paul Tissier, MS, and Laurent Chartier, PhD, CTGN, IRCCN, 1 Boulevard T Sueur, Rosny Sous Bois, 93111, FRANCE; Didier Buiret, MS, SCIJ, 31 av Franklin Roosevelt, Ecully, 69134, FRANCE; Gérard De Lassus, MS, IJPN, Paris, 75000, FRANCE; and Eric Baccino, MD, 371, av du Doyen Gaston GIRAUD, 34295 Montpellier, Hôpital Lapeyronie, Cedex 5, FRANCE

This presentation offers a paradigm for the identification of multiple charred bodies in situations where there is no existing medicolegal infrastructure.

This presentation will impact the forensic science community by demonstrating how a rush to immediate autopsy is not always the best first step. A first triage including sex, size, and personal effects allowed quick matching with antemortem data.

Since each mass disaster presents unique challenges, the medicolegal response must be tailored to the circumstances at hand. Scientific standards for identification vary from country to country, often in proportion to the urgency of identification and the country’s scientific capabilities.

On June 11 2007, a helicopter transporting twenty supporters of a soccer squad, among them two French nationals, ignited a couple of feet off the ground at an airport in Africa; investigation revealed that the private helicopter company was not certified to fly. The bodies, unnumbered, had been simply repatriated to local morgue. No forensic investigation were performed locally. The French embassy asked the french government to send a team to Africa in order to identify the french bodies and to help local government to identify their bodies. As the bodies were charred, the identification procedure might include all the victims.

A seven member team of French forensic experts, including two pathologists and an odontologist, were dispatched to the scene, accompanied by half a ton of equipment; a one week mission was planned.

The first step was to petition the local judiciary to confer official status on the mission. Next, a unit of the team worked with families to organize intake of antemortem data (medical and dental history, descriptions of personal effects) and exemplars for possible DNA comparison.

A second unit worked on analyzing the bodies. A decision was made to do an intake exam to assign the bodies case numbers, determine the sex and size, then describe any personal effects. This preliminary triage facilitated more exacting processing with regards to comparison with available antemortem data (scars, prostheses, dental irregularities). With that goal, an autopsy (minimal autopsy following the Interpol procedure) with odontologic evaluation was conducted on each body, and a segment of femur retained for possible DNA testing.

On-site identification was possible for fourteen of the twenty bodies as follows: dental charting – eight bodies; radiographic comparison – two

* Presenting Author

bodies; confirmation of a hip prosthesis - one body; anthropological identification of an old fracture – one body; identification by highly specific ritual scars – two bodies; fingerprints – one body. Some bodies were identified by multiple modalities. Finally, for six bodies, genetic testing was the only possible option, and was accomplished through mitochondrial DNA extracted from bone specimens sent to France packed in dry ice. Location work took one week, with DNA identification of the final six bodies completed in three weeks.

All site work was done by the specially french trained team, equipped to perform postmortem examinations without relying on local infrastructure (with the exception of access to water). This team includes police officers, crime scene investigators, forensic odontologists, and forensic pathologists, all trained in identification methods and technics.

The authors experience demonstrates that a rush to immediate autopsy is not always the best first step. In this case, preliminary triage on the basis of sex, size and personal effects allowed quick matching. Time for identification was reduced, and the bodies were rapidly released to families as identifications progressed, easing the political pressure.

Forensic, Mass Disaster, Identification

G92 Risk Factors for Pedestrian Deaths

William T. Gormley, MD, PhD, and Anna Noller, PhD, Office of the Chief Medical Examiner, Commonwealth of Virginia, 400 East Jackson Street, Richmond, VA, 23219*

After attending this presentation, attendees will understand some of the pertinent risk factors associated with pedestrian deaths.

This presentation will impact the forensic community and public health agencies by documenting and highlighting factors which can help focus injury prevention strategies.

All pedestrian deaths investigated by the Central Virginia District Office of the Chief Medical Examiner in the years 2002 through 2006 were reviewed using police reports, death certificates, and medical examiner investigation and autopsy reports. The decedent information and circumstances of the death were extracted to analyze factors such as age, sex, race, manner of death, intoxication, time of day, season, location of death, activity of decedent, and vehicles involved.

Approximately 70% of all deaths were adults (21 to 65 years old) and 70% of all deaths were males. The rate of pedestrian deaths (per million) was 21 for males compared with 8.7 for females. Rates were highest for Hispanics (24.2) followed by African Americans (19.3) then non-Hispanic Caucasians (12.1).

Considering individual risk factors in adult pedestrian deaths, the leading factor was darkness with approximately 76% of deaths occurring at night. The second most prominent factor was alcohol intoxication (Blood Alcohol $\geq 0.08\%$ by weight by volume) present in 44% of pedestrian deaths. The next most common factors were crossing a road (41%) or walking along or in a road (25%). Almost 8% of the pedestrian deaths were associated with a domestic dispute and 88% of the victims were male. Nearly 7% of the pedestrian deaths occurred in victims of or responders to a previous motor vehicle accident.

Most of the pedestrian deaths were certified as accidents (94%). Only 4% of the pedestrian deaths were certified as suicides but in an additional 6% of the deaths there were circumstances which were suspicious for but not diagnostic of suicide.

Education and enforcement focusing of risks of darkness, alcohol use and pedestrians crossing or walking on roads are focus areas for prevention. Pedestrians and responders on roads after motor vehicle collisions are at great risk. Domestic disputes are associated with a surprising number of pedestrian deaths. Pedestrian deaths require careful investigation to correctly establish manner of death.

Pedestrian, Motor Vehicle, Death

G93 Cervical Spine Injuries in Fatal Traffic Crash Victims: Microscopy and Diagnostic Imaging Findings

Lars Uhrenholt, DC, and Annie Vesterby Charles, DMSc, University of Aarhus, Institute of Forensic Medicine, Peter Sabroes Gade 15, Aarhus C, Europe 8000, DENMARK; Ellen Hauge, MD, PhD, Research Unit for Rheumatology and Bone Biology, Aarhus University Hospital, Aarhus Sygehus (NBG), Denmark; and Markil Gregersen, DMSc, University of Aarhus, Institute of Forensic Medicine, Peter Sabroes Gade 15, Aarhus C, Europe 8000, DENMARK*

The objective of this presentation is to familiarize the attendees with the presence of discrete lesions in the cervical spine facet joints in fatal traffic crash victims based on a large case-control forensic autopsy study utilizing advanced diagnostic imaging procedures and histological methods.

This presentation should encourage forensic specialists and researchers to include detailed examination of the posterior elements of the spinal column in the evaluation of trauma victims. Furthermore, clinical sciences should consider these findings as potentially relevant in cases of cervical spine symptomatology after severe road traffic crashes despite negative diagnostic imaging evaluation.

Occult lesions have previously been identified in the cervical spine in case studies on autopsy material using diagnostic imaging procedures and microscopy; very few case-control studies have, however, been performed.

The lower cervical spine facet joints from 42 subjects (20 fatalities from passenger car traffic crashes (cases) and 22 decedents due to non-traumatic causes (controls)) were removed *en bloc* during autopsy. The specimens were examined with: (1) advanced diagnostic imaging procedures (conventional x-rays, computed tomography and magnetic resonance imaging), (2) stereomicroscopy of 3-mm thick anatomical slices, and (3) microscopy of 10 μ m thick stained histological sections. Each facet joint was examined and described systematically with each of the three methods. The diagnostic imaging examination included evaluation of fractures and bleeding, the stereomicroscopy included evaluation of fractures, bleeding and damage to the synovial folds, and the microscopy included evaluation of fractures, bleeding in and disruption of the folds and haemarthrosis. Furthermore, age-related changes were evaluated microscopically with regard to cartilage fibrillation and fissures, vascular invasion of the tidemark and semi-quantitative histomorphometric measurements of the cartilage thickness, subchondral bone thickness, cartilage length, and percentage overlap of the anterior and posterior folds. Results from the diagnostic imaging procedures and the stereomicroscopy were compared to the microscopical findings.

Lesions in the lower cervical spine facet joints were common, particularly in the soft tissues, including bleeding in the joints spaces and the synovial folds. Among the diagnostic imaging procedures, computed tomography was the most sensitive towards identifying facet fractures, whereas soft tissue lesions could not be identified reliably in any of the diagnostic imaging procedures. None of the stereomicroscopical findings correlated significantly with the microscopical findings. Microscopical examination was the most sensitive method and identified all facet fractures, haemarthrosis, and bleeding in the folds. The microscopical findings correlated well with the exposure to trauma. None of the osseous or soft tissue lesions in the cervical spine facet joints were identified during the autopsy. Furthermore, histomorphometric data were collected for the normal anatomy of the lower cervical spine facet joints.

Discrete injuries in the lower cervical spine facet joints are common after fatal road traffic crashes. Osseous lesions of the facet joints can be reliably identified on computed tomography whereas soft tissue lesions can not. Stereomicroscopical examination does not reliably identify lesions in the facet joints in comparison to microscopical examination which identifies both osseous and soft tissue lesions in great detail.

This presentation should encourage forensic specialists and researchers to include detailed examination of the posterior elements of the spinal column in the evaluation of trauma victims. Furthermore, clinical sciences should consider these findings as potentially relevant in cases of cervical spine

symptomatology after severe road traffic crashes despite negative diagnostic imaging evaluation.

Fatal Traffic Crash, Cervical Spine Injury, Investigation

G94 Reconstruction of a Fatal Dragster Crash

Michael J. Shkrum, MD, London Health Sciences Centre, Department of Pathology, 339 Windermere Road, London, Ontario, N6A 5A5, CANADA; Kevin J. McClafferty, BESc*, Multi-Disciplinary Accident Research Team, Faculty of Engineering, University of Western Ontario, London, Ontario N6A 5B9, CANADA; and John R. Fernandes, MDCM, Forensic Pathology Unit, Hamilton Health Sciences, 237 Barton Street, East, Hamilton, Ontario L8L 2X2, CANADA*

After attending this presentation, attendees will understand the basic principles in crash reconstruction, vehicle crash dynamics, measures of impact severity, occupant kinematics, seatbelt overloading, and biomechanics of injury in the context of an unique type of motor vehicle collision.

This presentation will impact the forensic science community by presenting concepts in crash reconstruction vehicle crashworthiness, occupant protection and human tolerance to impact by an in-depth analysis of an uncommon type of high-severity collision, this presentation will be of interest to all motor vehicle collision investigators.

This presentation examines a number of different concepts in crash reconstruction, vehicle crashworthiness, occupant protection and human tolerance to impact through the in-depth analysis of an uncommon type of high-severity collision. This illustrative case will be of interest to anyone investigating motor vehicle collisions and consequent injury patterns.

A 17-year-old female driver lost control of her rail-type dragster at the finish line during a routine performance run. The vehicle struck a rigid left concrete barrier running parallel to the track. The driver's seatbelt failed during the crash, and she was ejected and fatally injured. The cause of the seatbelt failure and its role in the death of the young woman were major considerations during the in-depth investigation of the crash.

The light stiff dragster rail was propelled by a jet engine mounted behind the seat and was traveling at a speed of 305 mph when it suddenly veered to the left at the finish line. The driver shut off the jet engine just past the finish line, and the vehicle began to decelerate rapidly due to large aerodynamic forces that also put the vehicle into a hard counterclockwise rotation. The "jet car" was traveling at approximately 280 mph and slipping sideways when it struck the barrier with its front end just 80 yards past the finish line. At impact, the approach angle of the vehicle's center of mass was 9.3 degrees to the barrier as indicated by a single tire mark. The component of the vehicle's velocity directed perpendicular to the barrier was 45 mph. Impact speed is often a poor measure of crash severity, and the velocity change (delta-V) and time duration (delta-t) of the impact must be considered. The delta-V in this case would be similar in magnitude to the component of the impact velocity that was directed perpendicular to the barrier. A delta-V of 45 mph is indicative of a severe crash. By comparison, full-frontal passenger vehicle crash tests into fixed rigid barriers are conducted at test speeds of 30 mph by regulatory agencies in North America. While the delta-V sustained by the dragster was very high and well beyond the compliance limits of passenger vehicles, there are additional considerations when evaluating impact severity. Due to the low mass and very stiff construction of the vehicle it sustained minor front-end crush. As a result of the short ride-down distance, the delta-t would be much less than a similar severity crash by a passenger vehicle. Consequently, the resulting decelerations sustained by the dragster were very large, and the impact extremely severe.

The occupant compartment remained intact, but the driver's five-point restraint harness failed during the crash. The left lap belt, right lap belt latch plate and central crotch strap separated due to occupant loading. The failure of the left lap belt occurred at the adjuster mechanism and appeared similar to the restraint failure observed after Dale Earnhardt's fatal NASCAR crash. The dragster driver was ejected and slipped out of her helmet, which remained tethered to the vehicle. Both driver and vehicle traveled approximately

275 yards from the point of impact before coming to rest near the barrier. The driver sustained severe injuries to the head, neck, torso and abdomen. Some of the injuries that contributed to her death resulted from excessive lap belt loading.

This case is an example of high severity crash occurring in a unique vehicle. The severity of the collision is due not only to the high delta-V of the crash but also its short time duration. Irrespective of the restraint system integrity, a fatal outcome was predictable.

Dragster, Crash, Reconstruction

G95 Death Due to Aquatic Erotic Asphyxia - Accident or Homicide?

Andrea Zaferes, BA, PO Box 211, Hurley, NY 12443; and Kari B. Reiber, MD, and Dennis J. Chute, MD, Office of the Medical Examiner, Dutchess County Department of Health, 387 Main Street, Poughkeepsie, NY 12601*

The objective of this presentation is to alert medical examiners, medico-legal investigators and other forensic experts to unusual and potentially deadly forms of erotic asphyxial behavior in an aquatic environment. Our concern is that such behavior can be misconstrued as autoerotic and classified "accident" in the event of a death.

This presentation will impact the forensic science community by illustrating that aquatic erotic asphyxia is a potentially deadly activity that can be a venue for more sinister activities such as aquatic sexual sadism and child abuse. Since aquatic erotic asphyxia requires the participation of two or more individuals, it should not be confused with autoerotic asphyxia. In the event of a death, a thorough investigation is needed to assign manner of death.

Accidental autoerotic deaths generally occur during solitary sexual activity involving the use of props or other stimulatory devices, when the victim miscalculates or when a safety mechanism or breathing apparatus fails. Some of the mechanisms used to produce cerebral hypoxia include ligatures, plastic bags, body wrapping and submersion in water. Aquatic erotic asphyxia (AEA) a potentially dangerous but less known form of erotic asphyxial behavior, may involve more than one participant, whereby the manner of death is at issue in the event of a death. Illustrative cases and a brief review of the literature will be presented.

AEA and its many subcategories as advertised on the internet with particular attention to the more pernicious forms of the practice such as aquatic sexual sadism and the forceful immersion of children are described. Surprisingly, references to aquatic pedophilia can be found on some of the websites catering to "aquaphiles". AEA can involve more than one participant in various gender combinations, with one dominant figure dunking or drowning a submissive figure, or with two individuals wrestling under water for dominance. AEA enthusiasts are careful to avoid injury and even post detailed medical questionnaires on their websites. AEA activity sometimes involves the use of actors wearing underwater makeup and props to ensure a safe and controlled environment. Aquatic sadists on the other hand derive pleasure from the dunking-related torture and/or actual drowning of another person, and promote more "realistic" scenarios.

Given that the AEA community is becoming increasingly organized, with personal ad websites, commercially available videos, DVD's and photographs, and even conventions and hosted parties, the authors strongly recommend that the practice be taken into consideration when investigating a death in water. Investigators should search for unusual items such as cinderblocks, cut lengths of rope, large clear plastic tarps, diver weight belts, unusually set-up scuba regulators, large empty fish tanks, and other apparel not usually worn in hot tubs or pools. Evidence suggesting the participation of more than one individual should also be carefully looked for, since the death scene may have been altered or sanitized. The concern is that when aquatic erotic asphyxial activity results in the death of a participant, we may be dealing with homicidal violence and sexual sadism and not accidental autoerotic activity. The fact that death can potentially occur after the person

exits the water further underscores the need for a thorough and thoughtful death investigation whenever a drowning is suspected.

Aquatic Erotic Asphyxia, Aquatic Sexual Sadism, Autoerotic Asphyxia

G96 Bear Facts Alaska: The Good, The Bad, and the Ugly

Kathleen Day, MA, MS, University of Alaska, Anchorage, PO Box 670276, Chugiak, AK 99567; and Franc Fallico, MD, Office of the Chief Medical Examiner, State of Alaska, 4500 South Boniface Parkway, Anchorage, AK 99567*

After attending this presentation participants will understand characteristic trauma patterns found in fatal bear maulings , how these patterns relate to bear etiology in the wild and the latest research about and how to avoid bear attacks. The presentation will include autopsy results from highly publized attacks, as well as those that are less well known looking at data from all species of bears.

This presentation will impact the forensic community/humanity by providing the latest information on bear fatality trauma and pathology with data accumulated by wildlife biologists in a synthesized fashion. It will provide the forensic community with a model of the injury patterns that are found in fatal bear attacks and hopefully help in the prevention of future attacks.

There has not been much forensic research conducted in the realm of bear fatal bear maulings and attacks. Because human development continues to encroach on natural habitats the numbers of bear- human encounters appear to be on the increase. A review of the literature consists mainly of brief case studies or papers that have been written in past decades in the context of emergency medicine or wildlife biology. Although being fatally mauled by a bear may be at the fringes of popular forensic science, these deaths usually enter the realm of forensic pathologists either because the death is unattended, suspicious or gets attention from the media. Because of these reasons, pathologists should have an understanding of injury patterns and a general understanding of why they occur. Biologists have contributed a great deal of data to aid pathologists in explaining why particular injuries occur. It is hoped that when fatal bear injuries are carefully documented and analyzed, pathologists can reciprocate and help biologists better understand bear species behavior with the goal of preventing further deaths.

Numerous case studies of bear mauling injury patterns found at autopsy are presented as well as the most recent scientific data from biologists that examine the specific nature of bear-human interactions and the best way to avoid them.

Bear Fatality, Trauma Patterns, Etiology

G97 Concussive Head Injury and Alcohol

Jane Willman Turner, PhD, MD, St. Louis University School of Medicine, 1402 South Grand Boulevard, St. Louis, MO 63104*

Upon completion of this presentation, attendees will gain an appreciation of the combined effects of ethanol and concussive head injury in causing sudden death. A detailed review of autopsies of individuals whose cause of death was concussive head injury with alcohol will be presented along with outlines of the scene investigations and examination of the toxicology results.

This study is of use to the forensic community in supporting the theory that sudden death occurs from concussive injry of the brain in the presence of alcohol. Consideration of this entity can unquestionably impact the medicolegal investigation of some deaths.

The spectrum of diffuse brain injury ranges from mild concussive injury to diffuse axonal injury resulting in death. The cases of diffuse axonal injury are often apparent to the forensic pathologist at the time of autopsy as the associated markers of injury are often present. That is to say, in cases of sudden death from severe head injury, significant intracranial injuries are often

present. However, there exist rare cases of head injury in which only soft tissue injury is found and there are no epidural, subdural or subarachnoid hemorrhages, or gross injuries to the brain, and yet sudden death has occurred. In these specific rare cases the blood ethanol levels are elevated. The proposed mechanism of death is that the combined effect of concussive brain injury and elevated blood alcohol produces postinjury apnea, leading to sudden death. Normally, concussive brain injury rarely causes postinjury apnea. However, the presence of elevated blood ethanol, a respiratory depressant, appears to potentiate fatal apnea in even mild concussive injury.

A computer search was used to identify all cases in the City of St. Louis and four of the adjacent counties in the past ten years. Eight such cases were found. The ages ranged from 23 to 64 years. Each of the individuals suffered blunt trauma about the head and/or face and had blood ethanol levels ranging from 0.18 to 0.40 g/dl. Two of the cases involved women who had been sexually assaulted and in which the manner of death was homicide. In each of these cases the thorough scene investigations and the circumstances surrounding their deaths exclude other possible causes of death.

Milovanovic and DiMaio published a series of cases of death due to concussion and alcohol in 1999. This review of autopsies in the St. Louis metropolitan area corroborates the findings of these authors and their description of the pathophysiologic processes that take place in such deaths and provides additional cases for review.

This study is of use to the forensic community in supporting the theory that sudden death occurs from concussive injury of the brain in the presence of alcohol. This diagnosis must be seriously considered in any death in which there is injury to the head without visible injury of the intracranial structures and the blood ethanol levels are elevated. Overlooking this cause of death may result in erroneous classifications of manner of death as natural or accidental, for example, when the manner may indeed be homicide. As such, consideration of this entity can unquestionably impact the medicolegal investigation of some deaths.

Blunt Head Trauma, Concussion, Alcohol

G98 Preliminary Study and Potential Role of CT Imaging Autopsy in the Investigation of Death Due to Accidental Blunt Trauma

Barry Daly, MD, and Clint W. Slicker, MD, University of Maryland Medical Center, Diagnostic Imaging Department, 22 South Greene Street, Baltimore, MD 21201; Zabiullah Ali, MD, Dawn Zulauf, RN, and Jack M. Titus, MD, Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201; Mary G. Ripple, MD, 68 Bluebird Road, Port Deposit, MD 21094; and David R. Fowler, MD, Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201*

The goals of this presentation are: (1) to understand the investigational technique of 2 dimensional and 3 dimensional CT imaging autopsy in the medical examiners investigation of death, (2) to review a U.S. medical examiners office early experience and results of CT imaging autopsy compared with conventional autopsy for fatal accidental blunt trauma, and (3) to describe circumstances where CT imaging autopsy may evolve into a triage tool for the medical examiners investigation of sudden death.

This presentation will impact the forensic community and humanity by addressing the potential role of non-invasive CT imaging autopsy to replace conventional autopsy or enable performance of limited, focused autopsy in the U.S. medical examiners investigation of fatal accidental blunt trauma. CT imaging autopsy has potential for rapid and cost effective investigation in such circumstances, including mass casualty investigations. It may also provide options in the setting of religious and cultural objections to conventional autopsy.

Recent publications have suggested a potential role for high-resolution CT imaging using 2D and 3D techniques in the forensic investigation of death. This pilot study evaluated the sensitivity of CT imaging autopsy for major injuries and accuracy for the cause of death. The study also evalua-

ted the potential role of CT imaging autopsy as a replacement for or adjunct to conventional autopsy in the investigation of traumatic accidental death within a U.S. state medical examiner system.

Of 40 decedents prospectively investigated with whole body 40-detector row 2D and 3D CT within 24 hours of death, 27 were identified as victims of suspected accidental blunt trauma. Each CT study acquired approximately 3,000 images in 10 minutes scanning time and required 30 minutes interpretation time. As this was a new technique, CT was interpreted with consensus reading by 2 radiologists and compared with medical examiners autopsy results for major findings and cause of death in all cases.

CT imaging autopsy correctly identified 217 major traumatic findings (average 8/decedent, sensitivity 93.4%). It correctly identified a specific injury or combination of blunt trauma injuries as the cause of death in 25 cases and excluded traumatic death in 2 others. Fourteen major false-negative CT findings included non-displaced atlanto-occipital subluxation ($n=4$); fractures of the ribs or sternum ($n=3$); lacerations of the aorta ($n=3$), bronchus ($n=1$), and liver ($n=1$); cardiac contusion ($n=1$); avulsion of the renal pedicle ($n=1$). CT identified 8 major findings not detected at conventional autopsy: fractures of sacrum ($n=2$), mandible ($n=2$), skull base ($n=2$), cervical spine ($n=1$); lung lacerations ($n=1$). Suspected significant air embolism associated with major skull base or thoracic trauma ($n=6$) and tension pneumothorax ($n=1$) were noted on CT but not found at autopsy, likely related to the technique used.

This early experience suggests that CT imaging autopsy has promise as a sensitive tool for the detection of major injuries and accurately determines the cause of death after accidental blunt trauma. It may be insensitive for some major findings including non-displaced fracture or subluxation and the exact site of vascular injury in the setting of obvious major hemorrhage. Air embolism appears to be more easily detected by CT than conventional autopsy and may play a greater role in death due to blunt trauma than previously recognized.

CT Imaging, Autopsy, Accidental Blunt Trauma

G99 Stairway Related Deaths: An Analysis of Autopsy Findings of Individuals Found Dead at the Bottom of a Stairway

Joyce L. deJong, DO, and Michael A. Markey, MD, Sparrow Forensic Services, Sparrow Hospital, 1215 East Michigan Avenue, Lansing, MI 48909-7980; and Rudy J. Castellani, MD, University of Maryland, Department of Pathology, 22 South Greene Street, Baltimore, MD 21201*

After attending this presentation, the attendee can expect to learn the characteristics of autopsy findings of individuals found dead at the bottom of a stairway.

This presentation will impact the forensic science community by showing that it is not possible to predict which individuals found dead at the bottom of a stairway died from injuries and which died from non-traumatic causes based on age, cutaneous injuries, or a past medical history of a disease that could cause sudden death.

Cases from the Sparrow Health System Forensic Pathology Department (Lansing, Michigan) database were searched for deaths of individuals found dead at the bottom of a stairway. Twenty-seven such cases were identified; all of the deaths had full autopsies and twenty-six had blood drug screens.

The cases were divided into two groups: those whose deaths were caused by injuries consistent with a fall and those in which no significant injuries were identified. The age range, natural diseases, toxicology findings, and external injuries were compared between the groups. For the group of individuals who died due to a fall, the types of lethal injuries were characterized.

Twenty-seven deaths investigated since January 1, 2000 were of individuals who were found dead at the bottom of a set of stairs. Nineteen of the twenty-seven died from injuries associated with a fall and eight of twenty-

seven were free of significant injuries.

Of the eight individuals who were found dead at the bottom of a stairway, but had no significant injuries, six were men and two were women. The age range was 48-87 years with an average age of 63 years. Six of the eight decedents had cutaneous head injuries. Six of the eight individuals had cutaneous injuries of the torso and/or the extremities. None of the individuals were free of cutaneous injuries. Seven of the eight deaths in this group resulted from atherosclerotic cardiovascular disease and/or hypertensive cardiovascular disease. One death resulted from a mixed drug intoxication with citalopram and ethanol. Cocaine intoxication was a contributing factor in one of the deaths due to cardiovascular disease. The drug screens in the remaining six were negative for significant findings. Four of the eight individuals in this subset had a reported significant chronic medical condition, known before the autopsy, that might explain a sudden death.

Of the nineteen individuals who died from injuries related to a fall, 15 were men and 4 were women. The age range of this subset was 30-93 with an average age of 63 years. Eighteen of the nineteen deaths in this category were caused by craniocerebral injuries. The one death in this group not caused by head injuries was a 93-year-old woman whose death resulted from a left femur fracture and multiple left rib fractures. Thirteen of the eighteen had cutaneous head injuries, and three of these thirteen had cutaneous head injuries and blood draining from the external auditory canal(s). Fifteen of the nineteen individuals had cutaneous injuries of the torso and/or the extremities. There were no cases of individuals without any cutaneous injuries.

Of the nineteen individuals who died from injuries due to a fall, the blood drug screens in seven were negative for significant findings. Ethanol was present in the blood of eleven of the twelve with positive findings and ranged from 0.04 – 0.30% (in six of these eleven, the level was greater than 0.20%). THC was present in the twelfth case with significant toxicology findings.

Of the eighteen individuals with lethal craniocerebral injuries, most had skull fractures, however, none of the individuals with lethal injuries had depressed skull fractures.

Ten of the nineteen individuals in this subset of individuals who died from injuries had a reported significant chronic medical condition, known before the autopsy that might explain a sudden death.

Conclusions: The majority of individuals found dead at the bottom of a stairway have sustained lethal injuries. The factors that were evaluated (age of decedent, past medical history, presence of cutaneous injuries) are not predictive of lethal internal injuries identified at autopsy. A very high percentage of individuals found dead at the bottom of a set of stairs have positive postmortem drug screens, primarily alcohol.

Stairway, Autopsy, Fall

G100 Discrimination of Falls and Blows in Blunt Head Trauma: Assessment of Predictability Through Combined Criteria

Anny Sauvageau, MD, S. Racette, BSc, and C. Kremer, MSc, Laboratoire de sciences judiciaires et de médecine légale, 1701 Parthenais Street, 12th Floor, Montreal, Quebec H2K 3S7, CANADA*

The goal of this presentation is to propose a criteria tool for the distinction of falls from blows in blunt head trauma.

This presentation will impact the forensic community by providing new insight into the evaluation of blunt head injuries.

The discrimination of falls from homicidal blows in blunt head injuries is a common but difficult problem in forensic pathology. One of the most often used criteria to evaluate this issue is the hat brim line rule. According to this rule, an injury located above the hat brim line (HBL) is more likely the result of a blow, while a fall would generally produce a wound at the level of HBL. The objective of this study was to evaluate the validity of this criterion, as long as of two other possible criteria: side lateralization of skull fractures and number of lacerations. Furthermore, a combined criteria tool

will be developed.

Over a 6-year period (2000-2005), all autopsy cases from the Montreal *Laboratoire de sciences judiciaires et de médecine légale* were analyzed. Cases selected consisted of falls downstairs, falls from one's own height, and head trauma by a blunt weapon. Upon review of photographs and autopsy reports, all cranial fractures and lacerations were positioned on figures representing the head and the skull in different anatomical views. For the present study, HBL was defined as the area located between two lines parallel to a line inspired by the Frankfort horizontal plane (horizontal plane passing through right and left porion points and the left orbitale), the superior margin passing through the glabella (G line) and the inferior margin passing through the center of the external auditory meatus (EAM line). For each case, the following elements were compiled: location of fractures in relation to HBL, side lateralization of skull fractures and number of lacerations.

A total of 114 cases were selected: 21 cases of downstairs falls, 29 cases of falls from one's own height, and 64 cases of head trauma by a blunt weapon. The location of a cranial fracture inside HBL was of little interest in the distinction of falls from blows. On the other hand, fractures located above HBL were associated to blows in 75.9% and to falls in only 24.1%. Hence, a fracture positioned above HBL was in favour of a blow ($\alpha=0.02$, contingency coefficient=0.25). Side lateralization of fractures was also of interest in the distinction of falls from blows: right skull fractures were more likely to result from falls whereas left skull fractures were more often associated with blows ($\alpha=0.007$, contingency coefficient=0.36). Even more interesting was the number of lacerations: cases presenting 3 or less lacerations were mostly falls cases (60.5%), whereas all cases (100%) with more than 3 lacerations were cases of blows ($\alpha =0.000$, contingency coefficient=0.48).

By combining those criteria, a better predicting rate was achieved. Indeed, the presence of at least two criteria in favor of a fall was successfully predicting cases in 65.9%, whereas the presence of at least two criteria in favor of a blow revealed a perfect score of 100% of successful prediction. Furthermore, by combining the three criteria altogether, the predictability of the criteria tool was even better: the presence of a combination of three criteria in favour of blows still demonstrated a success rate of 100%, while the success rate for falls reached 83.3% ($\alpha=0.001$, contingency coefficient=0.62).

Considering the previous results, the presence of a fracture above HBL, of a left side lateralization of skull fractures and the presence of more than three lacerations are criteria in favor of a blow. On the contrary, a typical fall case is more likely to present with a fracture inside HBL, a right side lateralization of skull fractures and 3 lacerations or less. A criteria tool based on combination of those criteria can achieve a predictability rate of 100% for cases of blows and 83.3% in falls cases.

Blunt Head Trauma, Hat Brim Line, Skull Fracture

G101 Unusual Death of a Transsexual (Identification of Damaging Means and Death Time)

Alessandro Dell'Erba, Sandra Cornetta, MD, Fiorenza Zotti, PhD, and Annalisa Addante, MD, PHD, Section of Legal Medicine, Place G. Cesare, BARI, 70124, ITALY*

After attending this presentation, the attendees will understand how scanning electron microscopy and immunohistochemistry can assist the forensic investigator and pathologist in correlating the scene, autopsy findings, and cause of death.

This presentation will impact the forensic science community by illustrating the importance of ancillary studies in the forensic autopsy.

February 2007 in Puglia, a transsexual homicide victim was discovered on a suburban road. The body was adjacent to the victim's automobile.

The autopsy confirmed that the cause of death was a serious encephalic concussion. There were doubts about the means of trauma, and for such a reason further analysis was conducted with the scanning electron microscope. Material that was deposited on the epidermic borders of the scalp was compared with the varnish rests of the automobile. It was suspected that the collision/impact of the victim's head was to the lower clapper of the right front door.

The time of death was evaluated by immunohistochemical surveys executed on samples of cerebral parenchyma using the anti-betaAPP antibody.

Transsexual Homicide, Damaging Means, Immunohistochemical Investigation

Pathology/Biology

G1 Sudden Unexpected Death in a Case of Human Immunodeficiency Virus (HIV) and Mycobacterium Infection Diagnosed Postmortem

Hydow Park, MD, Atlantic County Medical Examiner's Office, 201 Shore Road, Northfield, NJ 08225-2319*

After attending this presentation, attendees will learn: 1) Initial diagnosis of HIV/AIDS can be made postmortem by performing thorough histological examination and necessary laboratory tests, 2) Sudden death can occur in cases of unsuspected HIV/AIDS cases with non-tuberculous Mycobacterium infection in spleen and lymph nodes, 3) PCR technique is available for identifying Mycobacterium species in formalin-fixed paraffin-embedded tissues.

This presentation will impact the forensic community and/or humanity by assisting the forensic pathologists in better identifying HIV/AIDS cases at an early stage, so that it will benefit the immediate family and the community.

This 35-year-old female was found unresponsive at her residence at 6:00 pm. She was pronounced dead at emergency room after the usual resuscitative measures. She had a full-day work as a clerk stenographer and left work at 4:00 pm. She stated to her co-worker that she had chills while riding down on the elevator to leave work. She had a history of cervical carcinoma-in-situ that was treated with total hysterectomy and recently had laser vaporization for dysplasia of vaginal wall. She had been otherwise in good health. At autopsy the spleen was slightly enlarged and had gray nodules and there were skin ulcers in perineum. Microscopic examination of the spleen revealed ill-defined epithelioid cell granulomas containing rare acid-fast bacilli (AFB). Sections of mesenteric lymph nodes revealed lymphoid depletion and numerous AFB in ill-defined epithelioid cell granulomas. The skin ulcers were microscopically consistent with herpes simplex virus infection. In view of the presence of cervical carcinoma-situ, vaginal wall dysplasia, Mycobacterium infection, and herpes simplex skin infection, HIV-1 antibody tests (enzyme-linked immunosorbent assay and Western blot assay) were performed on a blood specimen taken at autopsy. Both tests were positive. Further investigation revealed that the decedent's brother had known that the decedent might have had HIV infection, because her ex-boyfriend had told him that she might have been infected with HIV. To identify Mycobacterium species the formalin-fixed paraffin-embedded tissues of mesenteric lymph nodes were sent to Central Arkansas VA Medical Center laboratory, where Mycobacterium tuberculosis DNA complex was not detected by use of polymerase chain reaction (PCR) assays. This case was reported as HIV/AIDS to NJ State since the diagnosis had not been made antemortem.

HIV/AIDS, Sudden Death, Mycobacterium

G2 Assisted Suicide as Practiced in the French Part of Switzerland

Sandra E. Burkhardt, MD, Jerome Sobel, MD, and Romano La Harpe, MD, Institute of Forensic Medicine, 9, Avenue de Champel, Geneva, 1206, Switzerland*

After attending this presentation, attendees will understand the legal aspects of assisted suicide in Switzerland, where the penal code condones this practice for altruistic reasons, even if not performed by a doctor; the prevalence of this type of death and the way it is treated.

This presentation will impact the forensic community and/or humanity by demonstrating how the number of cases of assisted suicide is growing every year in Switzerland, responding to the requests of very sick patients, when palliative care and other alternatives are not efficient enough anymore.

Assisted suicide is permitted in several countries and jurisdictions: Belgium, the Netherlands, the state of Oregon (USA) and Switzerland. The practice of assisted suicide is controversial leading to debates among doctors, jurists, and ethicists.

In Switzerland, article 115 of the Swiss penal code considers assistance suicide a crime if and only if the motive is for personal gain. It condones assisting suicide for altruistic reasons. This allows associations such as EXIT-ADMD (French Switzerland), EXIT German Switzerland, or DIGNITAS to assist severely ill patients under certain conditions in their desire to end their lives.

This study takes into consideration 200 cases of assisted suicide performed by the association EXIT-ADMD between 2001 and 2005. The districts of Vaud and Geneva were the primary focus of this study, with and the number of cases increasing continually over this time period. Most of the patients were female. The most frequent pathologic conditions were neoplasia, neurological diseases, and cardio-vascular diseases. The average age of patients was over 70. More than $\frac{3}{4}$ of assisted suicides occurred at home; 20 patients died at a nursing home. Due to internal policy restrictions, some of the patients had to leave the hospital or nursing home in which they were staying in order to receive assistance with their suicide.

The most common lethal substance used by patients, when assisted in their suicide, was sodium pentobarbital (between 11 and 15 grams) inducing coma within less than ten minutes, and leading to a painless death within than 30 minutes. At the moment of death, their family or relatives surrounded most patients.

Legal requirements following such a death are quite simple in Geneva. As it is a violent death, the forensic physician must examine the remains, and completes a death certificate noting the unnatural nature of death. Based on these medicolegal observations, the police officer completes a document called the "Nihil Obstat." This permits burial of the remains to take place without any other formality, allowing for full respect of the deceased and his/her family.

Assisted Suicide, EXIT Association, Switzerland

G3 Firearms Injuries: Beyond Entry and Exit Wounds

Rosa Falamingo, MD, PhD, and Francesco Vinci, MD, Section of Legal Medicine (Di.M.I.M.P.) - University of Bari, Piazza Giulio Cesare, Policlinico, Bari, 70124, Italy; and Carlo P. Campobasso, MD, PhD, Department of Health Sciences (Di.S.pe.S.), University of Molise, via De Sanctis, snc, Campobasso, 86100, Italy*

After attending this presentation, attendees will learn (1) the diagnostic features of pattern injuries made by firearms; and (2) their relevant role in criminal investigations.

This presentation will impact the forensic community and/or humanity by showing several case studies in which patterned abrasions and wounds were useful in the identification of the firearms used and in the reconstruction of the assaults.

Patterned injuries usually occur when the force is applied at or near a right angle to the skin surface, rather than with the skidding impact of a graze. If a weapon with a patterned surface strikes the skin, abrasions or bruises and even lacerations follow the ridges of the object if it has a

profile of varying height. Formerly it was often claimed that abrasions retained the pattern of the impacting object more accurately than other injuries such as bruises and lacerations. However, even if abrasions do preserve such patterns well, bruises and lacerations may also follow the profile of the inflicting object reproducing exactly the imprint of firearm weapons and/or its parts.

The plastic grip of a firearm weapon can easily imprint its design on the skin producing bruises and/or lacerations at the edges of the impact site such as heavy objects with firm impacts used to do. The skin between the thumb and index finger of the hand holding a pistol may slightly overlap the lumen of the barrel so that a graze wound can occur. Shape and size of pattern injuries are often useful for the identification of the weapon used in the assault. In the literature, there have been many reported cases in which additional pattern injuries have been found in the area surrounding the entry wounds produced by shotguns, revolvers, and semiautomatic pistols due to the peculiar firearm muzzle design. These findings have been used in shooting reconstruction and also to establish the range of fire. It is well known that if the discharge is contact, the muzzle of a firearm can imprint an abrasion on the skin surface. Hard and loose-contact wounds have been described depending on whether the muzzle of the weapon is jammed "hard" against the skin (so that the skin envelops the muzzle) or held lightly against the skin. Even when there is a gap between the muzzle and the skin, for example when the barrel of the weapon is held at an acute angle to the skin, the muzzle can imprint part of its circumference thus producing angled or incomplete-contact wounds. Difficulties in interpreting such pattern injuries may occur when the injury involves a surface not completely flat such as the head. In these cases the position of the edge that digs in most deeply may give an indication of the angle of the blow.

Pattern Injuries, Firearm Wounds, Ballistic

G4 The Mummified Corpse Found in a Domestic Setting

Carlo P. Campobasso, MD, PhD, Department of Health Sciences (Di.S.pe.S.), University of Molise, via De Sanctis, snc, Campobasso, Italy 86100, Italy; and Rosa Falamingo, MD, PhD, Domenica Laviola, MD, Claudia Liuzzi, MD, and Francesco Vinci, MD, Section of Legal Medicine (Di.M.I.M.P.) - University of Bari, Piazza Giulio Cesare, Policlinico, Bari, 70124, Italy*

After attending this presentation, attendees will gain an understanding of the forensic and ethical issues pertaining to unattended deaths of those with little or no contact with society and the mummified remains found after a significant period of time after death.

This presentation will impact the forensic community and/or humanity by presenting a case of a mummified corpse found several years after death.

Mummification refers to all natural and artificial processes that bring about preservation of the body or its parts. Such processes include primarily the drying of the soft tissues instead of liquefying putrefaction. The essential requirement for mummification is a dry environment, preferably with a moving air current, which is usually in a warm environment. The most widely known form of mummification is in hot and arid areas like Egypt, Chile, and Peru. It is also likely to occur in temperate climates especially when the body is left undisturbed in warm dry place such as closed rooms, closets, and attics.

A mummified body of an 86-year-old white male with a history of coronary atherosclerosis was found in the entryway of his apartment located in a condominium of the city of Bari (Southern Italy) approximately seven years after death. The body was sitting on the carpet in front of an easy chair, clothed in a woolen vest with dark pants and shoes. The head was lying face down on the easy chair and the scalp with long grey hair was still present. The appearances of mummification

included desiccation and brittleness of the skin, which was stretched tightly across anatomical prominences such as the cheekbones, chin, costal margin, and hips. The skin and the underlying tissues of the body were darkened, hard, forming a leathery shell over the body and making autopsy dissection difficult. The corpse was well preserved through the mummification process and no external injuries were observed. There was little evidence of insect activity. The shutters of the entry way were closed but the windows were open so that there was accessibility to air. The carpet on which the body was sitting and the upholstery of the easy chair on which the head was lying absorbed most of the early putrefactive fluids. Several empty pupae of *Lucilia sericata* and *Calliphora vicina*, cast larval skins of Dermestidae (Coleoptera) along with dermestid frass (excreta) were found on the floor close to the body suggesting a death occurred during the spring season.

Mummification often occurs in elderly bodies due to rapid dehydration of the outer surface. The rapidity of dehydration may reduce the usual swelling of the body preventing also putrefaction by enteric microorganisms, soil bacteria, and other decay organisms. The rapid drying of soft tissues may also protect the internal organs even from insect colonization as in this case where after the drying had taken place, the corpse remained in that state for many years with no insect activity at all. Larval infestation for all blow fly species is usually hindered by the rapid dehydration of the skin surface; female adults recognize dehydrated and/or mummified skin as hospitable to the larval stages which need both moisture and accessibility to air. Radiographs of the body disclosed osteoporosis but no fractures or other evidence of blunt trauma. The internal organs were well preserved. However, the cause of death was undetermined. Based on the antemortem data available the remains were rapidly identified by dental comparison. The man had been missing seven years. The neighbors stated they had thought that the man had died a long time ago. Unpaid electricity bills resulted in termination of electrical service. The paid condominium bills forced the manager of the condominium led to the entry of the apartment.

Mummification, Postmortem Changes, Forensic Taphonomy and Entomology

G5 Acute Hemorrhagic Leukoencephalopathy (Weston-Hurst Disease): A Natural Disease Presents as Head Trauma

Kenneth D. Hutchins, MD, Miami-Dade County Medical Examiner Department, Number 1 Bob Hope Road, Miami, FL 33136; and Lyla E. Perez, MD, Southern Regional Medical Examiner Office, 1175 DeHirsch Avenue, Woodbine, NJ 08270*

The goal of this presentation is to describe a case of death due to acute hemorrhagic leukoencephalopathy (AHL), a natural disease masquerading as head trauma.

This presentation will impact the forensic community and/or humanity by demonstrating how AHL, a natural occurring brain disease which may mimic brain trauma and must be considered in the differential diagnosis of cerebral hemorrhage.

Naturally occurring neurologic disease may occasionally mimic traumatic injury.

A 19-year-old man complained of headache after bouncing a soccer-ball on his head. He was admitted to a hospital where he became lethargic, then comatose. A computed tomographic (CT) scan revealed dense, bilateral, frontal lobe hematomas. Angiography did not demonstrate vascular abnormalities. A craniotomy was performed to evacuate the hematomas; however the patient died after a four day hospitalization. Further history revealed that the patient may have sustained head trauma during an altercation in the days previous to the hospital admission. Because of the possibility of a trauma related death, jurisdiction was assumed by the medical examiner and an autopsy was performed. Gross

neuropathologic examination revealed a swollen, soft brain that exhibited evidence of surgical intervention and transtentorial herniation. The frontal lobes had dense, confluent hemorrhages, located predominantly in the white matter, extending across the genu of the corpus callosum. Additional foci of hemorrhage were in the convolutional white matter of the cingulate gyrus and the internal and external capsules. There were no cortical contusions or other traumatic pathology. Histologic examination demonstrated perivascular hemorrhage surrounding necrotic blood vessels with fibrinous exudates within the Virchow Robin spaces, perivascular inflammation, and demyelination. These findings were diagnostic of AHL.

AHL, or Weston-Hurst disease, is a rare inflammatory, demyelinating disease of the brain characterized clinically by an abrupt onset of neurologic symptoms and signs with rapid progression. Its onset is frequently associated with an antecedent viral illness. The disease is usually fatal, although recovery has been described with medical treatment. The clinical differential diagnosis includes herpes simplex virus type 1 encephalitis, meningoencephalitis, encephalomyelitis, sagittal sinus thrombosis, central nervous system vasculitis, and in the elderly, congophilic angiopathy. Traumatic injuries are usually not entertained in the differential diagnosis, although the gross findings are similar to those associated with fat embolism following skeletal fractures. In this case, the unusual CT scan findings and the history of possible antecedent head injuries led to the suspicion that the lesions resulted from head trauma. This case illustrates the importance for forensic pathologists to recognize AHL as a natural disease process that may rarely mimic traumatic brain injury.

Head Trauma, Acute Hemorrhagic Leukoencephalopathy, Demyelinating Disease

G6 Weight That Kills: Adults With Natural Deaths are Heavier Than Those Dying Non-Naturally — A Cross-Sectional Study

Ana Rubio, MD, PhD, and David Reisz, BS, State of Maryland Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201; Christopher Cox, PhD, Bloomberg School of Public Health, Johns Hopkins University, Monument Street, Baltimore, MD 21205; and David M. Fowler, MD, State of Maryland Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201*

After attending this presentation, attendees will understand the impact of obesity on natural death by applying standard epidemiologic techniques to data obtained at the State of Maryland Medical Examiner Office.

This presentation will impact the forensic community and/or humanity by highlighting the problem of obesity and raising awareness of how deep and broad the problem is and the need to address it.

Introduction: The morbidity and mortality produced by obesity in the United States and other developed societies has reached epidemic proportions. Although the problem starts in childhood and adolescence, the medical impact takes hold in adult life. Clinical studies have shown the effect of obesity on cardiovascular disease, diabetes, cancer degenerative joint diseases among others, and some autopsy studies have confirmed the clinical findings.

Aim: To evaluate the magnitude and severity of the impact of obesity on mortality

Hypothesis: Excess weight is a risk factor for mortality; thus Body Mass Index (BMI) in individuals with a natural death is higher than in those with non-natural deaths (they would be alive if not for the non-natural factors).

Methods: Cross-sectional study involving young and middle age adults (ages 20 – 50 years) in the state of Maryland whose death during a recent three year period (2002-2005) was either unexpected or violent.

Cases were selected from the State of Maryland Office of the Chief Medical Examiner (OCME) database. The State of Maryland has a single,

centralized office that covers the entire state. All non-natural deaths and purely natural deaths that are unexpected or unsupervised by a physician, affecting persons under 50 years of age are transported to the office for cause of death investigation.

- Each body was measured and weighed upon arrival at the OCME.
- BMI was calculated following a standard formula ($BMI = \text{weight in kilograms} / \text{height in meters}^2$)
- Cases were tabulated by age, gender, manner of death, height, weight, BMI and BMI NIH categories (normal [$BMI < 25$], overweight [$25 \leq BMI < 30$], obese [$30 \leq BMI < 40$] and very obese [$BMI \geq 40$])
- Non-natural deaths (Accident, Suicide, Homicide and Undetermined) were analyzed separately and grouped together for comparison
- Statistical analysis included descriptive statistics and multivariate logistic regression, using likelihood ratio tests of statistical significance. Effect sizes were estimated by odds ratios (OR)
- Possible bias (systematic errors impacting the different groups differently) were sought and discussed

Results: The study included 6987 individuals, 2097 (30.0%) had natural deaths and 4890 had non-natural [1345 (19.3%) were accidents, 1210 (17.3%) were homicides, 642 (9.2%) were suicides and 1693 (24.2%) undetermined.

- The percentage of women in the natural death group was higher (34.0%) than in the non-natural deaths (21.5%), and the average age (SD) was higher for the group of natural deaths (41.3 ± 7.0) than the group of non-natural deaths (35.1 ± 9.0).
- BMI was an independent risk factor ($p < 0.0001$, OR=9.4) for natural death when adjusted for age ($p < 0.0001$, OR=15.4) and gender ($p < 0.0001$, OR=1.7 F/M) in a multivariate logistic regression analysis. Per unit of measure, BMI was a comparable risk factor to age.
- The mean (SD) BMI in natural deaths was higher than that of non-natural deaths: $29.3 (9.1)$ vs. $27.5 (6.5)$.
- The percent of natural deaths among the different BMI levels was 26.9% for people in the normal weight range, 27.9% in the overweight group, 32.1% in the obese group, and 48.6% among the very obese.

Conclusions: In an adult population, the relative frequency of natural death increases steadily with increasing levels of obesity. This increase persists when adjusted for both age and gender, indicating that obesity is an independent risk factor, comparable or greater in its effect to age.

Obesity, Body Mass Index, Natural Deaths

G7 Forensic Science “Case Derived” Templates Formulated With Relational Database Software

Gilbert E. Corrigan, MD, PhD, East Baton Rouge Coroner's Office, 4030 T.B. Hearndon Drive, Baton Rouge, LA 70807; and Sarah P. Corrigan, MS, Jefferson Parish Forensic Laboratory, Jefferson Parish Government, Metairie, LA 70001*

This presentation demonstrates the forensic science utility of commercial open-marketed relational databases in template and table production, report and forms formulations, and query fashioning.

This presentation will impact the forensic community and/or humanity by demonstrating the valuable and available merits of relational database use in the forensic sciences as a readily learned, available, and important tool in the armamentarium of the forensic scientist.

Using Microsoft Access relational database software, a series of templates are presented covering forensic science topics, especially those arising in forensic pathology and crime laboratory environment.

Templates are important graphic aids in data entry and case analysis; in relational databases they are formulated by critically selecting fields for data tables. Precise and accurate derivations of essential factors pertaining to the selected data item are necessary; however, database structures are readily edited, improve with review, making templates dynamic and progressive. The ease of template production is emphasized.

Other dimensions of relational database software are demonstrated and include the production of relational tables, the use of queries, and the production of forms and reports. Relational database application mastery is presented as a legitimate forensic science skill.

Evaluations of the available relational databases on the basis of ease of use, availability of support services and educational courses, certifications, personal application, and cost are presented. A summative reference is made available.

Relational Database, Templates, Computer Software

G8 Three Unusual Neuropathologic-Related Causes of Sudden Death

Dennis J. Chute, MD, and Kari Reiber, MD, Dutchess County Medical Examiner's Office, 387 Main Street, Poughkeepsie, NY 12601*

The goal of this presentation is to make the audience familiar with three unusual neuropathologic entities that may contribute to sudden death in the medicolegal setting.

This presentation will impact the forensic community and/or humanity by demonstrating cases that exemplify the range of neuropathologic maladies that may contribute to sudden, unexpected or suspicious deaths highlight the asset a neuropathology consultation provides and emphasize the utility of postmortem examinations in the elucidation of medical diseases and co-morbidity.

The autopsy findings of three medicolegal cases of sudden death associated with uncommon neuropathologic findings of which the general forensic pathologist may not be familiar are reviewed. Two cases were unexpected deaths that involved relatively young patients with histories of seizure disorders. Neurologic disorders were suspected but the exact relationship to the cause of death was not defined until postmortem examination. The other patient was elderly, thus, not an unexpected death; however, because of circumstances surrounding the scene investigation an autopsy was performed and an unexpected rare neuropathologic abnormality was found.

Case 1 was a 43-year-old male with a history of congenital nevi of his head, torso, and extremities. The patient also suffered from hypertension, chronic alcoholism, and a poorly controlled grand mal seizure disorder of five years duration prior to death. He was discovered unresponsive in a bathroom and autopsy revealed a malignant melanocytic tumor diffusely infiltrating the leptomeninges and focally the cortex of the superior gyrus of his left temporal lobe. The cause of death was attributed to a seizure due to a malignant melanoma of the temporal lobe arising in the context of neurocutaneous melanosis.

Case 2 was a 57-year-old female with a history of mental retardation, clumsiness, incoordination, and a childhood seizure disorder that developed as a sequel to chronic infantile lead poisoning. She was discovered unresponsive and asystolic on her bedroom floor. Twelve days prior to her death she had a witnessed fall down a staircase, and fractured her left leg. The cause of death was a pulmonary thromboembolism due to deep venous thrombosis status post left leg fracture. Autopsy also revealed profound atrophy and gliosis of her cerebellum consistent with residual damage from chronic lead poisoning. Although peripheral nervous system involvement in chronic lead poisoning is well known, less so is marked cerebellar atrophy with subsequent incoordination as occurred in this case.

Case 3 was a 75-year-old female with a history of chronic osteoarthritis, hypertensive atherosclerotic cardiovascular disease, and

depression and, six month duration of neck and head pain. She was found dead in bed under suspicious circumstances so a postmortem examination was performed. The cause of death was due to acute bacterial leptomeningitis at the cervico-medullary junction, acute inflammation of the adjacent dura mater and the tissue of her upper cervical spinal column associated with subluxation and instability of her atlanto axial (AA) joint. The case compares to what is known as Grisel's syndrome, a subluxation of the AA joint due to inflammation-induced ligamentous instability associated with an infectious/inflammatory process of the head or neck. Grisel's syndrome is more often found in children than adults; it may produce spinal and neurologic complications and, rarely, death.

Neurocutaneous Melanosis, Lead Encephalopathy, Grisel's Syndrome

G9 Ruptured Cerebral Artery Aneurysm Mimicking Home Invasion and Assault

Albert Y. Chu, MD, MHS, and Luis A. Sanchez, MD, Harris County Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054*

After attending this presentation, attendees will understand a case of a 48-year-old white female with blunt force injuries who was found nude and semi-conscious in her ransacked residence. While the case was initially investigated as a possible home invasion and assault, the "victim" was ultimately diagnosed with a ruptured left posterior communicating artery aneurysm before dying.

This presentation will impact the forensic community and/or humanity by demonstrating that cases of ruptured cerebral artery aneurysm may rarely present with psychotic and/or violent behavior and that this behavior may in turn result in scene findings and injuries that may initially be confused with criminal activity and awareness of psychotic and/or violent behavior as an unusual presenting symptom of ruptured cerebral artery aneurysm and its potential to mimic assault at the scene.

A 48-year-old white female with a history of hypertension was found at her residence during a welfare check performed by her landlord and her best friend. The decedent was nude, semi-conscious, and "appeared to have been beaten." In addition, the house, which according to the landlord was typically kept very clean and tidy, was "trashed." EMS was activated, and the decedent was taken to the hospital.

Police arrived on the scene and investigated the case as an assault. The doors to the residence were locked but not secure and showed no signs of forced entry. Disarray at the scene was limited to the living room, kitchen, dining room, and bathroom; the two bedrooms were tidy. In the living room and dining room, various pieces of furniture and the television had been overturned, and broken dishes and glassware were strewn about. A lampshade had been torn to pieces. In the kitchen, the door of the oven had been removed and was located in an adjacent hallway, a bathrobe was in the refrigerator, and pieces of chicken were scattered throughout. Vacuum cleaner parts were in the washing machine. In the bathroom, vomit was on the floor and a can of insect repellent was in the toilet. No valuables were missing from the house.

At the hospital, the decedent was noted to have numerous contusions and abrasions, predominantly on the extremities. Toxicologic screening for drugs of abuse and alcohol performed the day of admission was negative. A sexual assault examination was also negative, and ultimately no evidence of semen was detected in any of the swabs or clothing collected. A computed tomography scan detected subarachnoid hemorrhage at the base of the brain, and angiography detected a ruptured left posterior communicating artery aneurysm. Despite a coil embolization procedure, the decedent never became coherent and expired nine days after arrival to the hospital. Because the attending physician thought that the decedent's blunt force injuries may have contributed to death, the decedent was brought to the Harris County Medical Examiner's Office for autopsy.

Autopsy examination confirmed the presence of subarachnoid hemorrhage associated with the treated left posterior communicating artery aneurysm. Injuries were limited to cutaneous injuries of the torso and extremities detected externally; no internal evidence of blunt force or penetrating trauma was identified. Additional findings included evidence of the decedent's known hypertensive cardiovascular disease including cardiomegaly with concentric left ventricular hypertrophy and myocyte hypertrophy and renal arteriolosclerosis. The cause of death was classified as ruptured cerebral artery aneurysm due to hypertensive cardiovascular disease, and the manner was classified as natural.

Cerebral artery aneurysms are relatively common and have been reported as incidental findings in up to five percent of all autopsies. Typically, these aneurysms are asymptomatic unless they rupture, in which case most symptoms are due to the resulting subarachnoid hemorrhage. The classic presentation is that of "the worst headache in my life"; other common symptoms include loss of consciousness, seizures, meningeal signs, nausea and vomiting, drowsiness, dizziness, and cranial nerve deficits. Psychiatric symptoms, while previously reported, are unusual. This rare presentation of ruptured cerebral aneurysm resulted in a criminal investigation of possible assault.

Cerebral Artery Aneurysm, Psychosis, Assault

G10 Checking In to Check Out: The New Mexico Experience of Suicide Occurring in Hotels

Rebecca A. Irvine, MD, University of New Mexico, Office of the Medical Investigator, MSC 11 6030, 1 University of New Mexico, Albuquerque, NM 87131-0001*

After attending this presentation, attendees will have an awareness of features of hotel facilities, which may attract individuals contemplating suicide and the characteristic findings of the population that complete the act in this setting.

This presentation will impact the forensic community and/or humanity by delineating findings and behavior, which may assist in the determination of manner of death as suicide occurring in a hotel as well as facilitate discussion with the family under these circumstances. Possible points of intervention by hotel personnel are examined. Safety issues in the hospitality industry are underscored.

Hotels offer many advantages to the individual contemplating suicide, including but not limited to, privacy, an expected guarantee of timely discovery which will not traumatize loved ones, a place to stay when one has traveled to avoid recognition in their own community, sanctuary, a place to act out, neutral ground during disputes, or simply a high building with access to the roof. For others, it may be the end of a long road trip during which suicide was contemplated. Perhaps the sterility and depersonalized setting appeals to those with depression. All cases in New Mexico certified as suicide where the death occurred in a hotel setting or equivalent between 1995 and 2005 were reviewed for demographics and unique features (N=74, 2% of suicides certified in the State in this time frame).

This setting is preferred by White (73%) males (74%) between the ages of 30 and 50 (69%).

Firearm injuries are the method of choice in 42% of cases; no firearm suicides were immediately discovered because of the sound of the discharge of the weapon.

Drug intoxications accounted for 22% of the deaths; 22% of the non-illicit drug intoxications had detectable antiemetic substances. Although *Final Exit* recommends the use of an antiemetic in cases of contemplated overdose, it is also recommended that when death occurs in a hotel, a note of apology to the staff and a large tip be left. Neither of these was present in any of the cases.

There were a surprising number of somewhat unusual deaths, including cyanide poisoning, a stab wound of the leg (in a paraplegic individual), cold exposure, helium inhalation, jumping from a height (through a skylight into the lobby), and self-immolation.

Notes were present in 30% of cases and 18% of cases were considered to be highly organized (photographs, wills, insurance policies, "do-not-resuscitate" statements, Hemlock Society membership, religious material, etc.). Suicide in a hotel would seem to require at least some degree of planning and organization. Of the six deaths due to incised wounds, only one employed a weapon at hand (broken bottle). Of the five hangings, only two individuals brought a ligature to the scene; the remainder used linens or clothes hangers, items likely to be found in a hotel setting. In nine cases, there was multiple occupancy of the hotel room, although most of these were not witnessed.

The suicide notes in two cases indicated that the decedents had an advanced malignancy. At autopsy, neither case had an identifiable neoplasm. It is not known if this was a sincere belief on the part of the decedent or an attempt to console the family.

Cocaine was present in 12% of cases and was related to the cause of death in only one. It was by far the most common drug of abuse detected. Alcohol was present in 38% of cases, with 18% of these less than 0.04 mg/dL (possible bracing effect) and 36% greater than 0.2 mg/dL. It appears that when alcohol is consumed in this setting, the blood concentration is likely to be high. In three cases where death was attributed to illicit drug intoxication, all had suicide notes.

Decedents resided out of state in 28% of cases, almost half of these in states adjacent to New Mexico. Over half of the cases resided less than 100 miles from the scene, with 22% less than ten miles. It is possible that a polite question or inquiry by registering personnel regarding nearby residence may be a point of intervention.

There should be concern for the safety and welfare of personnel in the hospitality industry as these cases included physical domestic violence (x3), violent felons (x2), law enforcement stand-offs (x2), shooting outside the hotel room (x2) and a prison escapee. The case of self-immolation in particular could have caused a large-scale tragedy.

Suicide, Hotel, New Mexico

G11 Liver Laceration as a Result of Resuscitation in an Adult Man

Ellen G. Moffatt, MD, Office of the Chief Medical Examiner, 850 Bryant Street, San Francisco, CA 94103*

After attending this presentation, attendees will understand some of the more obscure complications of resuscitation in adults, in order to identify them at autopsy. This case is presented as an example of an injury that may be mistakenly interpreted as one that caused or contributed to death.

This presentation will impact the forensic community and/or humanity by differentiating injuries as the result of trauma and as the result of postmortem (or perimortem) resuscitation and reasons for their formation.

A 41-year-old male police officer on a nighttime training exercise collapsed suddenly. His fellow police officers immediately began CPR. His past medical history included controlled hypercholesterolemia, and complaints of left arm tingling the week prior to his death.

At autopsy, abrasions were on the center of the chest with fractures of the right fourth and fifth ribs at the sternum and the right fifth rib laterally. An 8.0 centimeter laceration was at the falciform ligament. Approximately 750 milliliters of unclotted blood was in the abdominal cavity.

Although the total cardiac weight (380 grams) was normal for his height and weight, the left ventricle measured 2.0 centimeters and the

septum thickness ranged from 2.0 centimeters to 1.1 centimeters. Histologically the heart showed focal cytomyolysis and fibrosis adjacent to the bundle of His. Occasional parenchymal vessels had medial hypertrophy with narrowing of their lumens. Toxicology studies were negative. There was no evidence of head injury.

Liver lacerations are an uncommon, but recognized, complication in resuscitation in children. Liver lacerations as a complication of resuscitation in adults have been rarely reported, and are usually seen in patients receiving thrombolytic or anticoagulant therapy (1, 2). Other uncommon complications of resuscitation include tracheal rupture (3), lung herniation (4), heart rupture (5, 6) and gastric rupture (7,8). Other more common complications of resuscitation in adult include broken ribs, along with heart and splenic lacerations.

Proposed mechanisms of this injury include disparate size between rescuer and victim, and over-enthusiastic or incorrect placement of chest compressions.

Resuscitation, Complication, Laceration

G12 The Epidemiology of Sudden Cardiac Death in Young Decedent Medical Examiner Cases

Sharon M. Derrick, PhD, Stacey A. Mitchell, MSN, RN, and Luis A. Sanchez, MD, Harris County Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054*

After attending this presentation, attendees will understand the epidemiology of sudden cardiac death cases (SCD) presenting to a large medical examiner's office over a five year time span (2001-2005) resulting in increased understanding of the etiology of this cause of death.

This presentation will impact the forensic community and/or humanity by providing detailed medical and social history information recovered from a population of young individuals who died from sudden cardiac death. The resulting database is large enough to provide statistically significant data that can be used as a basis for further research. Dissemination of this information may support an emphasis on innovative screening and prevention practices targeting youth, ultimately contributing to decreased mortality from SCD in this at-risk segment of the United States population.

Sudden Cardiac Death (SCD) is the leading cause of natural death each year in the United States. This poster presentation will inform attendees regarding the epidemiology of SCD cases presenting to a large medical examiner's office over a five year time span (2001-2005), resulting in increased understanding of the etiology of this cause of death. SCD is often the result of untreated rapid ventricular tachycardia or ventricular fibrillation but it may be due to a variety of different conditions, including but not limited to acute myocardial infarction, coronary artery disease, cardiomyopathies, myocarditis, valvular heart disease, conduction abnormalities and drug toxicity (prescription and recreational).

SCD is a significant public health problem, the basis of which will be more effectively addressed through building a clear and accurate picture of young SCD decedents, thereby broadening innovative intervention projects to include previously underserved at-risk segments of the population.

A retrospective record review was conducted at the Harris County Medical Examiner's Office in Houston, Texas (HCME) that identified natural deaths reported to the HCME from 2002 through 2004. A full case review was performed for all of the cases in which cardiac death was listed as the primary cause of death after autopsy or external exam and in which the decedent was under the age of 50 years. Socially influenced factors, such as obesity (listed as contributory on the death certificate), tobacco use, and chronic ethanolism were noted for each case in addition to the decedents' medical histories.

Decedents whose cause of death was cardiac-related comprised 52% of cases presenting to the HCME during the 2002-2004 time period. Of those cases, 20% were under the age of 50, 72% were male and 51% were of Caucasian descent. A notable 43% were smokers. Obesity was listed on the death certificate as a contributing factor in 5% of the cases and chronic ethanolism contributed in 3%. Atherosclerotic Cardiovascular Disease and Hypertensive Cardiovascular Disease were diagnosed in 54% of those individuals under the age of 20 years. From 2002 to 2004, cardiovascular disease was shown to be the cause of death in 16 children between the ages of 12 and 18, with the majority collapsing while participating in athletic events. In light of these findings further study has been initiated at the HCME, expanding the study to the five year span of 2001-2005, reducing the upper age limit to 40 years, and exploring other case history factors for all of the cases such as cardiac enzyme levels, and prescription and recreational drug use. Body Mass Index was also calculated for each decedent. The analyzed results of the expanded findings are described in the poster presentation.

The important contribution of socio-cultural behaviors to health status has been documented in the medical and public health literature. Modifications of these behaviors, combined with the use of basic non-invasive cardiac diagnostic screening tests may greatly reduce the risk of SCD among younger individuals, such as student athletes. The HCME and other medical examiner offices can be instrumental in raising community awareness of SCD. A key goal of this public health education should be to promote the benefits of screening and prevention measures.

Cardiac, SCD, Epidemiology

G13 Significance of Blood Neopterin Measurement in Forensic Autopsy Cases

Takaki Ishikawa, MD, PhD, Department of Legal Medicine, Osaka City University Medical School, Asahi-machi 1-4-3, Abeno, Osaka, 545-8585, Japan; Marianne Hamel, MD, PhD, Thomas Jefferson University Hospital, Department of Pathology, 132 South 10th Street, Suite 285 Main Building, Philadelphia, PA 19107; and Bao-Li Zhu, MD, PhD, and Hitoshi Maeda, MD, PhD, Department of Legal Medicine, Osaka City University Medical School, Asahi-machi 1-4-3, Abeno, Osaka, 545-8585, Japan*

After attending this presentation, attendees will understand how increased neopterin levels in postmortem blood samples identified with immunohistochemistry indicate non-specific viral infection.

This presentation will impact the forensic community and/or humanity by demonstrating how correct interpretation of postmortem blood neopterin levels can direct the postmortem examination in a cost-effective and efficient manner.

Definitive and specific diagnoses regarding infection with fatal viral pathogens are often hampered by the significant cost and labor associated with immunohistochemical staining. However, examination of non-specific markers for viral infection through high-throughput laboratory methods serves to direct the postmortem examination in a cost-effective and efficient manner. Neopterin, a pteridine released by macrophages, is a well-established marker of immune system activation. This study analyzes postmortem blood neopterin levels from multiple anatomic sites in an attempt to elucidate their accuracy in diagnosis of fatal viral infection. Medicolegal autopsy cases (n=521, 1-96 years of age, 366 males and 155 females) were examined. Causes of death were blunt injury (n=118), sharp injury (n=27), poisoning (n=26), drowning (n=30), fire fatalities (n=85), hypothermia (n=10), asphyxiation (n=30), hyperthermia (n=7), and natural death (n=143). Blood samples were collected at the time of postmortem examination from the subclavian and femoral veins and from the left and right heart. Neopterin levels were measured by high performance liquid chromatography. Neopterin levels greater than 500 pmol/mL correlated with fatal viral infection. Viral infection was

confirmed by histology and PCR. Levels of C-reactive protein, an additional marker of immune system activation, and neopterin were compared and a high correlation was observed in right heart blood. However, neopterin levels from all sites were significantly higher in cases of multiple organ failure that was not associated with viral infection than in other cases.

This study indicates that postmortem blood neopterin levels are both useful and cost-effective as a non-specific marker of viral infection. As the purpose of the postmortem examination is to provide the most specific information regarding cause of death possible, it is appropriate, though expensive, to elucidate the specific pathogen. Increased neopterin levels, in cases of possible viral infection, should trigger the immunohistochemical examination of tissue samples for specific viral antigens. However, neopterin levels may also be elevated in the face of drug use, chronic heart failure, and renal disease and caution should be used in interpreting blood neopterin content in the presence of these conditions.

Neopterin, C-reactive Protein, Viral Infection

G14 Evaluation of Nasopharyngeal Viral Swabs in Infants Dying of Natural Causes

Wendy A. Stroh, DO, and Deborah Kay, MD, Office of the Chief Medical Examiner, 400 East Jackson Street, Richmond, VA 23219*

After attending this presentation, attendees will be more informed on viral nasopharyngeal swabs in the infant population regarding frequency of use, results, and their impact on cause of death.

This presentation will impact the forensic community and/or humanity by elucidating the impact of viral postmortem testing in infants dying of natural causes.

This presentation will acquaint conference attendees with viral nasopharyngeal culture swabs use in an infant population less than one-year-old, dying of natural causes as well as the use of positive results in determining the cause of death. Information on the viral nasopharyngeal swab such as appropriate collection and submission techniques, sample rejection criteria utilized at the laboratory, and laboratory technology employed in determining results and its limitations of the technology is also provided.

The Office of the Chief Medical Examiner in Richmond, Virginia has used nasopharyngeal swabs to obtain viral culture samples since 2003. Viral nasopharyngeal culture swabs are performed in the vast majority of infant autopsies at this institution. They are routinely submitted along with blood and cerebrospinal spinal fluid cultures as part of the postmortem evaluation of all infants in whom Sudden Infant Death Syndrome is a consideration.

Autopsy charts on all infants under the age on one year dying of natural causes were reviewed. Data was tabulated on the total number of autopsies, total number of viral nasopharyngeal cultures obtained, submitted resulted and rejected or not performed and reasons for rejection, total number of positive cultures including virus type detected and total number of negative results (no virus identified).

The viral nasopharyngeal swab kit contents are discussed. Appropriate procedures for obtaining optimal results in regards to sampling, storage of the specimen and proper submission are provided. Examples of rejection criteria are included as are factors that adversely affect culture results.

A discussion of the laboratory technology employed to obtain viral nasopharyngeal culture results is included. The limitations of the technology are listed. A list of types of viruses detected is included. Other technologies for obtaining viral culture results are mentioned as well as the limitations of these methods and factors affecting culture results.

Postmortem viral nasopharyngeal swab culture results are compared with antemortem results on infants of a similar age group. Factors, which

may contribute to differences in the results of the two groups, are postulated.

The influence of positive viral nasopharyngeal swab culture results on the cause of death is discussed including correlation of the viral results with other autopsy findings such as microscopy. Negative culture results and factors, which may contribute to negative results, are also mentioned. Brief case summaries on several autopsies with positive viral nasopharyngeal culture results are presented as examples of correlation of culture results with other autopsy findings to determine the causes of death.

Nasopharyngeal Swabs, Infants, Autopsy

G15 Succession of Microfungi in Grave Soil

Shari L. Forbes, PhD, University of Ontario Institute of Technology, 2000 Simcoe Street North, Oshawa, Ontario L1H 7K4, Canada; Trevor Lumley, PhD, Environment Canada, Environment Technology Centre, 335 River Road, Ottawa, Ontario K1A0H3, Canada; and David Carter, PhD, University of Nebraska Lincoln, 202 Plant Industry Building, Lincoln, NE 68583-0816*

After attending this presentation, attendees will understand that soil microfungi possess the potential to act as a tool to estimate extended postmortem and postburial interval.

This presentation will impact the forensic community and/or humanity by providing investigators with a novel method for estimating time since death in cases involving buried remains.

The estimation of postmortem interval (PMI) becomes increasingly inaccurate as decomposition proceeds. Estimating postmortem period in cases where a body is buried in soil is particularly difficult because soil typically prevents forensically important insects from accessing the body. Thus, the development of insect larvae is generally unavailable as a forensic tool in investigations involving burials. Therefore, a need exists to develop new techniques for estimating PMI of buried bodies and postburial interval (PBI). This need is particularly great for bodies associated with an extended postmortem period (months to years).

The forensic application of microfungal ecology has the potential to improve the estimation of extended postmortem periods. Like the macrofungi, microfungi respond to nutrient amendment. This response typically results in fungal proliferation and, as the nutrient source is utilized, a succession of microfungal taxa occurs. This phenomenon is similar to insect succession associated with cadaver decomposition on the soil surface. In addition, some microfungi, primarily from order Onygenales, possess the ability to access keratin as a food source. This might be of particular importance to forensic science, as a body in extended PMI primarily comprises keratinaceous material such as skin, hair and nails.

A study was carried out to identify fungal species present in grave soil over a period of six months following inhumation. In spring 2006 five pig (*Sus scrofa*) carcasses were placed in separate shallow graves (40-50 cm) and covered with soil. Carcasses were exhumed at monthly intervals for the 6-month period. Soil was collected from the walls and base of each grave. These soils were sprinkled or diluted in water and spread onto tapwater, cornmeal, or Mycosel® agar plates containing the antibiotic chloramphenicol. This antibiotic was used to suppress the growth of bacteria and rapidly proliferating fungi that can overwhelm the fungi of interest.

Following the first exhumation, minimal decomposition had occurred and the carcass was classified as being in the fresh/bloat stage. As expected, there was no discernable difference between microfungus communities in control soil samples (taken at four depths one meter away from the cadaver) and soil taken from various microsites in contact with the cadaver. Communities were dominated by *Trichoderma* spp., *Mucor* spp., *Acremonium* spp., *Sordaria fimicola*, and coelomycete spp.; all common soil microfungi. These findings were able to provide a thorough background of the microfungi community in the soil.

Following the second exhumation, considerable decomposition had occurred and the carcass was classified as being in the active/advanced decomposition stage. Discernible differences in the microfungi community were apparent between grave soil and control soil samples, particularly with regard to the soil nematode community. This stage of decomposition is associated with an increase in bacterial-feeding nematodes that are then succeeded by fungal-feeding nematodes.

Exhumations will continue for the remainder of the trial and results for the six month period will be presented. Based on the preliminary results, it is anticipated that communities of nematophagous fungi will change in response to shifts in nematode community composition. These changes should be predictable over time. As a result, community structure data for nematophagous fungi has the potential to act as an additional forensic tool in estimating PMI and PBI of buried remains.

Microfungi, Grave Soil, Postburial Interval

G16 Improved Estimation of Postmortem Interval With Multiple Protein Markers and Improved Analytical Methods

Behnoush Memari, MS, Kenneth G Furton, PhD, and Alberto Sabucedo, PhD, Florida International University, Department of Chemistry and Biochemistry, 11200 SW 8th Street University Park CP-345, Miami, FL 33199*

After attending this presentation, attendees will learn about the development and utility of cardiac Troponin I (cTnI) and Troponin T (cTnT) as time since death markers for PMI Estimation.

This presentation will impact the forensic community and/or humanity by improving the accuracy in postmortem interval estimates. PMI provides crucial information required in many criminal, civil, and forensic investigations.

Time since death markers have lagged behind advances in forensics technology. Knight (1994) explains, "regrettably, the accuracy of estimating the postmortem interval (PMI) has by no means kept pace with the enormous strides made in technological sophistication." Early work on time since death focused on postmortem temperature measurements and algorithms to model postmortem cooling behavior. Current technology is still largely based on postmortem temperature methods similar to those described in the 1800's. Marshall summarized the temperature measurement method as follows, "It would seem that the timing of death by means of temperature can never be more than an approximation."

Biochemical markers for estimating time since death offer the possibility of increased accuracy and reliability in time since death estimates. Cardiac Troponin I (cTnI) and cardiac Troponin T (cTnT) are heart tissue proteins and selective markers of cardiac muscle damage. Investigation of these proteins as a marker for time since death shows great promise in mammalian heart tissue. cTnI and cTnT are found as intact protein in freshly sampled tissue at the onset of death, (T_0). These proteins are good substrates for several enzymes released in cardiac tissue upon death (necrosis). The proteolytic breakdown of these proteins by proteases in postmortem cardiac tissue is exploited to determine the postmortem interval. Both bovine and human heart tissue show similar banding patterns upon degradation. This technique takes a small sample of cardiac tissue that is homogenized and extracted with magnetic microparticles. The proteins are separated by SDS-PAGE electrophoresis and selectively visualized by Western blot. The Western blot is probed with mouse monoclonal antibodies against cardiac TnI and TnT. This step is followed by an anti-mouse conjugate labeled with alkaline phosphatase that is developed with a precipitating colored substrate. The degradation pattern of cTnI and cTnT is monitored using this bioanalytical protocol. The area of the bands within a lane is quantitated by scanning and digitizing the bands. Project methodology will be migrated to more

automated system such as capillary electrophoresis. This technique exploits the use of separation of the complex fraction isolated followed by detection of the fragments.

The results show a linear relationship between percent protein degraded and the log of postmortem time. A fresh "reference" human heart tissue obtained at time T_0 was incubated to obtain a temporal degradation profile. Comparison of human cardiac tissue samples with unknown time of death can be evaluated qualitatively against the "reference" human heart tissue. The time of death can be estimated by matching the "degradation fingerprint." Similarly, a calibration curve ($r > 0.95$) can be obtained with the percent cTnI degraded plotted against the log of the time postmortem using the reference human heart tissue. This curve can be used to estimate the time since death relative to the "reference" tissue based on the percent degradation. Data indicates that the degradation of cTnI in heart tissue shows very specific bands during a postmortem interval of a week. Troponin T is more stable in comparison to Troponin I so the degradation of cTnT should be longer. Data combined from cTnI and cTnT could be used for extended PMI estimate. Human cardiac tissue samples frozen at known time of death were analyzed by both semi-quantitative and qualitative techniques and both show similar agreement with the known time of death.

Overall, the data demonstrates that this technique represents a major advance in time of death determination providing a reliable semi-quantitative biochemical marker from a protected organ versus estimates based on direct temperature measurements. Tissue cardiac Troponin I and Troponin T shows excellent characteristics as time of death markers in the extended postmortem interval that is difficult to estimate with current methods.

TnI (Troponin I), TnT (TroponinT), Postmortem Interval (PMI)

G17 Drowning of a Child With a Cardiac Fibroma of the Interventricular Septum

Darshan R. Phatak, MD, and Luis A Sanchez, MD, Harris County Medical Examiner Office, 1885 Old Spanish Trail, Houston, TX 77054*

After attending this presentation, attendees will have a better comprehension of the nature of the presentation of this potentially fatal mesenchymal cardiac tumor, an understanding of the gross and microscopic pathology and the physiology of potentially fatal disturbances to cardiac function resulting from the size of the tumor and location in the heart.

This presentation will impact the forensic community and/or humanity by demonstrating why it is strongly recommended that those involved in the determination and certification of the cause and manner of death familiarize themselves with cardiac tumors" presentation, pathology and lethal potential and remember to include them in their differential diagnosis when confronted by cases such as this one.

This presentation will have a positive impact on pathologists, coroners, medical examiners, other autopsy practitioners and humanity at large as it can heighten general awareness towards a potentially treatable cardiac tumor that may be found either incidentally or strike down children, a vulnerable population subset, without warning.

A four-year-old Hispanic female child drowned in a swimming pool at a family gathering and had a past medical history of cardiomegaly and a heart murmur which were diagnosed neonatally, yet reportedly neither treated nor followed medically since infancy. Prior to death, the decedent had no health complaints or behavioral changes. At the scene, the decedent's stomach was bloated and clear fluid was reported in the respiratory tract.

Pertinent autopsy findings included cerebral edema, serous fluid within the pleural cavities, pneumonomegaly, and hepatosplenomegaly. Cardiomegaly and a fibroma of the interventricular septum were also found at autopsy. Toxicological tests were negative.

The majority of primary cardiac tumors are benign, with fibromas representing five percent of all cases. In the pediatric population, it is the second most common primary tumor of the heart after rhabdomyomas. The tumor also has a predilection to form within the interventricular septum and grows in size rapidly. Despite the lack of aggressive behavior or any metastatic potential, fibromas of the heart can interfere with normal physiologic function due to the interdigititation of tumor cells around and between cardiomyocytes and cardiac blood vessels and the possibility of entrapment and disruption of the cardiac conduction system that can result in a fatal arrhythmia. In addition to immediate local effects, the physical alteration of the cardiac muscle also results in pathologic changes of the other organ systems that will also impair the health of the individual over time.

The tumor is often surgically resectable or treatable by heart transplantation so therefore, proper diagnosis and prompt treatment can be lifesaving. Cardiac fibromas may also occur in the setting of the nevoid basal cell carcinoma syndrome (Gorlin-Goltz syndrome), so it can be beneficial for parents and other relatives to know the diagnosis. The most important lesion in the differential diagnosis is fibrosarcoma, a malignancy that is rare in the heart and in the general pediatric population. In a primary cardiac tumor, it is also of crucial importance to rule out a metastasis from a primary tumor of another location, as the treatment will vary.

This case of cardiac fibroma serves as a good example of a primary cardiac tumor's potential for fatal presentation in a child. Sometimes children with congenital heart abnormalities do not receive close monitoring of their health under a physician's care, and it is strongly recommended that those involved in the determination and certification of the cause and manner of death familiarize themselves with cardiac tumors' presentation, pathology and lethal potential and remember to include them in their differential diagnosis when confronted by cases such as this one.

Cardiac, Fibroma, Drowning

G18 Estimating Time of Death From Livor Mortis Patterns: A Case Presentation

William Massello III, MD, Office of the Chief Medical Examiner; 6600 Northside HS Road, Roanoke, VA 24019*

After attending this presentation, attendees will understand the forensic importance of recognizing patterns of lividity produced by articles of clothing and of documenting these patterns of lividity photographically. Patterns of lividity can be useful in estimating the time of death. Attendees will also come to appreciate how a pains taking analysis of postmortem photographs can have relevance to the application of the proper criminal charges.

This presentation will impact the forensic community and/or humanity by demonstrating how both scene photography and postmortem photography of the remains, when used in conjunction with computer resources, can be valuable in estimating the time of death. It also demonstrates that a careful analysis of patterns of lividity, even in postmortem digital photographs, can be important in providing evidentiary material for use in helping resolve important questions in criminal law.

Following this case presentation, the attendees will understand the forensic importance of recognizing patterns of lividity produced by articles of clothing and of documenting these patterns of lividity photographically. Additionally, it will be shown how these patterns of lividity can be useful in estimating the time of death. An understanding of the importance of postmortem photography as a tool in death investigation will be underscored. Attendees will also come to appreciate how a pains taking analysis of postmortem photographs can have relevance to the application of the proper criminal charges.

This case involves a 19-year-old white female who was a still-life photography model participating in a pornographic photo shoot in a studio in a small rural community. Following a photo shooting session, she voluntarily, orally took an unknown amount of a proprietary liquid morphine preparation and lay down to take a nap. While she was asleep on the bed, the photographer took some additional photographs and, later, by his own admission, performed sodomy on the individual while she was asleep. Approximately one hour later, he noticed that she wasn't breathing and called the local rescue squad. She was rushed to the hospital, where it was determined that she was pulseless, apneic, cold, and blue. It was determined by postmortem examination and toxicology that she had died from a lethal concentration of morphine, in combination with two other benzodiazepines, dextromethorphan in the presence of a residual concentration of cocaine and its metabolite, benzoylecgonine. Questions arose during the investigation concerning whether the decedent was alive and/or was capable of consent during the purported act of sodomy by the photographer.

Postmortem police scene photographs and digital photographs taken at the studio by the photographer while the decedent was asleep on the bed were reviewed. It was revealed that numerous patterned lividity markings, made by the decedent's clothing, had persisted for several hours after the clothing items had been removed. These photographs were matched up with the "date and time modified" column on the computer explorer window. They demonstrated that the decedent had expired at least more than an hour before the photographer admitted to sodomizing her. This finding was instrumental in showing that charges of non-consensual sexual assault, to include animate object penetration, were not appropriate in this case, because the decedent was already dead at the time the act of sodomy and digital insertion were performed.

Time of Death, Livor Mortis, Digital Photography

G19 Dispersion of Hesitation Marks and Defense Wounds: A New Criterion of Differentiation of Sharp Force Suicide and Homicide

Stéphanie Racette, BSc, Célia Kremer, MSc, Anne Desjarlais, and Anny Sauvageau, MD, Laboratoire de Sciences Judiciaires et de Médecine Légale, 1701, Parthenais Street, 12th floor, Montreal, Quebec H2K 3S7, Canada*

After attending this presentation, attendees will be introduced to a new criterion of differentiation of hesitation marks and defense wounds in sharp force injuries.

This presentation will impact the forensic community and/or humanity by providing new insight in the evaluation of hesitation marks and defense wounds.

In evaluating manner of death, forensic pathologists often rely on widely accepted criteria of differentiation at autopsy. For example, the presence of hesitation marks or defense wounds in sharp force injury cases has been accepted as a criterion of differentiation between sharp force suicide and homicide.

With this study, the authors wanted to enrich the description of hesitation marks and defense wounds. The authors hypothesize that (1) hesitation marks would predominantly be present on inner surface of upper limbs while such predominance would not be found for defense wounds, (2) a possible left predominance in hesitation marks could be found, considering the higher proportion in the general population of right-handed person and finally that (3) hesitation marks and defense wounds would show a different pattern of dispersion on upper limbs.

Over a 5-year period, in the Quebec province (Canada), all cases of suicidal and homicidal sharp force injury presenting hesitation marks (n=43) and defense wounds (n=91) were retrospectively reviewed. For

each case, hesitation marks or defense wounds were drawn on an upper limb chart divided into 12 sections covering the upper arm to the hands. The total amount of lesions for each section was compiled as well as the total amount of wounded sections. For all suicidal victims, a general chart of upper limbs was done by superimposing every chart with hesitation marks. The same was achieved with homicidal victims for defense wounds.

- (1) Sharp force victims of suicide presented a significant higher average amount of hesitation marks on inner aspect of upper limbs then on exterior surface ($p<0.05$). In victims of homicide, no difference was revealed between inner and exterior average amounts of defense wounds.
- (2) In terms of left and right comparison, a left predominance was not found for hesitation marks cases or for defense wounds cases. In fact, in suicide cases, the average amount of hesitation marks was the same on each inner side of upper limbs.
- (3) Graphical superimposition of hesitation marks/defense wounds for all victims visually revealed low dispersion of hesitation marks and high dispersion of defense wounds. This was statistically confirmed by comparing the average amount of hesitation marks/defense wounds and the average total number of wounded sections. For both inner and exterior aspects of upper limbs, the average total number of wounded sections was significantly higher for defense wounds compared to hesitation marks ($p<0.05$), while no significant difference was revealed for the comparison of average amount of wounds. In other words, for a similar average amount of hesitation marks and defense wounds, the average number of wounded sections on upper limbs revealed to be higher for defense wounds than for hesitation marks. Thus, defense wounds show higher dispersion on upper limbs compared to hesitation marks.

This retrospective study of hesitation marks and defense wounds first confirmed the initial hypothesis of predominance of hesitation marks on inner surface of upper limbs. However, while it is often said that sharp force victims, considering the proportion of right-handed person in the general population, are more likely to present hesitation marks on their left upper limb, this five year study failed to confirm such predominance. Consequently, the authors discourage the use of a left-right characteristic in the evaluation of hesitation marks and defense wounds. The pattern of dispersion of hesitation marks and defense wounds suggests a difference in the pattern of dispersion as a new criterion for hesitation marks and defense wounds.

Hesitation Marks, Defense Wounds, Sharp Force Injury

G20 Neck and Scleral Hemorrhage Due to Drowning

Russell T. Alexander, MD, and Jeffrey M. Jentzen, MD, Milwaukee County Medical Examiner's Office, 933 West Highland Avenue, Milwaukee, WI 53233*

The goal of this presentation is to review a case of drowning associated with extensive bilateral scleral and neck hemorrhage.

This presentation will impact the forensic community and/or humanity by discussing the occurrence and possible mechanisms for the creation of scleral and neck hemorrhage in drowning related deaths.

The decedent was a 30-year-old male who was found with his 5-year-old stepson at the bottom of a nine foot deep hotel pool after hotel workers noted two of the decedent's other young children playing unattended on the steps in the shallow end of the pool. The decedent and his stepson were pulled unresponsive from the pool. Firefighters arrived at the scene and started CPR after finding the decedent pulseless and not breathing. After 30 minutes of resuscitative efforts, he was declared dead at the scene. The child was taken in "critical" condition to a nearby children's hospital, and was discharged the next day with no neurological deficits. At

that time, the stepchild reported that the last thing he remembered was falling into the pool.

The decedent's wife last saw him alive 2.5 hours before he was found. She thought he and the three children were going back to their room to watch television. She did not know why they would go to the pool, since he and the children were unable to swim. An investigation by law enforcement found no evidence of foul play.

A "foam cone" was at the mouth and nose of the decedent at the scene. At autopsy, there was marked bilateral scleral hemorrhage. No abrasions or contusions were on the anterior or posterior neck. Internally, the lungs were hyperinflated. Frothy fluid filled the airways and exuded from the cut surfaces of the lungs. The sphenoid sinus contained 3 ml of bloody fluid. Blood was in the mastoid air cells bilaterally. The right ventricle of the heart was dilated and the thyroid gland was markedly congested. A layered anterior neck dissection revealed hemorrhage on the surface of multiple strap muscles that was confined to the fascial surfaces of the muscle; sectioning did not reveal contusion within the substance of the muscle. A comprehensive toxicology screen did not detect alcohol or drugs within iliac blood. A vitreous electrolyte screen was within normal limits. The cause of death was determined to be drowning. The manner of death was accident.

Despite the assertion that anterior neck muscle hemorrhage "do not occur in drowning and should always raise the suspicion of foul play" (Spitz, 2006), others have reported this finding (Carter et al., 1998; Puschel et al., 1999). This hemorrhage has been attributed to hypostasis (livor mortis), muscular injury due to violent neck movements or an artifact of decomposition (Carter et al., 1998). Conjunctival and facial petechiae are due to increased cephalic venous pressure; a phenomena that may be exaggerated by coughing, gagging or a struggle that increases cardiac output and blood pressure (Ely and Hirsch, 1999).

Increased central venous pressure due to coughing and gagging, as well as increased cardiac output and blood pressure during the struggle of the drowning process, led to the scleral and neck hemorrhages described in this case. The elevated central venous pressure would be transmitted through valveless veins to the neck musculature as well as the head. Such elevated pressure could also cause right heart dilation and congestion of the thyroid gland.

Strangulation can result in neck and scleral hemorrhages similar to those described in the current case. Direct trauma to the neck during strangulation would typically cause hemorrhage within the substance of the muscle rather than just fascial hemorrhage. When a body recovered from water has these findings, it is imperative to consider all scene, autopsy, and toxicology findings to arrive at the proper cause and manner of death.

This case presentation demonstrates that drowning can result in significant neck and scleral hemorrhage, probably due to increased central venous pressure during the drowning process.

Drowning, Hemorrhage, Strangulation

G21 Papillomacular Folds: Whiplash Maculopathy or Postmortem Artifact?

Patrick E. Lantz, MD, Wake Forest University Health Sciences, Department of Pathology, Medical Center Boulevard, Winston Salem, NC 27157*

After attending this presentation, attendees will understand the usefulness of postmortem monocular indirect ophthalmoscopy in differentiating postmortem fundal artifacts from pathologically significant retinal folds.

This presentation will impact the forensic community and/or humanity by demonstrating that horizontal, hypopigmented, non-hemorrhagic retinal folds represent a postmortem artifact and must not be misinterpreted as retinal injury from putative vitreoretinal traction associated with whiplash or presumed shaking (Shaken Baby Syndrome or Inflicted Childhood Neurotrauma).

Clinically, whiplash maculopathy has been associated with three subtle macular disturbances following head/neck trauma from hyperextension/flexion. These include mild reduction of central visual acuity or paracentral scotoma, grayish swelling of the foveal zone and a small pit or depression in the fovea. The retinal opacity usually resolves and visual acuity most often returns to 20/20 but the foveal depression invariably remains. No specific pathophysiologic mechanism has explained the development of traumatic retinopathy after this indirect ocular trauma. Some authors favor a mixed mechanism, mechanic and vascular, to explain these alterations while others postulate that local microcirculatory disturbances are the cause of the retinopathy as opposed to the systemic disturbance associated with Purtscher's retinopathy.

A recent publication claimed the first account of the macroscopic and microscopic pathologic findings that they believed were the result of whiplash maculopathy and retinopathy (*Forensic Sci Med Pathol* 2005;1:19-25). The macular and retinal findings were found at autopsy in 20-year-old woman who suffered fatal head and neck injuries following a roller-coaster accident. Both eyes had horizontal folds extending temporally from the optic disc just beyond the fovea presumably secondary to vitreous traction.

However, the horizontal hypopigmented, non-hemorrhagic papillomacular retinal folds depicted in this case report represent postmortem artifacts readily apparent by postmortem monocular indirect ophthalmoscopy as evidenced by the following case. A 4-month-old infant presented to the Emergency Department of a regional medical center apneic and pulseless. Resuscitative efforts re-established cardiac activity but mechanical ventilation was required. Direct and indirect ophthalmoscopy in the Pediatric Intensive Care unit did not reveal any fundal hemorrhages or retinal folds. Death occurred 56 hours after admission. Postmortem monocular indirect ophthalmoscopy performed four hours after death confirmed clinical fundoscopic findings; however, the following morning, 21 hours after death bilateral hypopigmented, non-hemorrhagic retinal papillomacular folds had formed that were grossly and microscopically similar to the retinal folds attributed to whiplash maculopathy.

Subsequent examination of infants and adults who have died from natural disease processes has demonstrated that these artifactual papillomacular retinal folds initially form a few hours after death as retinal elevations around the fovea centralis then extend nasally and temporally. This fairly uniform sequence has been demonstrated by serial postmortem fundal imaging utilizing monocular indirect ophthalmoscopy. It is imperative that this postmortem artifact is not misinterpreted as retinal injury from putative vitreoretinal traction associated with whiplash or presumed shaking (Shaken Baby Syndrome or Inflicted Childhood Neurotrauma).

Whiplash Maculopathy, Postmortem Monocular Indirect Ophthalmoscopy, Postmortem Artifact

G22 To Dye or Magnify! A Proposal to Study the Efficacy of Toluidine Blue Dye vs. Colposcopy in the Postmortem Anogenital Examination

Sharon R. Crowley, RN, MN, 122 Emeline Avenue, Santa Cruz, CA 95060*

The goals of this presentation is to determine if toluidine blue is a reliable or useful adjunct in the postmortem genital examination; to describe a baseline study protocol that compares results from photocolposcopy at 7.5X and 15X magnification vs. photocolposcopy plus the addition of toluidine blue dye; and to better understand the nature and appearance of the postmortem anogenital anatomy.

This presentation will impact the forensic community and/or humanity by demonstrating an increase in the reliability and consistency

of postmortem anogenital examination techniques; and increasing in the diagnostic acumen of the forensic examiner.

Recent studies have focused on the application of a 1% solution of toluidine blue dye, a general nuclear stain, as a practice standard for the medical-legal examination of *living* sexual assault victims. Specific recommendations, e.g., the sequence of the dye application during the pelvic examination, have been delineated and advocated. Some authors and numerous practitioners recommend application of the nuclear stain *prior* to insertion of the speculum. This is based on the assumption that the nuclear stain will delineate iatrogenic injury from pre-existing traumatic findings due to a sexual assault. In one study of antemortem sexual assault cases, Jones, Dunnuck, Rossman, et al described a 3.7% incidence (1/27 cases) where one additional genital injury was delineated via toluidine blue, after speculum insertion and removal by the examiner. This injury was located on the posterior labia minora.

In a study by Hochmeister, Whelan, et al., (JFS, 1997), there was no effect on either PCR or RFLP recovery when vaginal swabs were exposed to the dye. However, the sample size was limited to only five women and postcoital swabs were collected within six hours of coitus. In California, the medical-legal protocol recommends that dye application be deferred until *after* collection of biological specimens.

A review of the original methodologies from Richart (1963), Collins (1966), Lauber & Souma (1982), and McCauley (1987) was done by Crowley and Peterson (*To Dye or Not to Dye*, AAFS, 2005). Variability in interpretation of results in antemortem patients may be due to *many* factors. Toluidine blue is specific for zones of parakeratosis; thus positive results can be due to inflammatory, benign, or malignant vulvovaginal diseases. Twenty-three different benign vulvovaginal conditions, in addition to the presence of cervical mucous, will yield false positive results with application of this dye *in vivo*.

A paucity of data exists on the "normal" appearance of the anogenital tissues during the postmortem interval. Detailed observation and baseline studies are ideally done with colposcopy and documentation via magnified photos, to facilitate peer review. Colposcopy has been thoroughly utilized by numerous authors to enable the study of both normal and abnormal findings in both child and adult sexual assault victims since the late 1980s. The protocol for detailed postmortem inspection and the methodology for an evidentiary anogenital examination have been previously described (Crowley, JFS, 2004). The correct application and interpretation of results/findings were thoroughly described by the earlier authors (Richart, Collins, Lauber & Souma, and McCauley). The intensity of the stain is correlated to the nuclear density of the tissues. Most of the earlier authors reiterated that the proper decolorization of the dye was the most important part of the methodology. Conventional methodologies vary widely, as do the post-assault time intervals for application of the dye. Another salient factor in any discussion of the efficacy of a nuclear stain vs. colposcopy is the anatomic site to which the dye can be appropriately applied. Although used by the earliest authors for diagnosis of cervical and vulvar neoplasias, Lauber and Souma, in 1982, first described its use for evaluation of sexual assault victims and comparison to a control group of consenting women. It is important to remember that at that time, colposcopy was not widely available for examination of this population. These authors also limited the application of the dye to the posterior fourchette, an area that is histologically comprised of skin-like stratified squamous epithelium.

As mentioned previously, subtle findings may be an examiner issue (Slaughter, personal communication, 2004). Many programs do not routinely include follow-up examinations in their protocol. Without incorporation of follow-up examinations, it may be extremely difficult to evaluate findings such as localized redness and swelling. In all cases, both antemortem and postmortem, it is essential to employ the highest standards, in order to differentiate traumatic findings from either preexisting benign vulvovaginal conditions or postmortem artifact. Even experienced sexual assault examiners, whose expertise is confined to antemortem cases, may confuse normal postmortem changes or findings secondary to the cause and manner of death with traumatic lesions that are consistent with penetrating injury, i.e., sexual assault.

Materials and Methods: Using the mobile system of technology described by Crowley (*JFS*, 2004), the author proposes a baseline study of postmortem genital examinations with concomitant application of a 1% solution of toluidine blue dye. Utilizing colposcopy at 15X magnification, no injuries were noted in living sexual assault victims via the nuclear stain that had not already been visualized with colposcopy (Slaughter, Brown, Crowley, & Peck, *Amer. J of Ob Gyn.*, 1997).

Careful scrutiny and photo documentation with colposcopy at 7.5X and 15X should be done *prior* to speculum insertion and anoscopy. After the speculum (and anoscopic) examination, the dye can be applied to the following sites: lateral aspects of the **labia majora, posterior fourchette, fossa navicularis, perineum**, and the **perianal** area up to, but not beyond the area of the anal verge. The labia minora are moist and the epithelium is similar to mucous membrane. Only the lateral aspects are covered by skin. Thus, any positive findings at this anatomic site must be interpreted with caution. Application of the dye and scrupulous decolorization should then be done in the manner described by the original authors. These anatomic sites are selected based on histological composition and applicability to the techniques that were thoroughly described by previous authors, Richart (1963), Collins (1966), Lauber & Souma (1982), and McCauley (1987).

Another salient factor that requires further study and comparison to photocolposcopy is the interval of applicability for both antemortem and postmortem cases. Currently, a wide variation exists in standards. In non-genital sites, toluidine blue has been shown to yield positive uptake in granulation tissue. The great variety of normal artifact often present in postmortem cases presents many additional challenges. It is crucial that examiners avoid working in a vacuum. Often forensic nurse examiners are called to examine postmortem cases because of their expertise in living sexual assault cases. It is imperative that they consult and collaborate with the forensic pathologist, especially if their expertise has been previously confined only to the antemortem arena. Normal postmortem artifact has been misinterpreted as trauma and the additional use of toluidine blue will likely only complicate interpretation until it has been sufficiently studied. In equivocal cases, the forensic pathologist can remove the relevant tissues en bloc for dissection and microscopic evaluation. Prior to this, it is useful to have an initial *in situ* examination via colposcopy of the anogenital tissues.

The ultimate goal is to better visualize the anogenital tissue in the postmortem patient, in order to improve the understanding of what is normal, and what is not, at various postmortem intervals. It is possible that the application of toluidine blue dye may then enhance, for pictorial documentation.

Colposcopy, Toluidine Blue Dye, Forensic Nurse Death Investigator

G23 Viropsy - Virtual Autopsy, Where We Go?

Michael J. Thali, MD, University Bern, Centre Forensic Imaging and Viropsy, Buehlstrasse 20, Bern, Bern 3012, Switzerland*

After attending this presentation, attendees will learn about the newest imaging technologies for forensic medicine.

This presentation will impact the forensic community and/or humanity by discussing the upcoming cutting edge developments and steps in visual documentation and reconstruction of forensic cases. Therefore there will be a great impact of the paper. Invasive “body opening” autopsy is today’s state of the art in human postmortem investigation. Modern cross section techniques can supplement and may replace autopsy to some extent with several improvements for the forensic workflow.

A combination of 3D optical and photogrammetric surface scanning with full body CT scans as well as postmortem MRI investigations to correlate the radiological findings with the forensic findings documented in traditional autopsy performed afterwards is discussed. Using the Armed Forces Institute of Pathology (AFIP) design comparison approach, well

known from clinical radiology and pathology correlating radiological and pathological findings, different forensic morphological findings are presented. Additionally the application of micro CT and Magnetic Resonance Microscopy is introduced for the forensic use.

The new possibilities that are based on the combined data sets of forensic corpses (visible human in forensics) such as real data based forensic virtual reconstruction and application of “morphological fingerprints” are demonstrated. The article gives an overview on postmortem application of 3D surface scanning and radiological cross sectional scanning using CT and MRI in forensic medicine by correlating imaging appearances of essential forensic findings to their appearance in traditional autopsy.

This paper presents the newest developments in postmortem biopsy, postmortem angiography, and the MRI whole body imaging using “Total imaging Matrix.”

Viropsy, Virtual Autopsy, Imaging

G24 Female Firearm-Related Suicides: A Reappraisal

Kevin D. Whaley, MD, Anna Noller, PhD, and William T. Gormley, MD, PhD, Central District, Office of the Chief Medical Examiner, Commonwealth of Virginia, 400 East Jackson Street, Richmond, VA 23219*

After attending this presentation, attendees will recognize that suicides by women using firearms, including shotguns are not rare and may be increasing in incidence.

This presentation will impact the forensic community and/or humanity by demonstrating the increasing incidence of self-inflicted gunshot and shotgun wounds by women.

After attending this presentation, attendees will appreciate the increasing incidence of female firearm-related suicide. Moreover, they will become familiar with the most common risk factors associated with these cases.

When women die from apparently self-inflicted firearm wounds, especially shotgun wounds, many citizens, family members, and death investigators are very suspicious that the death is really a homicide. This presentation will impact the forensic community, particularly forensic pathologists, and medicolegal death investigators, by facilitating accurate and efficient determination of the manner of death in female firearm-related suicides. Furthermore, proper classification of these deaths as suicides will also result in a more efficient expenditure of time and other resources with regards to law enforcement and the judicial system.

Notwithstanding increasing data to the contrary, female suicides are often stereotypically associated with less violent means (i.e., poisoning, hanging, carbon monoxide) while their male counterparts are stereotypically associated with more destructive means (i.e., firearms, jumping from heights, motor vehicle accidents).

Despite being historically associated with male suicide, a retrospective review of female suicides occurring in Virginia from 2000 – 2005 revealed a significant percentage of female decedents utilized a firearm. This study reviewed the case files of all female firearm-related suicides from 2000 to 2005 at the Richmond District Office of the Chief Medical Examiner. Additional data was gathered from the other three districts with regards to the incidence female firearm-related over this five year period. Data collected from each case included the age, race, comorbidities, socioeconomic status, and substance abuse history, type of firearm utilized, firearm availability, and whether or not other methods of self-destruction accompanied the firearm injury. The demographics and risk factors associated with female firearm-related suicides differ from those associated with their male counterparts. Appreciating these differences will facilitate accurate and efficient medicolegal death investigation of female suicides involving a firearm.

Of particular concern is a gradual increase in the incidence of firearm-related female suicides annually. In Virginia, the incidence of firearm-related female suicides has increased by approximately ten percent over a four-year period. Moreover, of firearm-related female suicides, a significant percentage involves a shotgun rather than a handgun or rifle.

The presentation will include case examples that illustrate the most common scenarios involving female firearm-related suicide.

Shotgun, Suicide, Women

G25 Agonal Sequences in Four Filmed Hangings: Analysis of Respiratory and Movement Responses to Asphyxia by Hanging

Anny Sauvageau, MD*, and Stéphanie Racette, BSc, Laboratoire de Sciences Judiciaires et de Médecine Légale, 1701 Parthenais Street, 12th Floor, Montreal, Quebec H2K 3S7, Canada

The goal of this presentation is to first review the literature on physiological responses to asphyxia by hanging in human and animal literature, and then to compare such data to four cases of filmed hanging. In the conducting of investigations and trials, forensic pathologists are often asked to discuss the body's responses to hypoxia/anoxia and their temporal relationship to the timing of asphyxial deaths. However, those questions are difficult to answer considering the actual paucity of research literature.

This presentation will impact the forensic community and/or humanity by providing new insight into the physiopathology of human asphyxia.

Introduction: The human pathophysiology of asphyxia by hanging is still poorly understood, despite great advances in forensic science. Even though some studies have been conducted on animals, the extent to which those results can be applied to human is uncertain. Since experimental protocols are, of course, out of the question, filmed hangings hold the key element to answer questions regarding the sequence of events leading to death in the context of human asphyxia.

Methods: A total of four filmed hangings were analyzed: one suicide filmed by a video camera, two autoerotic deaths and one suicide in custody filmed by a surveillance camera. Those filmed hangings were compared in terms of loss of consciousness, convulsions, decortication, and decerebration rigidity, loss of muscle tone, last muscle movement, and respiratory responses. Two independent judges scored the time frame at which each of these responses occurred.

Results: With the time 0 representing the onset of hanging, rapid loss of consciousness was observed (at 13-18s), closely followed by appearance of convulsions (at 15-19s) in all cases. Within the first minute (19-21s in most cases, 46s in one case), decerebration rigidity was observed. Two phases of decortication rigidity was also noted, the first one being relatively sudden and quick (onset at around 1min00s -1min 08s in most cases, 21s in one case) while the second one (onset between 1min04s - 1min32s) extended for about one minute, with an observed climax of rigidity about 20 seconds after its onset. Appearance of loss of muscle tone varied between 1min 38s and 2min 47s, with last isolated muscle movement occurring between 2min 15s and 4min 10s. Similar patterns between cases was observed for respiratory responses: onset of very deep respiratory attempts between 20 and 22 seconds, last attempt between 2min 00s and 2min 04s for an average interval of 1min 40s to 1min 42s. Overall, total hanging time before apparent death was between 2min 47s - 4min 10s.

Conclusion: Despite differences in the types of hanging, similarities could be revealed regarding rapid loss of consciousness and onset of

convulsions, pattern of decortication rigidity and respiratory responses. To date, this is a unique study of agonal movements in asphyxia by hanging. The importance of inter-laboratory collaboration in extending this project by adding other available filmed hangings is discussed and the importance of a Working Group of Human Asphyxia (WGHA) is further emphasized.

Asphyxia, Hanging, Forensic Pathology

G26 The Methods of Committing and Alcohol Intoxication of Suicides in the Southwestern Croatia From 1996 to 2005

Alan Bosnar, MD, PhD*, Valter Stemberga, MD, Miran Coklo, MD, and Sanja Dobi Babic, BSc, Department of Forensic Medicine, Rijeka University School of Medicine, B. Branchetta 20, Rijeka, 51000, Croatia; and Emina Grgurevic, MD, Public Health Institute of Primorsko-Goranska County, Kresimirova 52a, Rijeka, 51000, Croatia

After attending this presentation, attendees will understand the relationship between alcohol intoxication and the choice of suicide method in the Southwestern Croatia from 1996 to 2005.

This presentation will impact the forensic community and/or humanity by through the contribution to a better understanding of the relationship between alcohol intoxication and the choice of suicide method, and by pointing towards efficiency of specific suicide prevention measures in specific methods of committing suicide.

This study was undertaken to determine if the level of alcohol intoxication and the choice of specific methods of committing suicide are related.

Suicides in the Southwestern Croatia in a ten year period, especially regarding the method of committing and alcohol intoxication, were analyzed. The examined region has an area of 7,993 km² with the population of 322,964, mostly living in the city of Rijeka, as a regional center.

In the examined period, 512 suicides were recorded, with 367 male and 154 female victims. The average age of male victims was 50.81 years, while female victims were older with the average age of 56.02 years. Ten various methods of committing suicide were recorded, with hanging as the most frequent (34%), followed by jumping from height (17%), firearms (15%), poisoning (14%), drowning (10%), jumping under/in front of a train (4%), explosive devices (4%), cutting/stabbing (1.2%), electrocution (0.4%) and self-immolation (0.4%). The average blood alcohol concentration at the moment of suicide was 0.68 g/kg with male, and 0.29 g/kg with female victims. The highest blood alcohol levels at the moment of suicide were recorded with suicides by explosive device (with the average blood alcohol concentration of 1.71 g/kg), while the lowest concentrations were recorded with female hanging suicides (with the average blood alcohol concentration of 0.0153 g/kg) and male cutting/stabbing suicides (with the average blood alcohol concentration of 0.103 g/kg).

This study suggests that the alcohol consumption before committing suicide is more significant in cases of suicide with an explosive device than in the other methods of suicide. This especially drastic method of suicide was rare in Croatia in a period prior to the Croatian Independence War (1991-1995), but its incidence significantly increased during the war and in a post-war period. These victims were not chronic alcoholics, but they consumed excessive alcohol as a result of psychiatric disorders as a consequence of war stress they suffered. This study showed that increased alcohol consumption in Croatia is more closely associated with certain methods of suicide over other methods.

Suicide, Alcohol, Croatia

G27 Suicide by Self Immolation in Cook County, Illinois, USA

Ponni Arunkumar, MD*, J. Scott Denton, MD, and Edmund R. Donoghue, MD, Cook County Medical Examiners Office, 2121 West Harrison Street, Chicago, IL 60612

After attending this presentation, attendees will learn of the prevalence of suicide by self-immolation and conditions leading to self-immolation.

This presentation will impact the forensic community and/or humanity by generating awareness of death by self-immolation, discuss, and describe the predisposing factors for this rare cause of death.

Suicide by self-immolation is extremely rare in the United States. This study aims to describe and determine the prevalence of such deaths in Cook County, Illinois, with an ethnically diverse population of 5.5 million people, which includes the city of Chicago and its neighboring suburbs. A thirteen year retrospective study from 1993 to 2005 was conducted to determine whether there were any common factors that lead to death by self-immolation. Computerized records of the Office of the Medical Examiner of Cook County were searched and reviewed for causes of death from self-immolation. The review identified 33 cases from 1993 to 2005 of such deaths. Seven cases were excluded from the study as one was a homicide, four were accident, and two were undetermined.

The age, sex, mental illness history, location of event, yearly incidence, use of accelerant, and presence of witnesses were studied.

Of the 33 cases, 23 were male and ten were female. The male: female ratio was 2.3:1. The ages ranged from 16 to 91 years old. The average age was 38.2 years. Most of the cases were in the 30-39 year age group with the following distribution: three cases (9.1%) were 11-19 years; eight cases (24.2%) were 20-29 years; nine cases (27.3%) were 30-39 years; three cases (9.1%) were 40-49 years; eight cases (24.2%) were 50-59 years; one case (3.0%) was 60-69 years; one case (3.0%) was 90-99 years. Of the 33 cases, 22 were white; ten were black, and one Asian.

Carbon monoxide determination was done in seventeen out of 33 cases. The carbon monoxide level ranged from negative to 45%. The average blood carbon monoxide level was 11.4%. Twenty-two cases received medical treatment.

An accelerant was used in 27 cases (81.84%). Gasoline was the most frequently used accelerant. It was used in 21 cases (63.6%). Charcoal lighter fluid was used in two cases. Acetone in nail polish remover was used in one case. An unknown accelerant was used in four cases.

The majority of self-immolation cases occurred at home, with nine cases. Three cases occurred in the garage adjacent to the home, one case in the front lawn of the home, two cases in the driveway of the home, two cases in the backyard of the home, two cases in a forest preserve, two cases in a parking lot, two cases in an alley, two cases near or on railroad tracks, two cases on a street, and one case each in a church, a college, a grassy area near major toll roads, and a shop.

Nine out of the 33 self-immolation cases were witnessed. Six of the cases had attempted suicide before. One had a prior attempt of self-immolation. Ten subjects had talked previously about suicide. In only five cases, a suicide note was left.

Twenty-seven cases (81.8%) had a history of mental illness, mostly depression. A history of depression was seen in seventeen cases (51.5%).

In ten cases, the cause of death was thermal burns due to self-immolation. Seven cases were determined as thermal burns due to house fire or fire. Four cases were determined as thermal burns due to gasoline fire. Three cases were closed as thermal burns and two cases as simply self-immolation. In two cases, the cause of death was carbon monoxide intoxication due to clothing fire. One case was closed as inhalation of smoke and soot due to house fire. One case each was closed as thermal injury, inhalation injury due to self-immolation, sepsis due to self-immolation, and multisystem organ failure due to thermal burns due to motor vehicle fire.

The study confirms that suicide by self-immolation is extremely rare in Cook County, Illinois, USA with an overall yearly average of 2.54 cases (0.05%). The majority of cases were male, white, with a history of mental illness, and immolated themselves at home.

Forensic Science, Self-Immolation, Suicide

G28 Seasonal Incidence of Suicides in Crete Island: A Five Year Study

Marianna Kalyva, MD*, University of Crete, Department of Forensic Sciences, Medical School, Heraklion, 71110, Greece; Vasilios Stoukas, Telamonos 25, Anthoupoli, Peristeri, Athens 12135, Greece; and Anna Mavroforou, PhD, Elena F. Kranioti, MD, Panagiotis Mylonakis, MD, Antonios Papadomanolakis, MD, and Manolis Michalodimirakis, MD, JD, University of Crete, Medical School, Department of Forensic Sciences, Heraklion, 71110, Greece

After attending this presentation, attendees will learn information concerning seasonal peaks of the suicide rates, as well as the reasons for this distribution in Mediterranean countries.

This presentation will impact the forensic community and/or humanity by increasing understanding of the suicide incidence during all year round in a country with many special factors (religion, weather conditions, people's attitude, Mediterranean temperament etc.).

Suicide is defined as the intentional act of self-destruction committed by someone who knows what he or she is doing, and who is aware of the probable consequences of his or her action. The epidemiology of the suicide phenomenon is always of major interest in contemporary forensic science. Studies have shown that suicide in some countries constitutes the third, or even the second most common cause of death for persons aged between 15 and 24 years, including accidents and homicides.

In order to study this phenomenon on the island of Crete, a retrospective analysis of all suicide cases for the period 1999 to 2003 was conducted, based on the archive files of the Department of Forensic Sciences (Medical School, University of Crete, Greece), which serves the entire region. Crete is an island (the southernmost island in Europe) with a population of about 750,000 inhabitants with millions of tourists annually.

The parameters chosen were the personal data of the subjects (age, sex, and nationality), the information concerning time and location where death occurred (date and exact time of the incident, area, and exact location), and the cause of death. In a total of 183 cases, 80.0% of them involved men and 20.0% women. One hundred seventy-two cases concerned persons of Greek nationality (94.0%) and the rest concerned foreigners. Thirty-six incidents (19.7%) occurred in 1999, 51 (27.9%) in 2000, 30 (16.4%) in 2001, 30 (16.4%) in 2002 and 36 (19.7%) in 2003.

Hanging prevailed as the main cause of death (41.0%), followed by chemical substance overdose (drugs and pesticides, 26.8%), and firearm injuries (gunshot and shotgun wounds, 21.2%). The age specific suicide rates per year were 20.0%, 16.4%, 13.1%, 15.3%, 12.0%, 12.6%, and 7.7% for 21-30, 31-40, 41-50, 51-60, 61-70, 71-80, and 81-90 age groups respectively. Four persons were of undetermined age. Seventy-one out of 183 (39.0%) cases occurred at the region of Heraklion, which corresponds with the population distribution of Crete.

The bimodal seasonal peak in the suicide rate observed in this study was in agreement with several other reports, indicating that suicide follows a seasonal pattern with a dominant peak during the spring or early summer (months of maximum day light, 14.2% and 12.0% stand for June and May respectively) and a lesser peak in the autumn. The spring peak in the suicide rate has been typically observed in Mediterranean countries. It has also been reported that agricultural populations have a longer spring peak, while industrial populations have a shorter one. This should be considered as a further explanation for the extended spring peak observed, since the suicide incidence was higher in rural areas, which were represented by 61.2%.

The suicide incidence in Crete (3.9 per 100,000 inhabitants) seems to be lower than the reported average in Greece (7.1 per 100,000 inhabitants), but higher compared to other Greek geographical regions, e.g., a suicide incidence rate of about 2.7 stands for Epirus, at the north-western coast of Greece.

Suicide, Seasonal incidence, Crete Island

G29 Suicidal Electrocution in Australia

Peter Y. Chan, BSc*, and Johan A. Duflou, MBChB, MMed, Department of Forensic Medicine, PO Box 90, Glebe, NSW 2037, Australia

The goal of this presentation is to describe a series of electrocution suicides in Australia.

This presentation will impact the forensic community and/or humanity by providing details of the typical electrical suicide death scene, autopsy features, and some specific problems associated with suicidal electrocution.

Introduction: While suicide is a worldwide phenomenon, the method that is used frequently has a geographic correlation. For instance, firearm suicides make up 50% of all suicides in the USA, while intentional poisoning with agricultural pesticides is used in up to 80% of cases in some Third World countries. While electrocution is not the most common form of suicide in Australia, compared to most parts of the world it appears to be a relatively frequent mechanism of suicide that warrants further study.

Materials and methods: This retrospective study investigates the trend of suicide by electrocution in the period from 1996 to 2005 examined at the Department of Forensic Medicine, Glebe, Sydney. Reviewed were the common autopsy, histology, and death scene characteristics of individuals who commit suicide via electrocution. A total of 25,675 deaths were investigated at between 1996 and 2005, with definite or probable suicide as the manner of death in 2029 cases. Suicidal electrocution cases were obtained by searching the Department of forensic medicine autopsy text database. All cases in this study had a full autopsy, including toxicology and histology, and a detailed death scene investigation by criminalists and electricians had been performed.

Results: There were 25 cases of definite suicidal electrocution (mean 2.5 cases/annum, 1.2% of all completed suicides), and a further three cases of possible suicidal electrocution in the time period. The latter three cases were not analyzed further. Eighty-one percent of decedents were male, and the mean age was 57 years (range 22 to 90 years). At least 40% of decedents were either currently working or had worked as electricians. Psychological comorbidities, predominantly depression, were observed in 73% of cases.

In 20 of the 25 cases, the mechanism of electrocution was by attachment to a live main electrical power point using electrical flex. The flex was typically tied around the wrists, causing a lethal current to pass through the body. Deep circumferential electrical burn marks on the wrists or other extremities were typical, although there were three cases where the electrical flex had been placed elsewhere (chest or mouth). The remaining five cases had electrocuted themselves by dropping an electrical appliance in the bath. There were histological findings consistent with electrocution in one of these cases. Two showed no signs of electrocution despite the body being found immersed in water with an appliance active or recently turned off, and two others were too badly decomposed for any further assessment.

Toxicology was positive in 17 (68%) cases. These included a single drug in 14 (56%) cases, with alcohol and benzodiazepine use predominating (5 and four cases respectively). Autopsy revealed the presence of significant organic disease in 17 cases, with nine of these presenting with at least two separate pathological processes. Grossly, pulmonary congestion or edema was found in 12 cases. Histologically, morphology consistent with electrocution was found in 11 cases.

In 78% of cases, the mains circuit in the premises was still live, as was the electrical outlet used to cause electrocution. Timers had been used in eight cases, but the remaining 17 bodies were "live" on arrival of witnesses or electricity personnel. In at least one case it was reported that witnesses touched the electrically active body. Notes from the deceased warning of potential electrical hazard from touching the body were found in at least five of the cases. Safety mechanisms were not tripped in any of the cases, and were only tampered with in one case.

Discussion: While suicide by electrocution is typically described as the activation of electrical appliances while immersed in a body of water, cases in Sydney appears to have a high proportion of individuals who attach themselves to power points via exposed wires. In the majority of cases in this study the body was "live" at the time of discovery, presenting a life-threatening risk to initial responders to the death. Investigators and emergency workers should remain vigilant upon discovery of electrical suicides, due to the fact that most bodies remain electrically active long after death.

Electrocution, Suicide, Death Scene Hazards

G30 Open Fractures in Pedestrians Mimicking Gunshot Wounds

Melissa A. Brassell, MD*, Mary G. Ripple, MD, and David R. Fowler, MD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD 21201

After attending this presentation, attendees will understand the similarities and differences in the appearance of pedestrian injuries and gunshot wounds and the implications of non-forensic trained health care professionals confusing these types of injuries on initial inspection.

This presentation will impact the forensic community and/or humanity by emphasizing the need for continuing education and a close working relationship between medical examiner/coroner's offices and health care professionals.

In February and April 2006, autopsies were performed on two pedestrians that were thought to have sustained gunshot wounds. While it was clear that the individuals had been struck by a motor vehicle, there was concern in both instances based on initial external examination at the scene by emergency personnel and at the hospital emergency department, that they had sustained gunshot wounds prior to being struck.

The first case was a 27-year-old male who was struck by a Chrysler 300 as he ran across the intersection of a local street. Information obtained from paramedics following a preliminary external examination at the scene was that the individual sustained a gunshot wound to the right thigh prior to being struck. An investigation was begun by police into the probable shooting. At autopsy, there was an open right femur fracture with an associated $\frac{1}{2}'' \times \frac{5}{8}''$ irregular laceration with a surrounding irregular, contiguous abrasion located on the inner right thigh. In addition, there was a curvilinear, $3'' \times 4''$ laceration on the lateral thigh with associated extension lacerations, abrasions, and protrusion of the quadriceps muscle. Postmortem radiographs and dissection of the thigh showed no beveling and no bullet fragments or distinct wound path. Thus, the findings were not consistent with a gunshot wound. The second case was a 25-year-old female who was struck by a Nissan Maxima as she crossed a busy expressway at approximately 6:00 a.m. She was taken to the nearest hospital, where physicians interpreted injuries of the left eyebrow and right temporal region as a possible through and through gunshot wound. Because of suspicion of a gunshot wound, her hands were bagged for preservation of evidence. A homicide investigation was begun. At autopsy, a $3''$ curvilinear abrasion and adjacent $1''$ laceration with skin avulsion was present on the right temple and a $\frac{1}{2}''$ laceration with a contiguous curvilinear abrasion was present lateral to the left eyebrow. Autopsy, including radiographs showed linear and diastatic skull fractures, no beveled skull defects, no wound track, and no bullet fragments. Thus, the findings were not consistent with a gunshot wound.

Open fractures of long bones sustained as a pedestrian struck by a motor vehicle primarily mimic gunshot wound defects at the skin surface. The overlying skin surface can show a full thickness laceration produced by the blunt trauma. Some of these lacerations are roughly circular to irregular with contiguous abrasions similar to that of an atypical entrance gunshot wound with its surrounding abrasion collar. Closer external examination of these wounds shows that the edges can be re-approximated, unlike that seen in an entrance gunshot wound. In addition, internal dissection and radiography reveal typical compound fractures with distinct linear edges, no bone dust or minute bone fragments, no beveling, no wound track and no bullet fragments.

Since open fractures can mimic gunshot wounds, close inspection of the external wound and evaluation of the internal injury both by dissection and radiography are essential in determining whether the injuries were caused by a gunshot. This presentation emphasizes the need for educating health care professionals, especially first responders and emergency room staff, in injury patterns in order to prevent an unnecessary homicide investigation.

Gunshot Wound, Pedestrian, Laceration

G31 Homicide in a Surgical Intensive Care Unit

A. Thambirajah Balachandra, MBBS, Johanna Abbott, and Carol Youngson, RN, Office of the Chief Medical Examiner, Manitoba Justice, 210-1 Wesley Avenue, Winnipeg, Manitoba R3C 4C6, Canada; John Burchill, Hate Crimes Unit Coordinator/Major Crimes Analyst, Winnipeg Police Service, PO Box 1680, 151 Princess Street, Winnipeg, Manitoba R3C 2Z7, Canada; and N.D.N. Asela Mendis, MBBS, and Sholeh Barooni, MD, Office of the Chief Medical Examiner, Manitoba Justice, 210-1 Wesley Avenue, Winnipeg, Manitoba R3C 4C6, Canada*

The goals of this presentation will be to increase the forensic community's awareness of the potential for potassium overdose to be intentionally administered to patients in health care facilities; to explore the problems and difficulties encountered in the medicolegal investigation of such cases; and, to devise means of preventing hyperkalemic deaths as a result of intentional overdose.

With the increasing number of frail, elderly patients with multiple medical complications, it may be tempting for health care workers who are taking care of these patients to put them "out of their misery." However logical it may sound, it is unethical and contrary to law. The criminal use of intravenous potassium salts on these victims usually will not leave any evidence to identify the cause of death or the perpetrator. Investigating these cases is very difficult because the victims have multiple problems and police departments, medical examiners, and forensic pathologists are reluctant to conduct a homicide investigation in a hospital, especially the intensive care unit. Publicizing these cases will keep the forensic community alert. This presentation will impact the forensic community and/or humanity by discussing the various means of investigating such cases.

Case Background: On January 3, 2002 at 09:30 hours, E.J.M., an 83-year old woman who lived alone, was found by police in a semi-conscious state in her home. She was taken to the emergency department of a tertiary care hospital in Winnipeg, Manitoba. She was diagnosed with a fractured left hip, renal failure, myoglobinuria, and pneumonia. She was admitted at 17:47 hours and transferred to the Surgical Intensive Care Unit (SICU). The plan was to stabilize her condition before she underwent corrective hip surgery.

The following day, at 15:45 hours, her serum electrolytes revealed a potassium level of 3.3 mmol/L. As her serum chloride level was elevated, the physician prescribed potassium acetate – to be infused at a rate of 5 mmol/hour for four hours for a total of 20 mmol. A 50 cc vial of potassium

acetate (with a concentration of 4 mmol/ml) was sent to the SICU by the pharmacy. Apparently 5 ml of the potassium acetate was drawn into a 10 cc syringe and injected into a 100 ml buretrol and topped with 95 ml of normal saline and 5% dextrose. The pump was set to run at 25 ml/hour beginning at 17:00 hours.

E.J.M. was also started on 4 ml of magnesium sulfate (2000 mmol/L) intravenously to run over two hours. At 18:40 hours, as the primary nurse was otherwise occupied, the nurse responsible for the patient in the next bed added 4 ml of magnesium sulfate to the same buretrol. This nurse noted that the buretrol contained 60 ml of fluid and the pump was running at 25 ml/hour.

At 19:30 hours a shift change occurred and a third nurse became involved with E.J.M. On taking over the patient's care, the nurse "eyeballed" the buretrol and noted it contained about 75 ml of fluid and that the fluid was infusing at a rate of 50 ml/hour. Although the patient's chart contained instructions for the pump to run at 25 ml/hour, based on the volume remaining in the buretrol (75 ml) and that it would take two hours to complete the infusion, the nurse apparently, at 20:00 hours, overwrote the order to read 50 ml/hour. Around this time it also became apparent that E.J.M.'s condition was becoming unstable. Blood was drawn at 20:30 hours and sent to the hospital laboratory for electrolyte and hemoglobin levels. At 20:38 hours, E.J.M. went into cardiac arrest. An emergency code was called and she was pronounced dead after 15 minutes of resuscitation.

At 21:13 hours, the SICU was notified by the laboratory of a critical potassium level of 7.6 mmol/L. The physician was informed of these results and immediately suspected a medication error. The buretrol was seized and sent to the hospital laboratory for analysis. A search for the used 50 cc vial of potassium acetate, however, was not successful.

The death of E.J.M. was reported to the medical examiner's office on January 4, 2002 at 22:35 hours by the physician due to the possible medication error. The medical examiner commenced an investigation that included the results of the medicolegal autopsy (concluded that hyperkalemia was the cause of death), as well as the findings from the internal investigation done concurrently by the hospital. Following extensive meetings between the medical examiner's office, the hospital and the police; hours of interviewing physicians, nursing staff and other health care workers; numerous searches for the missing potassium acetate vial; and repeated testing on the buretrol contents, the medical examiner's office and the hospital jointly concurred that E.J.M.'s death was not an accident, but the result of an intentional act. Consequently, detectives from the Winnipeg Police Service officially took over the investigation on February 12, 2002.

Results: Repeated laboratory analyses of the buretrol contents revealed a potassium concentration ten times higher than what had been prescribed for the patient, an increased amount of chloride, and a trace amount of diphenhydramine, which had never been prescribed. It was also evident from the investigation that the pump speed had been doubled and additional fluids had been injected into the buretrol. Lastly, the used 50 cc vial of potassium acetate had never been recovered. Thus, it was reasonable to conclude that someone, probably a member of staff at the hospital, had doubled the pump speed and added potassium acetate, potassium chloride and diphenhydramine to the buretrol to intentionally cause E.J.M.'s death. Therefore, the manner of death was homicide. Despite a thorough police investigation, which included an extensive report by a Major Crimes analyst, there was insufficient evidence to lay charges against any individual or individuals involved.

Conclusion: This death clearly illustrates that administering excessive amounts of potassium can kill patients in health care facilities. However, hyperkalemia as a result of intentional overdose is next to impossible to diagnose by autopsy alone. Other, thorough investigations, including a review of the medical chart, analyses of any remaining fluids, and examination of the pump's memory system, are vital to the investigator in reaching a conclusion of intentional overdose. Following the death of E.J.M., it is now the practice in intensive care units in

Manitoba hospitals not to store potassium acetate or potassium chloride on the wards.

In February 2003, in the absence of criminal charges, the Chief Medical Examiner directed that an inquest be held into the death of E.J.M. The findings of the inquest judge were released in September 2005. The report can be accessed by visiting website: http://www.manitoba.courts.mb.ca/inquest_reports.html (Report No. 6 - E.J.M. – September 12, 2005).

Hyperkalemia, Intensive Care Unit Death, Homicide

G32 Subdural Hemorrhage, Subarachnoid Hemorrhage, and a Healing Tibia Fracture: Abuse or Complications of Leukemia?

Veena D. Singh, MD, MPH, University of New Mexico Health Sciences Center, Department of Pathology MSC08 4640, 1 University of New Mexico, Albuquerque, NM 87131; and Kurt B. Nolte, MD, and Ross Reichard, MD, Office of the Medical Investigator, MSC11 6030, 1 University of New Mexico, Albuquerque, NM 87131*

The goal of this presentation is to discuss the natural diseases that may mimic inflicted trauma and discuss methods of differentiating natural disease from neglect and inflicted trauma.

This presentation will impact the forensic community and/or humanity by highlighting issues related to pediatric autopsy and findings that may obscure cause and manner of death. A better understanding of ways that natural disease can mimic inflicted trauma will better enable forensic pathologists to avoid inaccurate diagnoses.

Objective: Child fatalities due to natural disease vs. abuse and/or neglect are challenging forensic autopsies.

Case Summary: A two-year-old boy was found dead in his foster care bed. He was receiving treatment with L-asparaginase and steroids for acute lymphoblastic leukemia. In the weeks prior to his death he became increasingly weak and had several falls witnessed by therapists and family members. In the days prior to his death he had marked thrombocytopenia.

Autopsy revealed acute small cerebral subdural and subarachnoid hemorrhage, and superior sagittal sinus and cerebral venous thromboses, a healing tibial compression fracture and extensive bronchopneumonia. There were no retinal or optic nerve sheath hemorrhages.

Discussion: Although subdural and subarachnoid hemorrhages in children are suggestive of inflicted injury, correlation of the medical history with autopsy findings in this case indicated that the neuropathologic findings were likely a result of minor trauma associated with underlying leukemia and treatment effects. L-asparaginase has been associated with abnormal blood clotting. Careful review of a decedent's medical history and correlation with autopsy findings is crucial to distinguish inflicted trauma from accidental trauma, and from natural disease processes that mimic trauma. The cause of death in this case was certified as complications of acute lymphoblastic leukemia and the manner of death was certified as natural.

Thrombosis, Neuropathology, Pediatric

G33 An Exceptional Case of Death Due to Lesions of Water Nozzle

Nunzio Di Nunno, MD, PhD, Università degli Studi di Lecce, Via G. Dorso n. 9, Bari, 70125, Italy; Luigi Viola, MD, Università degli Studi di Bari, Sezione di Medicina Legale, DIMIMP, Policlinico di Bari, Piazza G Cesare 11, Bari, 70124, Italy; Fulvio Costantinides, MD, Università degli Studi di Trieste, San Pelagio n. 45, Duino-Aurisina, 34100, Italy; and Giandomenico Maria Battista, MD, and Cosimo Di Nunno, MD, Università degli Studi di Bari, Sezione di Medicina Legale, DIMIMP, Policlinico di Bari, Piazza G. Cesare 11, Bari, 70124, Italy*

The goal of this presentation is to describe an exceptional case of mortal lesions due to water nozzle, a professional tool used to wash solid surfaces.

This presentation will impact the forensic community and/or humanity by describing unusual high pressure water injuries.

A 28-year-old young worker at a navy yard, died while he was trying to clean the hold ports of a ship moored at wharf of Arsenale S. Marco in Trieste (Italy).

During the investigation, the remains of the man was found laying face down on the floor of a little mobile platform raised several meters from the ground, where he was working alone.

Close to the body there was the water nozzle with the switch in the off position. There was a wide tear in the overall she was wearing and "homogenized" organic tissues were found on the platform. Skeletal elements of the remains were exposed where soft tissue had been avulsed. The postmortem examination showed skin abrasions on the right half of the face with a fracture of the skull, wide and deep soft tissue injuries of the right upper limb with areas of complete soft tissue avulsion. The soft tissue of the right side of the chest was largely absent and perforated with laceration of the lung and heart. Technical testing of the tool by an engineer showed the equipment for water cleaning was working properly, providing of water with a pressure of about 500 bars by an auto-turning nozzle. However, the safety devices had been altered. Unaltered, the jet of water should be stopped automatically if the water release and safety buttons (the last one has to be activated by the other hand) are not activated at the same time.

The scene investigation, with particular reference to the remains position, and the water nozzle found close to the body, the nature of the injuries, the negative toxicology testing, along with the technical findings about the functioning of the tool and its altered safety devices provided a clear sequence of events that led to this death. This accidental death was caused by the inappropriate use of a water cleaning device.

Water Nozzle, Crime Scene Investigation, High Pressure Water Injuries

G34 Hanging Deaths in Ontario: Retrospective Analysis of 755 Cases

Elena Tugaleva, MD, and Michael J. Shkrum, MD, Department of Pathology, London Health Sciences Centre, 339 Windermere Road, London, Ontario N6A 5A5, Canada; Donald R. Gorassini, PhD, Department of Psychology, King's University College at The University of Western Ontario, 266 Epworth Avenue, London, Ontario N6A 2M3, Canada; and Barry A. McLellan, MD, Office of the Chief Coroner, 26 Grenville Street, Toronto, Ontario M7A 2G9, Canada*

After attending this presentation, attendees will gain an appreciation of the demographics and pathology of hanging deaths in Ontario. The findings will be compared to the other series and discussed with regards to influencing factors and quality assurance standards.

This presentation will impact the forensic community and/or humanity by emphasizing the importance of documenting neck injuries in

hanging deaths, and will discuss factors influencing their frequency. It will address quality assurance issues, such as an importance of recording of pertinent negatives, use of standardized autopsy reports and dissection protocols, and utilization of additional postmortem techniques.

The frequency of neck injuries in deaths by hanging is controversial. In the literature, the range is wide, varying from 0 to 76.6% for hyoid and laryngeal fractures. Multiple factors account for this variation. Complete neck examination and accurate recording of not only positive but also negative findings are important.

This study is a retrospective analysis of deaths by hanging that happened in Ontario during a two-year period (January 1998 to December 1999). The main goal of the study was to determine the frequency of different hanging-related neck injuries. Fractures of the neck structures and soft tissue injuries were studied. Secondly, factors recognized as important in the incidence of neck fractures, such as age, sex, and weight of the deceased were evaluated. The third goal was to determine whether the frequency of hyoid/laryngeal injuries varied depending on autopsy location, i.e., forensic pathology unit, teaching hospital, or community hospital.

A total of 755 cases were available for evaluation of which 632 had a complete autopsy and 68 were limited to external examination only. In 55 cases, no postmortem examination was conducted. The largest category was suicidal hanging, at 737 cases (97.6%). Nine cases (1.2%) were accidents and two cases (0.3%) were homicides. In seven (0.9%) cases the manner of death was not determined. The mean age of the deceased was 40.58 years (the youngest victim was two and the oldest 94 years old), and there was a male predominance (82.6%). The following represents a breakdown, by location, of the cases that were examined: 240 (34.3%) in forensic facilities (of which 72.9% were complete autopsies and 27.1% were external examinations); 48 (6.9%) in teaching hospitals (of which all were complete autopsies), and 412 (58.9%) in community hospitals (of which only three were limited to external examination).

Of the 632 cases that had complete autopsies, the most common hanging related neck injuries were those of soft tissue. The latter were quite variable in severity, ranging from minute soft tissue hemorrhages to complete transection of the neck structures. Soft tissue injuries not associated with skeletal trauma were reported in 59 cases (9.3%). Associated fractures of the hyoid bone and/or laryngeal cartilages were present in 46 cases (7.3%) with the most common being hyoid fractures (30 cases). Less common were fractures of thyroid cartilage alone (10 cases), combination of hyoid and thyroid cartilage fractures (3 cases), and cricoid cartilage (3 cases). Seven cases of cervical spine injuries (fractures or dislocations) were documented.

A higher incidence of neck fractures occurred among men. There was a tendency for the number of fractures to increase with increasing age and weight/BMI of the deceased.

The frequencies of hyoid/laryngeal fractures distributed over forensic, teaching, and community facilities were as follows: 7.4%, 16.7% and 6.1%, respectively. The frequency of fractures reported in specialized forensic facilities reached 10.6% if the Forensic Pathology Unit in Toronto was excluded from the analysis. The lower frequency of fractures (2.8%) registered in this unit could be explained by different demographics of cases that underwent complete postmortem examination, specifically due to a higher proportion of complete autopsies performed on female and younger individuals. Higher frequency of fractures correlated with a higher percentage of cases in which there was accurate reporting, i.e., definite comments were made upon presence or absence of specific injuries and their site.

Hanging, Neck Injuries, Pathology

G35 Maternity and Paternity Testing of a Discarded Dead Neonate Involving a Young Girl and Her Father

Jian Tie, MD, PhD, Yuka Serizawa, BS, and Sesaku Uchigasaki, MD, PhD, Department of Legal Medicine, Nihon University School of Medicine, 30-1 Oyaguchi Kamimachi, Tokyo, 173-8610, Japan; Yoshihiro Mitsugi, Criminal Investigation Laboratory, Saitama Prefectural Police Headquarters, 3-10-1 Kizaki Urawa-ku, Saitama, Saitama 330-0042, Japan; and Shigemi Oshida, MD, PhD, Department of Legal Medicine, Nihon University School of Medicine, 30-1 Oyaguchi Kamimachi, Tokyo, 173-8610, Japan*

Upon completion of this presentation, participants will know how to gather evidence when the case involves a discarded dead neonate using DNA identification. In the presented case, the infant's mother was 16 years old and the infant's father was also the infant's mother's father. This is a rare paternity testing case. Sixteen Y-plex chromosomal STR testing was used to analyze the relationship of the girl's father and the infant.

This presentation will impact the forensic community and/or humanity by showing that Y-Plex STR is a very useful genetic marker for forensic practice.

A male neonate was found dead in a paper box, with the umbilical cord coarsely amputated. Next to the body there were several bloodstains on a pair of sandals marked with the name of a family living near the scene. A 16-year-old girl with the same family name was suspected as the neonate's mother, as her house was near the scene and blood was found in the toilette of her home. The girl's father and mother were divorced years ago, and her father was remarried to another woman. In order to obtain evidence to determine whether the infant was the girl's son and to establish the identity of the infant's father, DNA was extracted from the oral epithelium of the girl and her father. Blood taken at autopsy provided the source of DNA from the infant. Fifteen autosomal STR loci plus the amelogenin locus were investigated using DNA samples of the girl, her father, and the infant. To investigate the relationship between the infant and the girl's father, sixteen Y chromosomal STR loci were analyzed using DNA samples from the girl's father and the infant. The probabilities of maternity and paternity were 0.9999999 and 0.9999999, respectively, for all fifteen autosomal STR loci analyzed. Furthermore, the sixteen Y chromosomal STR loci were an exact match between the dead infant and the girl's father. These results conclusively proved that the 16-year-old girl and her father were the biological parents of the discarded dead neonate.

Discarded Dead Neonate, Maternity and Paternity Testing, STR

G36 Undetected Polyglandular Autoimmune Syndrome Type II (Schmidt Syndrome) as a Cause of Sudden Death

Michael S. Lantier, Villanova University, 800 Lancaster Avenue, Villanova, PA 19085; and Fredric N. Hellman, MD, MBA, Office of the Medical Examiner, Delaware County, Route 352-Fair Acres, Lima, PA 19037*

The goals of this presentation are to discuss the clinical features and disease association characteristics of the Polyglandular Autoimmune Syndrome Type II, and to increase the recognition of the morbidity and mortality arising from polyglandular autoimmune disorders.

This presentation will impact the forensic community and/or humanity by demonstrating how polyglandular autoimmune (PGA) syndromes are associated with a diversity of related diseases. Diabetes mellitus Type I is a common manifestation of PGA Types II and III. Less

frequently observed is Addisonian crisis arising from co-occurring thyroiditis and adrenalitis in the absence of pancreatic involvement and resulting in sudden, unexpected death. The premorbid clinical and laboratory manifestations of this disorder can be subtle and non-specific, yet are critical benchmarks to be recognized in order to avoid a potentially lethal outcome.

Immunologic syndromes impacting multiple endocrine organs and giving rise to other nonendocrine immune disorders are a rare cause of sudden, unexpected death. Endocrine deficiency due to Polyglandular Autoimmune Syndrome can be brought on by infection, infarction, or tumor that results in the destruction of all or a large part of an endocrine gland. In most cases, however, the activity of an endocrine gland is depressed as a result of an autoimmune reaction that produces inflammation, lymphocytic infiltration, and partial or complete destruction of the gland. There are three patterns of Polyglandular Autoimmune (PGA) Syndrome, referred to as types I, II, and III. PGA Type I usually occurs in childhood and is characterized by hyperparathyroidism (79% of cases), followed by adrenal cortical failure (72%). Diabetes mellitus Type I seldom occurs. PGA Type II generally occurs in adults and always involves the adrenal cortex and frequently the thyroid gland (Schmidt syndrome) and the pancreatic islets. Type II is the most common of the syndromes and is characterized by the occurrence of autoimmune Addison's disease in combination with thyroid autoimmune diseases and/or diabetes mellitus Type I. The most frequent clinical association is between Addison's disease and Hashimoto's thyroiditis, while the least frequent clinical combination is Addison's disease, Graves' disease, and diabetes mellitus Type I. PGA Type III occurs in adults and does not involve the adrenal cortex, but includes at least two of the following: thyroid deficiency, diabetes mellitus, pernicious anemia, vitiligo, and alopecia.

Following the sudden death of a 38-year-old Caucasian female an autopsy revealed findings consistent with the diagnosis of Schmidt syndrome, or Polyglandular Autoimmune Syndrome Type II. While diabetes mellitus Type I was not diagnosed, as is the case in 50% of PGA Type II presentations, her past medical history included an ill-defined thyroid disorder and recent premorbid history of listlessness to extreme fatigue and non-specific somatic complaints. Her healthcare professional failed to make the correct premortem diagnosis. The differential diagnosis of this disorder is addressed, as is a brief discussion of the polyglandular autoimmune syndromes, with particular emphasis on the etiology, epidemiology, morbidity, and mortality associated with Polyglandular Autoimmune Syndrome Type II.

Autoimmune, Polyglandular, Endocrine

G37 Suicide by Ingestion of Carbamate Insecticide: Case Report and Regional Variations

Lucas D. Duke, BS, Drexel School of Medicine, 2125 Spring Garden Street, #3R, Philadelphia, PA 19130; Sepideh Samzadeh, BS, Drexel University School of Medicine, 135 South 20th Street, Apartment #1506, Philadelphia, PA 19103; and Fredric N. Hellman, MD, MBA, Office of the Medical Examiner, Delaware County, Route 352-Fair Acres, Lima, PA 19037*

After attending this presentation, attendees will understand how insecticide ingestion is a significant method for suicide both globally and nationally. Attendees will also understand the possible threats to first responders and healthcare personnel attending to victims of insecticide self-ingestion.

This presentation will impact the forensic community and/or humanity by attempting to further increase understanding of suicide patterns, focusing upon a means not commonly observed in the United States but frequently employed in select regions of Asia. In addition to

addressing mechanisms of actions and common routes of administration, health risks that such ingestions present to responding personnel are also presented. Based upon commonly understood risk factors lending to insecticide-related suicide from certain areas of Asia, potential parallels to certain regions of the United States are reviewed. Additional issues explored include assessing the predisposition to insecticide-related suicide based on geography, agricultural intensity, accessibility to such poisoning agent(s), and relative lack of access to medical centers capable of rendering rapid treatment and antidote(s).

Propoxur (Baygon) is a potent carbamate insecticide used to control cockroaches, flies, mosquitoes, and lawn and turf insects. It is also a poison used to complete suicide. Insecticide intoxication is a significant method of suicide in some areas of the world. A 55-year-old black male was found unresponsive in his garage with a glass of Propoxur adjacent to him. Upon transport to a suburban Philadelphia hospital emergency department, fumes from the insecticide emanated from the victim's body, sickening 29 hospital workers and 12 hospital patients. As a safety precaution, the hospital was quarantined and its employees decontaminated. It is imperative for physicians, emergency medical service personnel, and investigators to be aware of the risks and detrimental consequences involving deaths associated with insecticide ingestion. While proper handling of patients is crucial, healthcare personnel should be aware of the public health risks created by individuals who ingest select poisons. Propoxur's mechanism of action relies upon the reversible carbamylation of acetylcholinesterase, resulting in a subsequent accumulation of acetylcholine in myoneuronal junctions (i.e., both in nicotinic and muscarinic systems). The modes of absorption include inhalation, ingestion, and dermal penetration, and the pertinent signs and symptoms include diaphoresis, urination, bradycardia, seizures, and bronchospasm. Insecticide ingestion as a means of suicide is stratified by two principal variables, these being availability of the agent(s) utilized and the related variable of agricultural intensity within the region of the world studied. In rural, agricultural regions of Sri Lanka and China, a high incidence of self-poisoning deaths have been attributed to harsh living conditions, stressful situations, accessibility to the poisoning agent(s), and relative lack of access to medical centers capable of rendering rapid treatment and an antidote(s). Access to lethal means is one principal variable observed from suicide patterns in the United States, though the most common injury associated with completed suicides in this country derives from firearms. The premise proposed is that those regions of the United States which parallel most closely those conditions predisposing to suicidality as observed in Sri Lanka and rural China should exhibit higher insecticide ingestion-related suicide rates in comparison to other areas of the country.

Insecticide, Suicide, Healthcare Worker Risks

G38 Chemical Asphyxia and Bondage: Autoerotic Fatality Induced by Chloroform Inhalation

Heather A. Cannon, Mercyhurst College, 501 East 38th Street, Erie, PA 16546; and Fredric N. Hellman, MD, MBA, Office of the Medical Examiner, Delaware County, Route 352-Fair Acres, Lima, PA 19037*

It is important to acknowledge variations from characteristic autoerotic asphyxial death practices. The use of chemical inhalation, more specifically chloroform, as a means to create a euphoric autoerotic state has rarely been discussed in past literature. After attending this presentation, attendees will learn how autoerotic asphyxia is also rarely observed in those older than the sixth decade.

It is well recognized in contemporary literature that autoerotic asphyxial deaths are most commonly observed among Caucasian males in the third to fourth decade of life. However, there are cases that are distinct from the common pattern of age demographics and the means of attaining

a hypoxic state. This presentation will impact the forensic community and/or humanity by demonstrating how it is imperative to acknowledge that significant variations from characteristic autoerotic asphyxial practices do occur. The possibility of autoerotic asphyxial death should be entertained in the aged population when corroborated by appropriate scene and evidentiary information.

Autoerotic asphyxia is a paraphilia in which a hypoxic state is induced in order to enhance orgasm during sexual activity. The medical examiner becomes involved in those situations in which the hypoxic state becomes irreversible and results in the death of the practitioner. While this practice is observed most commonly in Caucasian males whose ages range from the third through fourth decades, deviation from these demographic variables do occasionally occur. Autoerotic asphyxiation through the use of a ligature about the neck, with escape mechanism, is the most common means of this practice. More atypical approaches to reach a euphoric state through oxygen deprivation include rebreathing via the use of a plastic bag, positional asphyxia through thoracic compression, submersion, and chemical inhalation. Chemicals most frequently cited as hypoxic agents in available literature documenting autoerotic practices include propane, butane, ether, aerosol glue, tetrachloroethylene, 1-1-1 trichloroethane, and ketamine. Documentation of chloroform use in autoerotic asphyxial practice is distinctly uncommon.

A 67-year-old Caucasian male was discovered in bed and multiply bound within his suburban Philadelphia, PA residence. The decedent was discovered wearing a black rubber gas mask, with a bottle of chloroform situated on an end table adjacent to his head. A postmortem interval of at least two to three days had transpired from the time of death until the time of discovery. Toxicological assessment demonstrated the presence of chloroform in the blood, liver, brain, and lung of the decedent, consistent with inhalation of this agent in an effort to induce a hypoxic, reversible state. Scene investigation disclosed evidence supportive of multiple paraphilic acts engaged in by the decedent, including leather and black rubber fetishism and masochistic acts, including earplugs and genital entrapment. Numerous enema bags were distributed throughout portions of the otherwise fastidious residence, suggesting klismaphilia. While deaths arising from the performance of autoerotic asphyxia characteristically involve young Caucasian males through the use of a neck ligature, it is important to recognize significant variation from this general pattern. It is likewise imperative to consider the possibility of additional participants and criminal activity when confronted with such scenarios.

Chloroform, Autoerotic, Paraphilia

G39 Hemophagocytic Lymphohistiocytosis: A Case Report and Review of the Literature

Julia M. Braza, MD, and Meghan Delaney, DO, Beth Israel Deaconess Medical Center and Harvard Medical School, 330 Brookline Avenue, Boston, MA 02215*

The goal of this presentation is to discuss a case of a rare hematologic syndrome (Hemophagocytic Lymphohistiocytosis), and a literature review. New data has shown, that in the infection associated form of hemophagocytic syndrome, a selective loss of cytotoxic function in antigen presentation to T cells, creates an imbalance in the immune system, and promotes abnormal/excessive production of T cell derived cytokines, such as Interferon gamma (IFN γ), which is quite toxic, and leads to the characteristic clinical and histopathologic features of HLH. This is a rare entity, yet important, because it has a primary and secondary form, which may occur in the young, and in individuals with no known underlying immune deficiency/lymphoproliferative disorder.

This presentation will impact the forensic community and/or humanity by identifying and discussing the different forms of this syndrome, i.e., primary and secondary; its clinical, laboratory and histopathologic findings and its unusual cause of death in those individuals

affected by this syndrome. The entity is a hematologic and anatomic/forensic curiosity, with remarkable gross and microscopic findings.

Statement of Methods: This poster will present a case report and literature review of: Sporadic Hemophagocytic Syndrome, and its clinical, laboratory, and histopathologic manifestations, with a focus on its sometimes innocuous presentation as a viral illness, leading to rapid (within 14 days) death in both young and older patients.

Abstract: The focus of this case report is patient EC, a 77-year-old male, who was transferred from an outside hospital to the institution with confusion, ataxia, pancytopenia, diffuse lymphadenopathy/ splenomegaly, and a flu-like illness with temperature spikes to 103° F. His past medical history included CAD s/p MI, dermoid tumors, and hypercholesterolemia. He underwent a cervical lymph node biopsy during admission, which demonstrated a non-clonal proliferation of T-cells with Ebstein-Barr virus positivity (by in-situ hybridization, consistent with mononucleosis). EC was treated with steroids without improvement of his lymphadenopathy. Labs during admission: WBC 2.6; Hgb 9.5; Plt 34 Neut: 40.9%; Lymphs: 51.5 %; Eos: 3.6% Absolute Neutrophil Count: 5650. Serology tests showed EBV IgG positive/Ig negative, CMV IgG positive/IgM negative, RPR negative, HIV negative, toxoplasmosis negative. For his entire hospital admission, he had no bacterial growth in his blood cultures, but did have *S. aureus* positive respiratory cultures.

Within two weeks of admission, EC suffered a non-Q wave myocardial infarction, with an echocardiogram study showing an EF of 25 – 30%. Although the work up of his hematologic aberrancies continued, the patient's medical status deteriorated following his MI.

The patient developed hypoxic respiratory failure and cardiogenic shock, and expired on 15 days after admission.

At autopsy, the body was that of a cachectic older male with marked generalized lymphadenopathy. Histologic findings included a newly diagnosed pleomorphic high-grade large B-cell lymphoma, which showed EBV positivity and systemic hemophagocytic lymphohistiocytosis. The presence of the stain LMP-1 in most of the lymphoma cells is consistent with an EBV-driven disorder. There was also evidence of a remote myocardial infarct and pleural fibrosis.

Hemophagocytic lymphohistiocytosis (HLH) is a life-threatening condition characterized by uncontrolled hyper-inflammation on the basis of various inherited or acquired immune deficiencies. It is also characterized by clinical, laboratory and histologic findings. The clinical symptoms/signs include: fever, severe constitutional symptoms, lymphadenopathy, hepatosplenomegaly, icterus/jaundice, neurologic symptoms (seizures, CN palsies, encephalitis, meningismus) and rash (maculopapular/nodular eruptions). Laboratory criteria include: pancytopenia (cytopenia in at least two cell lineages), hypertriglyceridemia, high ferritin, transaminases, bilirubin, and LDH. Also, hypofibrinogenemia, high levels of the α chain of the soluble IL-2 receptor and Impaired function of Natural Killer Cells and cytotoxic T cells. Histopathologic findings are: reactive and systemic proliferation of benign histiocytes that phagocytose blood cells and their precursors in bone marrow, and or spleen. EC fulfilled the criteria for the acquired form of hemophagocytic syndrome, due either to an EBV infection, lymphoma, or a combination of both: an EBV-driven high-grade lymphoma.

Familial forms (FHLH) hemophagocytic lymphohistiocytosis is the entity where HLH is the primary and only manifestation, occurring in approximately in 1/50,000 births. FHLH is associated with immune deficiencies such as: Chédiak-Higashi Syndrome, Griscelli Syndrome, and X-linked lymphoproliferative Syndrome. Secondary (Sporadic) HLH is associated with the trigger of a benign or neoplastic disease (most patients have no known underlying immune deficiency), such as in the patient, EC. Various infectious microorganisms, mostly viruses, such as EBV, but also bacteria, protozoa and fungi, induce secondary HLH. In a review article from 1996 of children with infection-associated hemophagocytic syndrome (IAHS) EBV was found to be the triggering event in 74% of cases. HLH may also occur as a complication of

rheumatologic disorders (macrophage activation syndrome), malignancies (especially T cell lymphomas), also known as Lymphoma associated Hemophagocytic Syndrome (LAHS). EBV was detected only rarely in those with B-cell lymphomas, and much more so, 80%, in patients with T/NK lymphomas. The median survival time with pts with LAHS is about 11 days.

New data about what the possible etiologies are for sporadic hemophagocytic syndrome have shown that uncontrolled secretion of cytokines may stimulate the proliferation and phagocytic activity of macrophages, and therefore cause widespread inflammation, and the severe pancytopenia seen in this entity. More specifically, a selective loss of cytotoxic function in antigen presentation to T cells, creates an imbalance in the immune system, and promotes abnormal/excessive production of T cell derived cytokines, such as Interferon gamma (IFN α), which is quite toxic, and leads to the characteristic clinical and histopathologic features of HLH.

In conclusion, in the presented case, the clinical, laboratory, and autopsy findings demonstrate case of Secondary Hemophagocytic Lymphohistiocytosis. The disease entity has specific clinical, laboratory and histopathologic findings, and when sporadic, can present as an innocuous viral illness, as in EC's case, with fatalities occurring within two weeks of presentation, due to uncontrolled hyper-inflammation and activated macrophages/histiocytes that kill/ingest all hematopoietic elements, causing widespread pancytopenia.

Hemophagocytic Lymphohistiocytosis, Ebstein Barr Virus (EBV), Interferon Gamma (IFN α)

G40 Snake-Shot From a Handgun: An Unusual Gunshot Wound Suicide

Karen B. Looman, DO, and Wendy M. Gunther, MD, Tidewater Office of the Chief Medical Examiner, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510*

After attending this presentation, attendees will learn about projectiles for handguns that fire snake-shot and the use of such a projectile in this case of suicide and be able to recognize the following: How snake-shot can be fired from a handgun, how such a projectile can create an unusual entrance wound on postmortem examination, how to reconcile radiologic findings typical of a shotgun with a handgun as the weapon, and why such findings are not inconsistent with a suicide.

This presentation will impact the forensic community and/or humanity by providing useful information about unusual but not uncommon ammunition used in a suicide.

A 49-year-old man had an argument with his wife at his home. He got a revolver out of his locked gun cabinet, went out to his car, and was found dead in the car some time later with a gunshot wound. Scene investigation found the revolver in the deceased man's hand. There was no shotgun present in the house or the car. A suicide note to the son was located in the house.

Initially, the location of the gunshot wound made this suspicious for a homicide. He was shot behind the right ear. Autopsy procedures included photography, gunshot residue, X-Ray, toxicology, and visceral dissection. The X-Ray of the decedent's head showed unusually extensive fracturing of the cranium and numerous pellets in the cranial cavity.

Close examination of the gunshot wound revealed a hard contact, stellate, penetrating wound of the head, of unusual dimension for a handgun, located above and behind the right ear. A muzzle mark was difficult to distinguish because of the numerous stellate tears radiating from the entrance perforation. The parietal bone of the skull had a perforation with fouling beneath the periosteum. The right parietal and occipital lobes were perforated by multiple pellets, partially dividing the midbrain from the cerebral hemispheres. The pellets also perforated the left cerebral hemisphere, pulpifying the brain parenchyma.

These pellets on X-Ray and direct examination were consistent with snake-shot. This ammunition is most frequently used in shotguns. When it is fired from a handgun, it is typically used to kill reptiles and other thin-skinned small animals at short distances, up to approximately five yards. Handguns of many calibers including 9 mm, .357 Magnum, .38 Special, .40, .44 Special and Magnum, and .45 semi-automatic may accept small pellet-filled projectiles which contain shot of the same size as that used in a shotgun, but with a smaller load and charge.

The rounds consist of a hollow plastic projectile that contains the loose shot. If snake-shot is used in a gun without the encapsulating plastic, the lead shot may form pits in the rifling of the barrel. The cartridge moves down the barrel of the handgun and opens on leaving the muzzle; normally, the shot does not separate until after it has left the barrel. With shot of size #12, colloquially known as snake-shot, there might be as little as 1.5 to 3 ft-lb of energy in each pellet as it hits the target. While it might easily penetrate human skin at close ranges (but not contact), it would not be expected to penetrate deeper into the body than muscle tissue, and so would not be typically used in a homicide. Some experts report that the rounds are not useful for self-defense, especially against a human assailant, as the penetration is minimal and the shot diameter tiny. However, in the case of a direct hard contact gunshot wound this ammunition created a surprising amount of damage that was more than sufficient to kill.

The cause of death in this case was a hard contact gunshot wound of the head. The manner of death was suicide, based on the autopsy and scene investigation. The use of snake-shot as ammunition was unusual but just as lethal as a bullet.

Snake-Shot, Handgun, Suicide

G41 Non-Traumatic Homicide Following Assault: 16 Cases - A Review of Investigation, Pathology, Toxicology, and Judicial Outcome

Patricia A. Aronica-Pollak, MD, Jack M. Titus, MD, and David R. Fowler, MD, Office of the Chief Medical Examiner State Of Maryland, 111 Penn Street, Baltimore, MD 21201*

After attending this presentation, attendees will understand some principles of the classification of the manner of death as homicide when death occurs as the result of a physical altercation or a significant implicit threat in the absence of fatal traumatic injuries, by reviewing the investigation reports, the pathology reports, the toxicology reports, and the judicial outcomes of these cases.

This presentation will impact the forensic community and/or humanity by discussing how these types of cases can differ from traditional homicides which most often result from traumatic injuries and the classification problems which can arise including a review of the Davis guidelines written in 1978 and the judicial outcome differences.

Homicide is most often defined as death at the hands of another. When traumatic injuries are the cause of death, the manner of death is usually obvious and clear. However, when the traumatic injuries do not cause death and one must rely on the investigation for the manner of death, the case must be critically evaluated. If a physical altercation takes place immediately prior to death or the development of signs and symptoms such as chest pain begin during or within a short time after the assault, then temporal relationship between the assault and the death cannot be ignored and a manner of death of homicide must be considered. Likewise, if no contact between the decedent and the assailant(s) occurs, but there is a significant implicit threat to safety (Davis guidelines), one must also consider homicide, as again, the temporal relationship cannot be ignored.

Sixteen cases were reviewed from the state of Maryland from the years 1990 through 2006 where death was determined to be the direct

result of a struggle/assault or the result of a significant implied threat. All of the cases were classified as homicides on the death certificates. None had any traumatic injuries listed on the cause of death line or as contributory to the cause of death although some did have minor lacerations, contusions, and abrasions. Of the 16, three (19%) were female. Eight (50%) were African American. The ages ranged from 15 years to 89 years with a mean age of 55 years. Most of the causes of death were cardiac in nature including cardiac arrhythmias, coronary artery disease, hypertensive changes, congenital anomalies, aortic dissection, and coronary artery tunneling. In addition, one case of ruptured berry aneurysm was noted. Toxicology was negative for ethanol in 12 of the 15 cases (80%) cases and negative for illicit drugs in ten out of 13 (77%) cases in which drugs were tested. Of the positive cases, cocaine and morphine were the illicit drugs that were identified. Cocaine was detected in all three cases with morphine additionally detected in one of the three. Cocaine was listed as a contributing cause of death on the death certificate in all three cases.

In 15 of 16 cases (94%), there were physical altercations between at least two individuals. Of these, four (27%) were known to use a blunt object other than a fist such as a baseball bat (2), walking cane, or walker. In one case a blunt object (plank) was thought to have been used but was not confirmed through investigation. One individual was held at gunpoint but a physical struggle never ensued prior to loss of consciousness. In three (19%) cases no injuries, even minor, were described. The majority of cases (69%) involved individuals over 50 years of age. The remaining younger population could be further subdivided into those with congenital abnormalities and those with positive toxicology.

The judicial outcomes for these cases varied from no charges filed to full jury trials. The determination of the extent of prosecution for each case was case dependent because of their complexity and nature. In one case there was a bench trial with a conviction, subsequent appeal and retrial with a jury.

Davis Guidelines, Non-Traumatic Death, Homicide

G42 Death by Cue in the Parietal Pocket: An Unusual Injury Pattern Caused by the Use of a Blunt Object

Valerie S. Green, MD*, Mary L. Anzalone, MD, Dwayne A. Wolf, MD, PhD, and Luis A. Sanchez, MD, Harris County Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054

The goal of this presentation is to stress the importance of obtaining accurate and detailed investigative information, and keeping an open mind about the findings at autopsy. The injury pattern and the weapon may not be what you expect them to be.

This presentation will impact the forensic community and/or humanity by continuing to reiterate the need for excellence in forensic investigation and by alerting the community as to other potential uses of a seemingly harmless recreational object.

A 27-year-old man died from a penetrating injury of the head with perforation of the skull and brain by a pool cue. The decedent was involved in an altercation with another individual that began with an exchange of punches, and ended with the decedent lying on the floor with a pool cue in his head. Bystanders reported the decedent being immediately unresponsive following the altercation. Paramedics arrived and used a bolt cutter to cut the pool cue, leaving a portion remaining in the decedent's head. The decedent was then transferred to a local hospital where he remained in critical condition throughout his 8- day hospital stay.

Computed tomography of the head revealed a tubular piece of foreign material embedded into the skull with acute fractures in the left parietal bone, at the point of entry. The wound tract extended through the left parietal lobe, crossing the midline and traversing the thalamus. Acute fractures were seen in the squamosal portion of the right temporal bone at

the point of exit. Associated findings include hemorrhagic foci along the wound tract, scattered foci of subarachnoid hemorrhage, acute blood throughout the lateral, third, and fourth ventricles, air within the left temporal horn and a 1 to 2 millimeter thick acute subdural hematoma along the right fronto-temporal convexity.

The decedent was operated on immediately. The retained portion of pool cue was 16.8 centimeters in length and 1.4 centimeters in diameter. The distal end of the pool cue was intact with a blood stained disrupted white collar, 2.5 centimeters from the distal end. Dried blood and strands of attached hair were present on the cue up to approximately 4 centimeters from the distal end. The proximal end was uneven and broken off. The remaining portion of the pool cue was obtained from law enforcement and consisted of a traditional wooden stick with a broken distal end that matched the removed segment.

The findings at autopsy included a surgically altered left parietal scalp defect, and discrete foci of subscalpular hemorrhage at the points of entry and exit of the object through the skull. The oval left craniotomy window had a central round metal surgical device covering a 2 centimeter round defect with inward beveling. A 2.2 centimeter, somewhat square-shaped, fractured defect with partial outward beveling was within right temporal bone.

Small round defects are in the frontal bone and dura due to the insertion of pressure monitors. Gel foam and subdural hemorrhage were in the left parietal region and associated with a 3.0 centimeter sutured round dural patch. Approximately 20 milliliters of subdural hemorrhage was present over the right cerebral convexity. A circular, punched-out, round defect involved the dura of the right temporal bone and is associated with the aforementioned temporal bone defect. The calvarium was 2 to 3 millimeters in thickness, diffusely.

The brain weighs 1300 grams. It herniated through the right temporal bone defect. A 2.0 centimeter circular defect was in the left parietal convexity, and a 1.5 centimeter defect was in the right lateral temporal lobe. The cerebral hemispheres were symmetrical with marked swelling characterized by flattened gyri and narrowed sulci. Patchy subarachnoid hemorrhage was present over cerebral convexities and at the base of the brain.

Following formalin fixation, sections through the cerebral hemispheres, cerebellum, and brainstem revealed a hemorrhagic wound track coursing through the left parietal lobe, midline structures including the thalamus, and the right temporal lobe. Extensive hemorrhage and tissue destruction were associated with the wound track. Secondary hemorrhages are in the rostral brainstem.

Microscopic examination showed parenchymal hemorrhage in the brainstem, ischemic neuronal change, and hemorrhage with tissue destruction from the section of the wound track. Iron stains on the sections were negative.

Head Injury, Blunt Object, Unusual Pattern

G43 Pediatric Malignancies Presenting as Sudden Death: A Case Series

Allison S. Nixdorf-Miller, MD*, Tracey S. Corey, MD, Barbara Weakley-Jones, MD, and William R. Ralston, MD, Office of the Chief Medical Examiner, 810 Barrett Avenue, Louisville, KY 40204

After attending this presentation, attendees will learn how pediatric malignancies, though rare, may present as sudden death. Careful examination of the history and physical findings will aid in the ultimate cause of death.

This presentation will impact the forensic community and/or humanity by aiding in better understanding of pediatric malignancies in sudden death.

The goal of this presentation is to review causes of sudden death due to previously undiagnosed malignancies in the pediatric population from

1994 to 2006 at the Office of the Chief Medical Examiner in Louisville, Kentucky.

Five deaths due to malignancies in children between the ages of five months and fourteen years were identified during this time period. Two Wilm's tumors, a T-cell mediastinal acute lymphoblastic lymphoma, and two acute myeloblastic leukemias are listed as the causes of death. None of the five cases reported had a previous diagnosis of malignancy prior to death. In fact, one case (AML M5) was thought to be a victim of child abuse due to the physical findings of bilateral black eyes.

Cases 1 and 2: Unlike death in the case of Wilm's tumor due to intraperitoneal hemorrhage reported by Somers et al, the children in both of these Wilm's tumor cases died as a result of pulmonary tumor emboli. A five-year-old girl followed closely by her family physician for mild developmental delay was participating in class activities and was thought to have fallen asleep in class. She was unarousable, and subsequently it was determined she had died. At autopsy, a 6.5 cm Wilm's tumor was found in the upper pole of the left kidney, with extensive but microscopic pulmonary tumor emboli within all lobes of the lungs. The second Wilm's tumor was found in a three-year-old boy who had a three day history of vague abdominal pain and constipation. He collapsed after being given antacids for his pain. The 8.0 cm tumor within the left kidney caused a large tumor thrombus within the inferior vena cava and a tumor embolus with occlusion of the right ventricular outflow tract and pulmonic trunk.

Case 3: A ten-year-old boy presented to his primary care doctor five times in the three months preceding his death with complaints of fever, cough, wheezing, and neck swelling. He was diagnosed at the last visit as having pneumonia with a widened mediastinum. That evening he began gasping for air, became cyanotic, and collapsed. At autopsy a 470 gm, 22.0 cm mediastinal mass completely encased the aortic arch and great vessels, trachea, anterior pericardial sac and hilum. The superior border of the mass was the thyroid gland. Immunophenotyping confirmed a T-cell mediastinal acute lymphoblastic lymphoma. In this case no other organs were involved.

Case 4: A 14-year-old girl with a three week history of headache, abdominal pain, extreme fatigue and fevers, was brought to the emergency room in full arrest. She had been seen in the ER three times in the week prior to her death with the above listed symptoms and given a clinical diagnosis of pharyngitis with a suspected etiology of infectious mononucleosis. At autopsy a large intracerebral hemorrhage was found, with petechiae in all visceral organs. In addition to massively enlarged visceral lymph nodes, leukemic infiltrates were found within the spleen, liver, heart, adrenals, and brain. Immunohistochemical stains performed on the paraffin embedded tissue confirmed the diagnosis of acute myeloblastic leukemia.

Case 5: A five-month-old boy presented to an outlying hospital with a two day history of gasping for air, bloody emesis, lethargy, and decreased urine output. He rapidly deteriorated in the emergency room, and was brought to a local hospital where he was pronounced dead. A history of abuse or neglect by the family was suspected due to severe bilateral periorbital ecchymoses, and multiple additional contusions. After his death, laboratory results revealed his white count to be 269,000. At autopsy, small bowel intussusception with resultant bowel necrosis was identified, with an extensive leukemic infiltrate. Ensuing disseminated intravascular coagulation led to petechiae and the large periorbital ecchymoses, as well as extensive subarachnoid hemorrhages. Leukemic infiltrates were found within the pericardial sac, liver, kidneys, leptomeninges, pancreas, spleen, gastrointestinal tract, and lung leading to acute pulmonary crisis. Immunophenotyping revealed an acute monocytic leukemia (M5).

These cases correlate with one recent paper in which Wilm's tumor and white cell malignancies were the most common malignancies presenting as sudden death in the pediatric age group. These findings differ from another paper, which found that tumors, malignant or benign, involving the central nervous system and heart were most common in their case series. Accidents are the most common cause of death in the pediatric

age group, with cancer being second. Leukemia is the most common malignancy in children between the ages of 0-19, followed closely by central nervous system malignancies. These constitute the two most common causes of cancer deaths in this age group. Most malignancies are diagnosed by classic signs and symptoms, failure to thrive, weight loss, fatigue, feeling poorly, and autopsies on these patients, when requested, are undertaken in the hospital setting with a known or suspected diagnosis. In the five cases presented, preceding symptoms did not lead to a timely diagnosis. Sudden death is a rare, unfortunate presentation of pediatric malignancy.

Sudden Death, Malignancy, Pediatric

G44 An Experimental Comparison of Bone Wound Ballistics of Non-Lead and Lead Bullets

Bryce O. Anderson, PhD*, and Tyler A. Kress, PhD, BEST Engineering, 2312 Craig Cove, Knoxville, TN 37919; Anne M. Kroman, MA, University of Tennessee, Department of Anthropology, Knoxville, TN 37996; David J. Porta, PhD, Bellarmine University, Department of Biology, 2001 Newburg Road, Louisville, KY 40205; and John C. Hungerford, PhD, University of Tennessee, 208 ESH, Knoxville, TN 37996

After attending this presentation, attendees will gain an understanding of how the increasingly prevalent use of non-lead bullets affects forensic examination and investigation.

This presentation will impact the forensic community and/or humanity by increasing knowledge of wound ballistics extended to the non-lead bullet trajectory through results from experimental impact biomechanics testing.

In this work a new type of small arms ammunition is evaluated to determine its capability of producing wound trauma. This new ammunition dispenses the toxic lead core of conventional bullets in favor of a non-toxic pressed tungsten and tin powder core. The testing involved firing rifle and pistol caliber tungsten tin and lead core bullets against real porcine femurs encased in ballistic gelatin. The lead bullets were used to establish a benchmark of performance for the tungsten tin bullets to be measured against. Various metrics such as penetration depth and bone fragment weight were recorded.

The specific cartridge calibers used in the testing were the 9mm x 19mm (Luger) and the 5.56mm x 45mm (5.56 NATO). The specific bullet types evaluated were the semi-jacketed soft point with a brass enclosed base. The bullet weight of the 9mm projectile was 124 grains and the bullet weight of the 5.56mm projectile was 60 grains. The ratio of tungsten powder to tin powder was set by weight at 68% W and 32% Sn for a net density nearly identical to lead. This resulted in the tungsten tin bullets being the same shape, size, and density as the lead bullets.

Ordnance gelatin powder was mixed 10% by weight according to accepted standards to replicate within 3% the penetration depth measured in living swine leg muscle as established by Fackler (1985). The gelatin was molded into a rectangular block with a rounded front face. The overall dimensions of the block were 24" long, 8" wide, and 16" high and required 36 liters of water and 4 kilograms of gelatin powder to manufacture. The bones were mounted upright approximately 4" behind the front face. The blocks were maintained at 39° F for at least eight hours prior to and during the shot. The ballistic gelatin block was mounted on a table 10' away from the muzzle of the firearm in accordance with FBI ballistic testing protocol. Three separate 0.177" BB's were fired into each ballistic gelatin block to verify acceptable block density.

Four combinations of bullet type were evaluated and three shots of each combination were made. The tungsten tin pistol bullets had a mean velocity of 1035 ft/s and a total mean penetration depth of about 14.5" with a mean distance of 9.12" beyond the bone. There were

approximately 180 grains of bone fragments generated by the W-Sn bullet impact. The lead pistol bullets had a mean velocity of 1048 ft/s and a total mean penetration depth of about 13" with a mean distance of 6.78" beyond the bone. There were approximately 73 grains of bone fragments generated by the Pb pistol bullet impact. The lead rifle bullets had a mean velocity of 2792 ft/s and a total mean penetration depth of about 6" and went a mean distance of 1.08" beyond the bone. There were approximately 287 grains of bone fragments generated by the Pb rifle bullet impact. The tungsten tin rifle bullets had a mean velocity of 2843 ft/s and a total mean penetration depth of about 16" with a mean distance of 10.33" beyond the bone. There were approximately 266 grains of bone fragments created by the W-Sn rifle bullet impact.

It was found that the performance of the W-Sn pistol bullets was closely similar to that of the Pb pistol bullets, but the W-Sn bullets created a higher mean collective weight of bone fragments than the Pb pistol bullets did. The W-Sn rifle bullets exhibited much deeper post-bone penetration depth than the Pb rifle bullets, although the mean collective bone fragment weight was approximately the same. It was concluded that there was essentially no difference between the W-Sn and Pb pistol bullets but that the W-Sn rifle bullets would create a much deeper permanent cavity than Pb rifle bullets. The mechanism of this deeper penetration depth was attributed to the resistance to fragmentation of the W-Sn bullet in hard and soft tissue.

Bone Wound Ballistics, Non-Lead Bullet, Ballistic Gelatin

G45 Model Protocol for Forensic Medical Examination of Victims of Trafficking in Human Beings

Djordje M. Alempijevic, MD, PhD*, Dragan S. Jecmenica, MD, PhD, Snezana Pavlekic, MD, PhD, Slobodan N. Savic, MD, PhD, and Branimir V. Aleksandric, MD, PhD, Institute of Forensic Medicine, Faculty of Medicine, University of Belgrade, 31a Deligradska Street, Belgrade, 11000, Serbia

After attending this presentation, attendees will understand basic health issue related to trafficking in human beings (THB), in particular these related to physical trauma, sexual violence, and substance misuse. The attendees should also become familiar with advantages of early medicolegal examination of THB victims.

This presentation will impact the forensic community and/or humanity by giving arguments and advocate for necessity of medicolegal health-care for THB victims that is mostly being neglected in existing local anti-trafficking policies and intervention protocols. A positive example of Istanbul Protocol use in evaluation of torture victims would serve as an illustration of good practice in sound related field.

The presentation will discuss the experience gained through the trainings for medical and judiciary professionals in countries of Western Balkans (Serbia, Bosnia and Herzegovina, and Croatia). A protocol developed for forensic medical examination of victims of THB will be discussed in detail. It is recommended that the agenda of anti-trafficking policies needs to be redrawn to include forensic medical assessment of victims for legal purposes.

Human Trafficking, Forensic Medical Examination, Injury

G46 The Role of Postmortem Cardiac Enzymes in the Diagnosis Acute Cardiac Deaths

Nick I. Batalis, MD*, and Bradley J. Marcus, MD, Christine N. Papadea, PhD, and Kim A. Collins, MD, Medical University of South Carolina, 165 Ashley Avenue, Main Hospital, Suite 281, PO Box 250108, Charleston, SC 29425

After attending this presentation, attendees will have a greater understanding of biomarkers of acute myocardial injury and their role, or lack thereof, in the postmortem diagnosis of myocardial infarction. The information presented here will help guide the investigations and autopsies in cases of suspected acute cardiac deaths.

Sudden deaths due to myocardial infarction compose a large percentage of the workload of investigators, coroners, and forensic pathologists and others whose work involves death investigation. This presentation will impact the forensic community and/or humanity by aiding these workers in the approach and workup of suspected acute cardiac deaths. While biomarkers of myocardial damage may have some utility in the diagnosis of acute cardiac deaths, they should not be used exclusively to make the diagnosis. As deaths certified due to myocardial infarction occasionally incite legal battles involving employers and treating physicians, it is of the utmost importance to correctly classify these deaths and not simply rely on a single or series of biological markers. In addition, performing routine postmortem markers of myocardial damage can be costly and may consume resources that could be better utilized on other testing or equipment.

Sudden cardiac deaths due to myocardial infarction constitute a large percentage of the caseload for death investigators, coroners, and forensic pathologists. While sometimes one has a high level of suspicion of a myocardial infarction at autopsy, it is only by finding a thrombus or seeing characteristic gross or microscopic morphological changes in the myocardium that one can definitively make this diagnosis. Because of this, researchers continue to seek out a more sensitive method of determining acute myocardial damage. For years, treating clinicians have been able to measure serum levels of proteins and enzymes normally contained within the myocardium. Increased serum levels of these markers have been shown to be highly sensitive and specific for myocardial damage. The preferred markers have changed over time, but currently three of the more reliable markers include troponin (isoforms I and/or T), total creatine kinase (CK), and CK-MB a more specific isoform of CK.

Various authors have investigated the role of postmortem cardiac markers at autopsy and have had varying results. Some of the studies include a correlation of postmortem and antemortem levels of cardiac markers, a comparison of postmortem serum and pericardial fluid levels, and several have attempted to determine if postmortem levels are significantly higher in deaths due to myocardial ischemia than due to other causes of death. To date, though, there has not been a standardized study determining postmortem levels of cardiac markers from serum of different anatomic locations.

The current study included ten decedents, five with histories suspicious for myocardial infarction and confirmed at autopsy, and five control subjects who died of non-cardiac disease. For each decedent, six different samples (pericardial fluid and serum from the femoral veins, subclavian veins, aorta, left cardiac ventricle, and right cardiac ventricle) were drawn and tested for CK, CK-MB, and troponin-I (TnI). Three main conclusions were drawn; the levels of cardiac markers from the control group are significantly higher than the reference range for living patients; there are significant differences in the levels of cardiac markers between serum samples from different anatomic locations; and only three cardiac marker/anatomic site combinations were significantly different between the control and study groups (femoral/TnI, right ventricle/CK-MB, and pericardial fluid/CK-MB). These complete findings, a review of the literature, and a discussion about the role of postmortem cardiac markers in detecting acute myocardial damage will be discussed.

Cardiac Enzymes, Acute Myocardial Infarction, Death

G47 Histologic Evidence of Repetitive Blunt Force Abdominal Trauma in Three Pediatric Fatalities

Daniel W. Dye, MD*, University of Arkansas for Medical Sciences Department of Pathology, 4301 West Markham, Slot #517, Little Rock, AR 72205; and Charles P. Kokes, MD, Arkansas State Crime Laboratory, 2 Natural Resources Drive, Little Rock, AR 72211

After attending this presentation, attendees will understand the importance of retaining sections of the retroperitoneum for microscopic examination.

This presentation will impact the forensic community and/or humanity by increasing awareness of recognizing certain patterns of fibroblastic proliferation and reactive vasculature encountered if proper sections are taken in cases of repeated child abuse.

In cases of fatal child abuse, the discovery of external blunt force trauma, skull fractures, subdural hematomas, abdominal hemorrhage, as well as retinal hemorrhages are all well described in the pediatric and forensic literature. The gross findings at autopsy, when taken into consideration with scene investigation and interviews with caregivers, point to a clear manner and cause of death in many cases. In such cases, the discovery of changes attributable to older abusive injuries helps support a conclusion of death due to inflicted trauma. Three cases of fatal child abuse in which acute blunt force abdominal trauma was the cause of death and the manner of death was homicide are presented. In each of these cases, careful examination with proper sectioning and microscopy of select abdominal tissues revealed the presence of fibroblast proliferation, increased vascularity, and hemosiderin laden macrophages indicating abdominal injuries older than the acute, fatal blunt force trauma. Iron and trichrome stains were used to highlight hemosiderin and fibrosis in all three cases; however the recognition of a fibroblast proliferation and a reactive vascular pattern was best seen on routine hematoxylin and eosin stains. These findings at autopsy, along with good investigative evidence, were helpful in establishing the diagnosis of chronic physical abuse.

Fibroblast, Proliferation, Child Abuse

G48 Death by Suicide in Maryland: A Cross-Sectional Study, 2002 to 2005

Jonrika M. Malone, MD*, Ana Rubio, MD, PhD, Corey Tayman, and David M. Fowler, MD, State of Maryland Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201

After attending this presentation, attendees will recognize the impact of suicidal deaths among various age groups, races, and between genders, allowing them to better understand that suicide as a manner of death is not isolated to the young or the old.

This presentation will impact the forensic community and/or humanity by bringing to the forefront the significance of suicide in overall mortality, detailing the different causes of death in diverse groups, and drawing epidemiologic data from the entire state of Maryland, representing the population as a whole.

Introduction: An estimated 5,600,388 individuals called the state of Maryland home in 2005 according to the United States Census Bureau. The ratio of men to women is nearly 50-50, with 48.4% and 51.6% respectively. With a population increase of 5.7% from 2000, the state is steadily growing, as is the rest of the country.

The overall rate of suicide in the state of Maryland is 8.8 per 100,000 populations per year (about 493 deaths per year). Although age (both extremes of life with adolescents and the very old being at higher risk), race (Caucasians being overrepresented) and gender (males more likely to complete suicidal deaths) are known risk factors for suicide in the literature, a detailed analysis of these and other risk factors and the

interaction with the cause of death may reveal recent trends in suicide in the Maryland population.

Methods: The Office of the Chief Medical Examiner (OCME) for the State of Maryland oversees all suicidal deaths occurring in the state. From January 2003 to December 2005 there were 1477 suicidal deaths in the state. Cases within the time frame were extracted from the OCME database, each case was reviewed, and data were analyzed for age, ethnicity, cause of death, county of residence, history of depression and/or previous suicide attempts, and whether or not there was a suicide note and of what type. Of all cases, 800 (54.2%) had a complete autopsy, 264 (17.9%) had a partial autopsy, 56 (3.8%) were inspected at the OCME, 300 (20.3%) scene inspections in respective counties, and 57 (3.9%) were approvals (cases were not examined at the office, death certificates were signed by the certifying physician and co-signed at the OCME office).

Results: Men were more likely to commit suicide (80% of the cases versus 48.4% of the Maryland population), and were slightly younger (45.7 +/- 18.7 years of age) than women (46.5 +/- 16.9 years). Caucasians were over-represented (79.1% of cases and 59.8% of the population) while the remaining racial or ethnic groups had fewer suicides than the overall Maryland rate. The rate of suicide was highest among the elderly. While 11.4% of the population of Maryland are over 65 years of age, in this study 17.4% were in that age group. The three most common causes of death were gunshot wounds (46.7%), asphyxia (26.4%) and drug intoxication (13.5%). Less common were blunt force injuries (5.5%), carbon monoxide intoxication (3.8%), sharp force injuries (2.4%), and rarely other methods (such as electrocution) or more than one method (such as gunshot wound and hanging) were employed. Suicides were fewer than expected in Baltimore City per capita and other large metropolitan areas, in part due to the different racial and ethnic mix in urban versus rural populations. The cause of death was influenced by gender [men were nearly ten times (627 cases men versus 63 cases women) as likely to use guns, whereas drug intoxication was almost equally distributed between the genders], age (there were no suicides by sharp force injuries in the adolescent group, where the most common cause of death was asphyxia due to hanging) and racial/ethnic background (asphyxia was the most common cause of death among Asian [48.6% of all suicides in this group] and Hispanics [45.2%], while gunshot wounds were the most common cause in African Americans [49.3%] and Caucasians [47.8%]).

Conclusions: A three year cross sectional study of suicide in Maryland confirmed known risk factors (male gender, Caucasian race, and old age) and also found association between these risk factors and the cause of death (suicide method). These associations may be useful in targeting efforts at prevention.

Suicide, Cause of Death, Risk Factors

G49 Can Mandibular Fractures Occur in Non-Oral Contact Shotgun Wounds of the Head?

Edward L. Mazuchowski, MD, PhD*, Office of the Armed Forces Medical Examiner, 1413 Research Boulevard, Rockville, MD 20850; Mary G. Ripple, MD, Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201; Craig T. Mallak, JD, MD, Office of the Armed Forces Medical Examiner, 1413 Research Boulevard, Rockville, MD 20850; and David R. Fowler, MD, Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201

After attending this presentation, attendees will be aware of the characteristics of contact shotgun wounds of the head that do not directly involve the oral cavity, lower face, or mandible.

This presentation will impact the forensic community and/or humanity by demonstrating how mandibular fractures can occur with non-oral contact shotgun wounds of the head and that these fractures do not imply separate blunt force injury to the mandible.

Contact shotgun wounds of the head most commonly involve the oral cavity, submental region, temple, or frontal scalp. Although these wounds are usually suicides, homicides do occur. In all cases, autopsy findings should correlate with the investigation. Additional injury, such as a mandibular fracture in a contact shotgun wound to the temple region, must be explained in order to rule in or rule out the probability of separate blunt force injury.

The files of the Office of the Chief Medical Examiner (OCME) for the state of Maryland were reviewed for shotgun wounds to the head from January 1995 through June 2006. Review showed 215 total shotgun to the head cases with available records. Of those 215 cases, 133 were contact shotgun wounds to the head. According to available information, the location of the contact shotgun wounds included 26 cases (20%) that were intraoral, 49 cases (37%) with contact under the chin, 52 cases (39%) with contact at the level of the nose or above and 6 cases (4%) with contact at the side of the face at the mandible. Of the 52 cases with contact at the level of the nose or above, ten cases (19%) had mandibular fracture. Three of the ten cases (30%) were determined to be homicides and seven of the ten cases (70%) were determined to be suicides. Location of the shotgun wounds were right side of the head at the temple (3 cases), middle of forehead (2 cases), between the eyes (1 case), right eye (1 case), left eye (1 case), nose (1 case), and back of the head (1 case).

The gauge of the shotgun was known for seven of the ten cases with mandibular fractures. Six of the shotguns were 12 gauge (60%), one was a 20 gauge (10%), and three were unknown (30%). Of the 42 cases that did not produce a mandibular fracture, 21 were 12 gauge (50%), nine were 20 gauge (21.5%), three were .410 (7%) and nine were unknown (21.5%).

In a previous study by Harruff comparing the injury produced by different gauge shotguns, 20 of 89 cases (22%) of contact shotgun wounds of the head were located at the temple, scalp (above the level of the ears) or forehead. In these 20 cases, there was no reported difference in the internal features of the damage caused. The internal injuries included extensive fractures of the skull and maceration of the brain without injury to the facial structures. In contrast to the internal injuries, 12 gauge shotguns produced extensive external lacerations while larger gauge shotguns produced lacerations primarily at the site of contact. In the current study, the 12 gauge shotgun on average caused more extensive lacerations when compared to the larger gauge shotguns. However, both the 12 gauge and 20 gauge shotguns were able to cause a mandibular fracture.

In contact shotgun wounds of the head, fragmentation of the skull is caused by the increase in internal pressure of the skull due to the charge of the shot and the increase in pressure caused by the rapidly expanding gas from combustion of the propellant. It is postulated that this force is directly transmitted from the temporal bone to the mandible resulting in fracture.

This report emphasizes that mandibular fractures can occur with contact shotgun injuries at or above the level of the nose and that these injuries can occur regardless of the gauge of the shotgun. It is paramount not to report separate blunt force injury as the cause of the mandibular fractures without further investigation and autopsy findings supporting those conclusions. If there are allegations or concern of blunt force injury, then autopsy should show separate points of impact on the skin of the jaw area as evidenced by contusion, abrasion, or lacerations.

Contact Shotgun Wound, Head, Mandibular Fracture

G50 A Retrospective Review of Youth Suicide in New Mexico

Veena D. Singh, MD, MPH, University of New Mexico Health Sciences Center; Department of Pathology MSC08 4640, 1 University of New Mexico, Albuquerque, NM 87131; and Jeffrey S. Nine, MD, and Sarah Lathrop, DVM, PhD, Office of the Medical Investigator, MSC11 6030, 1 University of New Mexico, Albuquerque, NM 87131*

The goal of this presentation is to provide a brief overview of youth suicide in the United States; discuss one model of suicide and suicidal behavior; provide an overview of youth suicide in New Mexico including demographics, decedent characteristics, and circumstances of death; and discuss possible interventions to prevent youth suicide, based on the New Mexico experience.

This large-scale study on suicide in children and adolescents will impact the forensic community and/or humanity by demonstrating increasing understanding of this large (and growing) public health problem. With a solid understanding of the circumstances surrounding youth suicide, it may be possible to predict, and hopefully prevent, future cases of child and adolescent death.

Introduction: Although a suicidal behavior in children and adolescents is a major public health problem, large-scale research on suicide in this population is uncommon. Analysis of the methods and risk factors over time may permit more focused planning for suicide prevention programs.

Methods: All pediatric suicide cases referred to the New Mexico Office of the Medical Investigator from 1979 to 2005 were reviewed. For the purpose of this study, pediatric deaths were defined as deaths in the age group of one day up to and including 17 years of age. The autopsy, field investigator, and police reports were examined in detail regarding age, sex, location, and method of suicide; presence of suicide notes; and any contributing psychologic factors or stressors.

Results: There were 433 pediatric suicides during the study period, ranging in age from nine to 17; the age-adjusted suicide rate was 4.8 per 100,000 with a male-female ratio of 3.8:1. There was no significant change in gender, race, or age over time; however, there was a significant increase in the number of suicides per year. Greater numbers of suicides were observed during the months of December and February as compared to other months. Psychologic stressors were identified in some cases, such as psychiatric problems (46%) and chronic family problems including physical or sexual abuse (32%). There was a history of previous suicide attempt or suicidal ideation in 28% of the cases. Most of the suicides (76%) occurred in the victim's home or yard, and 25% left a suicide note. In 26% of cases alcohol or other drugs were detected postmortem; toxicology testing was more often positive in decedents over the age of 15 and only rarely positive in decedents younger than 15. Gunshot wound was the most common method overall (58%), followed by hanging (30%), overdose (5%), and other (including drowning, jumping from height, and blunt force vehicular trauma, 5%). Of note, hanging deaths were significantly more common among Native Americans as well as those decedents younger than 13. In addition, there has been a statistically significant decrease in deaths by firearm and a concurrent significant increase in hanging deaths.

Conclusions: Although the age-adjusted suicide rate is markedly higher in New Mexico than nationally, the trends in the regional population are similar to those seen nationally. The authors therefore present their findings in this 26-year retrospective study to increase understanding of pediatric suicides. With a solid understanding of the circumstances, it may be possible to predict, and hopefully prevent, future cases of child and adolescent death.

Adolescent, Death, Suicide

G51 A Homicide Due to a “Disguised Mail Bomb”

Margherita Neri, MD, Irene Riezzo, MD, and Emanuela Turillazzi, MD, PhD, Department of Forensic Pathology University of Foggia, Viale Pinto 1, Foggia, 71100, Italy*

Attendees will learn about a case of a homicide due to blast injuries from a bomb disguised as a package in the mail.” The goal of this study is to underline the importance of the cooperation between the forensic pathologists and the forensic laboratory section in cases of death due to explosion and the importance of the use of confocal microscope to identify the exact origin of the material present in skin samples.

This presentation will impact the forensic community and/or humanity by demonstrating the importance of histopathology in explosive-related death and the application of confocal microscope to support investigation to clarify the circumstances surrounding the death.

Explosive-related deaths fall into three types: accident, homicide, and suicide. Homicidal explosive deaths, although rare, are often associated with acts of terrorism.

An explosion following the opening of a mail package addressed to his father wounded a young Italian man. The boy was quickly taken by ambulance, but was declared dead before he arrived at the hospital. At the crime scene, along with biological material, several small and large pieces of yellow mail paper, metal, and glass fragments, and numerous shotgun pellets were collected.

Prosecutor arranged the autopsy on the body to clarify the exact mechanism of death and the correlation with the type of bomb. While undressing the body a gunshot pellet was discovered, but a preliminary total body radiographic examination exhibited no radiopaque metallic pellets within the body. A complete autopsy was performed. A large number of abrasions, burns, and contusions were present on the face, the anterior part of trunk, and upper and lower limbs. Additional solid gray metal fragments and white-gray granular material were deposited throughout the facial and trunk injuries. Eyebrows, eyelashes, head and trunk hair, were singed. Blast injury was present to left hand with skin loss, and to right hand with skin and bone loss. The posterior surface of the body was not injured. The internal examination showed confluent bruising of lungs and a band-like pattern related to the overlying ribs, bruising of the abdominal wall, both the skin and the underlying muscles, 900 cc of blood in the peritoneal cavity; extensive bruising of the gut and the mesentery; and lacerations of liver and spleen were present. Examinations of other organs were unremarkable; no fractures of ribs and sternum were detected. Routine histological investigations, applying hematoxylin and eosin staining, were performed on all organs samples. Lungs sections showed alveolar ruptures, thinning of alveolar septae, and enlargement of alveolar spaces, subpleural and intraalveolar hemorrhages, venous air embolism and soot aspiration in smaller bronchi. Fat red staining, used to document the occurrence of pulmonary fat embolism, was negative. The air embolism were confirmed by the positive results to the immunohistochemical stain for fibrinogen and CD 61 (platelet glycoprotein III a). Liver and spleen sections showed intraparenchymal diffuse hemorrhages. Samples of soot collected from the skin of face, and trunk showed a detachment of the upper epidermal areas, longitudinal elongation of the cells and nuclei of the basal cells. The cutaneous heat injuries were confirmed by the positive results by the immunohistochemical dye for HSP 90-70-27. Except for brain edema and generalized haemostasis, examination of other organs was unremarkable.

The skin samples were also examined with a light microscope, in transmitted bright field illumination and phase contrast mode, and with confocal microscope using auto-fluorescence emission of skin and metal deposited on corneum stratum and fixed in lower layers of epidermidis; a three-dimensional reconstruction of samples was performed. Fragments of the mail package were analyzed by Forensic Laboratory Section of R.A.C.I.S. (Raggruppamento Carabinieri Investigazioni Scientifiche - Grouping Scientific Investigations Carabinieri).

The trigger mechanism of the bomb was connected in turn to an electric blasting cap; such a setup affords subsequent detonation of the device. The package was a typical “disguised bomb” with the explosive contained in an innocuous appearing container.

According to the autopsy findings and histological data, death was attributed to primary blast injury (PBI). The primary blast injury arises from the overpressure of the wave that crushes the body and damages the air containing organs directly, and other organs indirectly.

The investigation of explosion-related fatalities can be a substantial challenge in forensic casework. Determining whether the mode of death is suicide, homicide, or accident in such cases can present an especially difficult task to the forensic pathologist.

Therefore the detailed forensic investigation performed with autopsyal and histological findings, and the study of metal fragments present in the skin using a confocal type laser profile microscope at the same time the analysis of the bomb package permitted the exact reconstruction of the homicidal explosion.

Blast Injury, Confocal Microscopy, Disguised Bomb

G52 Ocular Study in Pediatric Deaths Under Two Years of Age With Novel Findings in the Retina of Children Who Died of Sudden Infant Death Syndrome (1994 – 2004)

Jorge L. Arredondo Marin, MD, John R. Fernandes, MD, and Chitra Rao, MBBS, McMaster University, Department of Pathology and Molecular Medicine, Regional Forensic Pathology Unit, Hamilton Health Sciences Centre, 237 Barton Street East, Hamilton, Ontario L8L 2X2, Canada*

After attending this presentation, attendees will learn of novel findings of the retina of children who die with the diagnosis of SIDS.

This presentation will impact the forensic community and/or humanity by presenting novel findings which are easily demonstrated on routine histologic processing will aid in the understanding of a component of the pathophysiological process in children who die of SIDS.

Pediatric autopsies are considered one of the most difficult areas in Forensic Pathology, due to the small stature, different physiology, and the increased vulnerability of children to abuse.

Sudden infant death syndrome (SIDS) is defined as the sudden death of an infant less than one year of age that remains unexplained after a thorough case investigation, including performance of a complete autopsy with negative results, examination of the death scene, and review of the clinical history. SIDS is the leading cause of infant death beyond the neonatal period, mostly between one month and four months. Although the etiology largely remains unknown, many factors have been associated including metabolic, cardiac, and prone sleep position.

Differential diagnosis includes Shaken baby syndrome (SBS), subtle accidents, asphyxias, and inflicted trauma. The retinal findings are a key part of the investigation specifically identifying areas of retinal hemorrhage.

The purpose of the study was to describe ocular findings in children under two years of age who died suddenly.

One hundred two forensic pediatric cases of deaths under two years old were selected from the Regional Forensic Pathology Unit of Hamilton Ontario, over a period of 11 years (1994 – 2004).

Forensic reports were analyzed and data such as age, sex, cause of death, and postmortem intervals were obtained.

A grossing and microscopic protocol for eyes was created including description with measurements, fixation, sectioning, photography, and systematic histology.

Pigs' eyes were processed with same protocol at different postmortem intervals, as a control for postmortem tissue changes.

The majority of the cases (55%) were between one month and six months of age. The most common diagnosis was SIDS (59/102).

Seventy-two (70.5%) cases showed the presence of cytoid bodies in the retina. Cytoid bodies are smooth, rounded, eosinophilic balls that measure from 7-15 µm and can mimic red blood cells. They were located predominantly (90%) at the anterior part of retina involving the internal limiting membrane and nerve fiber layer of retina. Cytoid bodies were positive for S100, Synuclein, CD 56, and negative for Glycophorin A (an RBC marker).

Extramedullary hematopoiesis (EMH) was identified in 35 (34%) cases. The most frequent location of EMH was the choroid 29/35 (82%). Myeloid and erythroid precursors were confirmed by immunohistochemistry (myeloperoxidase and glycophorin A respectively). Electron microscopy verified the presence of neural filaments.

The changes were not seen with control samples, excluding postmortem artifact as the cause for the findings.

This study is the first to demonstrate the presence of extramedullary hematopoiesis and cytoid bodies in the retinas of SIDS children. The findings suggest a subtle hypoxic component in the natural process in SIDS. The two cases of victims of Shaken Baby Syndrome did not demonstrate EMH or cytoid bodies. Other causes of asphyxia show a 60% incidence of cytoid bodies and 30% incidence of EMH. SIDS cases did not show retinal hemorrhage.

The forensic community may benefit from these observations further aiding in the understanding of the pathogenesis of SIDS.

SIDS, Ocular Findings, Cytoid Bodies

G53 Exsanguination Associated With Vascular Access Sites in Hemodialysis Patients

Donna M. Vincenti, MD, and Patricia A. Aronica-Pollak, MD, Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201; Joshua M. Sharfstein, MD, City of Baltimore Health Department, 210 Guilford Avenue, Executive Suite, 3rd Floor, Baltimore, MD 21202; and David R. Fowler, MD, Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201*

After attending this presentation, attendees will understand some principles associated with death secondary to exsanguination from vascular access sites in hemodialysis patients including the vascular access types, the frequency at which this occurs, associated circumstances under which this occurs, and possible modalities for prevention.

This presentation will impact the forensic community and/or humanity by providing a review of exsanguination deaths that are directly related to arteriovenous fistulas, arteriovenous grafts and venous catheters used for hemodialysis in patients with end stage renal disease. This information can augment knowledge of this lethal complication associated with hemodialysis and thereby reinforce the need for patient, caregiver and health personnel education and vigilance.

Patients with end stage renal failure requiring hemodialysis have three options for vascular access depending on the severity of their disease, their vascular anatomy, and their vascular viability. Native arteriovenous fistulas are the preferred choice for long term dialysis treatment because of their lower rate of breakdown and infection. Arteriovenous grafts can also be used for long term dialysis treatment if the patient's anatomy is not conducive to the creation of a natural fistula but has a greater risk of infection and clotting. Intravenous catheters are preferably used for a short duration, usually for emergency dialysis or while waiting for a fistula to mature. Exsanguination from any of these vascular access sites is a lethal complication for hemodialysis dependent patients.

A retrospective search of cases from January 2000 to July 2006 in the State of Maryland yielded 24 deaths due to exsanguination from arteriovenous fistulas, arteriovenous grafts, and venous access catheters. The age range was from 28 years to 85 years with a mean age of 58 years. Fifteen (63%) of the decedents were male. Eighteen (75%) were African American and six (25%) were Caucasian. Seven access sites (29%) were arteriovenous fistulas and four (17%) were venous catheters. Ten access sites (42%) were arteriovenous grafts. Of these ten grafts, seven (70%) were synthetic, two (20%) were made of natural materials, and one (10%) was comprised both synthetic and natural materials. Exsanguination was due to erosion of an arteriovenous graft or fistula in 14/24 (58%), dislodgement of a venous catheter in 2/24 (8%), dehiscence of graft site sutures in 2/24 (8%), infection involving a graft or fistula in 2/24 (8%), perforation of an artery following venous catheter insertion in one case (4%), erosion due to an aneurysm involving a fistula in one case, one individual who cut her venous catheter at home presumably with scissors for unknown reasons and one individual who pulled out his active dialysis line from his arteriovenous graft in the dialysis center. The manner of death was classified as accident in 11 of 24 cases (46%), as natural in nine (38%) and as undetermined in four (17%). Of the 22 of 24 cases tested for ethanol, one case tested positive. Of the 13 of the 24 cases tested for drugs, three (23%) tested positive for illicit drugs. The substances identified included cocaine and morphine. In addition to these three cases, one decedent had pseudoephedrine intoxication that was considered a contributing cause of death.

Although the complications related to vascular access sites for hemodialysis are many and varied, the results indicate that death by exsanguination is an important risk for patients. Dialysis centers should educate patients about this potential and instruct them to periodically look for signs of fistula/graft compromise including fistula/graft failure, infection, or aneurysm formation. In addition, dialysis centers should consider encouraging patients to carry a tourniquet at all times after proper training as to its use. Therefore, if a fistula/graft does erode or perforate, one can survive until emergency care can be initiated.

Hemodialysis, Exsanguination, Arteriovenous Fistula/Graft

G54 Potential Errors in Autopsy Reports of Custodial Deaths Temporally Associated With Electronic Control Devices: A Cardiovascular Perspective

Mark W. Kroll, PhD, University of Minnesota, Box 23, Crystal Bay, MN 55323; Dorin Panescu, PhD, St. Jude Medical Cardiac Rhythm Management Division, 705 East Evelyn Avenue, Sunnyvale, CA 94086; Jeffrey Ho, MD, Department of Emergency Medicine, Hennepin County Medical Center; 730 8th Street South, Minneapolis, MN 55415; Richard M. Luceri, MD, Holy Cross Hospital, 4725 North Federal Highway, Ft. Lauderdale, FL 33308; Igor R. Efimov, PhD, Washington University, 1 Brookings Drive, St. Louis, MO 63130; Hugh Calkins, MD, Johns Hopkins Hospital, 601 North Caroline Street, Baltimore, MD 21287; and Patrick J. Tchou, MD, Cleveland Clinic Foundation, 9500 Euclid Avenue, Cleveland, OH 44195*

After attending this presentation, attendees will have a better understanding of Electronic Control Devices, such as the TASER® device, and how to better perform an autopsy in such cases.

This presentation will impact the forensic community and/or humanity by demonstrating more accurate autopsies where an Electronic Control Device was associated with a death.

Introduction: Sudden, in-custody death (SICD) events are alarming phenomena that occur numerous times per year in this country. With increasing usage of electronic control devices (ECD), such as TASER® brand devices by law enforcement, the number of SICD events that are

temporally related to ECD applications is growing. The autopsy in such a case presents a diagnostic challenge to the medical examiner, as there are no postmortem tests available to detect past electrical applications.

As ECD technology is relatively new, medical examiners may not be fully aware of what these devices are and are not capable of and may, therefore, be making errors in diagnostic judgment. This study analyzed the probable error rate in assigned causes of death based on a convenience sample population.

Methods: A press search for the years 2001-2005 for cases of an SICD with a temporal ECD association was undertaken and the autopsy reports obtained.

Sudden death from electrical discharge is caused by the induction of ventricular fibrillation (VF) and generally follows this sequence: (1) pulse disappears immediately, (2) there is loss of physical strength for continued resistance, (3) collapse occurs within 5-20 seconds, (4) a VF rhythm is shown on a cardiac monitor, and (5) immediate defibrillation is usually successful. Any material failure to appreciate the above facts was scored as an error.

Other errors were counted if the report reflected hypotheses not supported by known literature. These included: blaming the ECD for cardiac physical changes, inclusion of a publicity sensitive safe comment (e.g., “we were unable to eliminate the role” of the ECD), assuming prolonged ECD applications are more dangerous than other restraint techniques, claiming that ECDs impair breathing, presumption of a lethal synergy between stimulant drugs and the ECD, use of the ECD in the “drive stun” mode only since this involves current passing between two very close electrodes and does not create any major body mass involvement. Finally, the use of the metaphorical “last straw” was scored as an error.

Results: There were 176 SICD events reported over the 60 month period with a temporal ECD association. Twenty-Seven cases where the autopsy reports listed the ECD as a contributory or as an “unknown” factor. As expected, the rate of such reports appears to be growing at 2.6 per year ($r^2=.74$, $p = .06$). Autopsy reports were reviewed for these cases and errors were tabulated. The decedents were all male with mean age 35.6 ± 10.7 years (median = 32) which is consistent with recently reported SICD data.¹ A mean of 3.1 ± 1.2 scored errors per report with a range of 1-6. This rate was very stable across the study period. A sobering finding was the rate at which “last straw” was mentioned as a linkage in lieu of a scientific mechanism. Scored errors are listed in the following table:

Probable Error in Citing the ECD	N
Time to collapse \geq 1 minute	21
Continued resistance after ECD application	14
Rhythm other than VF	11
Publicity sensitive comments	9
Failure of immediate defibrillation	7
Drive stun mode	6
Assumed drug-ECD electrocution synergy	6
Discharge duration or parity	5
“Last straw” metaphor as a mechanism	4
Cardiac damage ascribed to ECD	3
Assumed ventilation impairment	2

Conclusions: While uncommon, autopsy reports involving electronic control devices do appear several times per year with material errors in the area of cardiogenic etiology. The results of this study suggest that medical examiners need to familiarize themselves with the time and causation elements of electrocution, ventricular fibrillation, and ECD technology to avoid this in the future.

G55 Headache and Sudden Death in a Young Adult: An Unexpected Finding at Autopsy

Adrienne Segovia, MD*, and Michelle A. Jorden, MD, Office of the Cook County Medical Examiner, 2121 West Harrison Street, Chicago, IL 60612

After attending this presentation, attendees will have gained a basic understanding of the different ways humans can contract *Taenia solium*, the pork tapeworm, and the different diseases that can develop from infection with this parasite, emphasizing involvement of the central nervous system.

A 33-year-old white female presented with a history of severe headaches, nausea, vomiting, and dizziness. The headaches, which were unassociated with fever, began in February 2006. A work up for meningitis including examination of cerebral spinal fluid was negative, resulting in a diagnosis of migraine headaches. The headaches and accompanying symptoms, however, persisted. Following an episode of one of the headaches, she was found unresponsive in bed and was unable to be resuscitated.

Autopsy examination revealed the presence of cerebral edema with tonsillar herniation. The posterior horns of the lateral ventricles in the temporal region were dilated. The fourth ventricle was dilated and obstructed by a colloidal appearing cystic structure that measured 1 cm in maximum dimension. The remainder of the autopsy examination was unremarkable. Blood cultures were negative, vitreous electrolytes showed a normal postmortem pattern and were unremarkable, and toxicology testing was negative.

Histologically, the brain showed an intense mononuclear infiltrate composed of lymphocytes and plasma cells that surrounded a homogenous amorphous eosinophilic structure in the ventricle. The choroid plexus focally showed a similar intense inflammatory reaction. Ependymitis and mononuclear perivascular cuffing were also present. The cystic structure seen grossly in the fourth ventricle had a wall that was composed of three layers: an eosinophilic outer cuticle with the grapelike appearance, a single layer of subcuticular cells, and a myxoid cytoplasm containing tubular structures. These findings are consistent with intraventricular neurocysticercosis.

Upon further questioning of the family, it was learned that the decedent had immigrated to the United States from Mexico 12 years ago. Her family in Mexico owned a restaurant type business where pigs were raised and slaughtered on the property. Prior to her recent complaints of headache, the decedent had been in good health.

Cysticercosis is the most common parasitic disease affecting the central nervous system. It is endemic in Latin America, India, China, Southeast Asia, and sub-Saharan Africa. It is estimated that up to 90 percent of patients with cysticercosis have central nervous system involvement. Sole involvement of the central nervous system is termed neurocysticercosis (NCC). The disease is reported in all age groups, but most cases present in the third and fourth decades. Reliable data regarding the incubation period are lacking, but it is estimated that months to decades can pass between initial infection/exposure and the subsequent development of neurological symptoms.

The pork tapeworm *Taenia solium* causes the infection. Humans can be either the definitive host or the intermediate host and thus two different diseases are recognized. Infection with the larval form as would occur from eating contaminated undercooked meat leads to taeniasis. The larva hatches in the small intestine and develops into tapeworms. In this situation humans are the definitive host because they harbor the adult form of the parasite – the tapeworm. In contrast, when humans harbor the larval form of the parasite, they are the intermediate host and the disease is called cysticercosis. This occurs when *T. solium* eggs are ingested. Sources of eggs include contaminated food and water, fruit, or vegetables fertilized with contaminated human or pig feces and contact with individuals harboring the tapeworm and shedding the eggs. The disease may be

contracted from fomites because the eggs are resistant to environmental conditions.

In the small intestine the eggs hatch releasing oncospheres. The oncosphere penetrates the intestinal mucosa, travels to the pulmonary circulation, and is disseminated systemically. The oncosphere, which develops into the larval form, may reach several different organ systems, but seem to have a predilection for the central nervous system, skeletal muscle, subcutaneous tissue, and eyes. Central nervous system involvement most commonly involves the parenchyma and may cause seizures.

Involvement in the central nervous system may be extraparenchymal affecting the ventricles, subarachnoid space, eyes, and spinal cord. It is estimated that between ten to 30 percent of patients with NCC have intraventricular cysts. Ventricular cysts can be attached to the ependyma or float freely migrating throughout the cerebral spinal fluid pathways. Unlike parenchymal cysts, which are typically multiple, ventricular cysts tend to be solitary and ventricular involvement typically occurs without accompanying parenchymal cysts. Ventricular cysts are more likely to be symptomatic than parenchymal cysts. Ventricular cysts can cause hydrocephalus either by blocking the flow of cerebral spinal fluid or by producing ependymitis with scarring, obstruction, and ventriculitis. Individuals having involvement of the ventricle most commonly present with signs of increased intracranial pressure such as headache, nausea, and vomiting. These symptoms are commonly attributed to migraine or tension headaches.

NCC is generally a chronic disease whose natural progression includes four stages: vesicular, colloidal, granular/nodular and calcified. Symptoms typically develop as the parasite begins to die losing its ability to control host defenses. The ensuing inflammatory response results in degeneration of the larva and the formation of a granuloma.

Making the diagnosis in a clinical setting can be difficult because the clinical manifestations are variable and nonspecific and depend on the number and location of cysts and the host's immune response. Proposed diagnostic criteria incorporate absolute, major, minor, and epidemiological criteria. Interpretation of the criteria allows for two degrees of diagnostic certainty – definitive and probable.

No reliable information is available regarding mortality rates. Large autopsy series from endemic areas suggests that the majority of cases are asymptomatic making calculation of the true incidence and prevalence difficult. It is estimated that 50 million people are infected worldwide. The disease carries a high cost in morbidity. In endemic countries NCC may be responsible for 50 percent of adult-onset seizure disorders and those with intraventricular and subarachnoid involvement can develop complications such as vasculitis and hydrocephalus. The annual treatment cost in endemic areas is estimated to be close to \$90 million per year. In the United States, there are more cases of imported NCC than in all other developed countries combined, and the annual treatment cost is estimated at \$9 million per year. The disease is generally encountered in the southwest United States and among Hispanic immigrants. The increasing number of reported cases in the United States is most likely due to increased immigration and travel to endemic areas. The long latent period and variable clinical presentations make it go undetected or unrecognized clinically. Although autopsy studies suggest that NCC is most commonly an incidental finding, the disease can result in death. NCC should be considered in the differential diagnosis of calcified, nodular, or cystic lesions of the central nervous system.

Neurocysticercosis, Headache, Central Nervous System

G56 Sudden Death in Duchenne Muscular Dystrophy With Noncompaction of the Ventricular Myocardium: A New Cardiomyopathy or a Compensatory Regression to Fetal Myocardiogenesis?

Michael J. Caplan, MD, and Kelly Rose, MD*, Medical University of South Carolina, Department of Pathology & Laboratory Medicine, Suite 309, 165 Ashley Avenue, Charleston, SC 29425*

The goal of this presentation is to evaluate morphologic changes in the myocardium critically in order to gain insight into their role in the pathogenesis of apparent cardiomyopathies. What may appear initially to be a primary derangement in cardiac muscle (the definition of cardiomyopathy) may in fact be a secondary response to another primary insult.

This presentation will impact the forensic community and/or humanity by creating an awareness of an abnormal morphologic pattern within the myocardium and the spectrum of its association with disease states, particularly the muscular dystrophies.

Noncompaction of the ventricular myocardium (NVM) is a condition describing a rare type of cardiomyopathy believed to be due to an interruption in cardiac development. It refers specifically to persistence of the trabecular network of sponge like cardiac muscle that accompanies mid- to late embryonic development, during which time the myocardial blood supply is provided by direct diffusion from the intertrabecular spaces that communicate directly with the cardiac chambers. NVM may occur either as an isolated condition, in association with other structural heart derangements, or as part of a syndrome of anomalies. NVM has been described as a component of several muscular disorders and mitochondrialopathies, including Barth syndrome, Becker muscular dystrophy, Emery-Dreifuss muscular dystrophy, myoadenylate deaminase deficiency, myotubular and metabolic myopathies, and with mutations in the G4.5 and a-dystrobrevin genes (Xq28 chromosome region), with possible X-linked inheritance. However, until quite recently, an association between NVM and Duchenne muscular dystrophy (DMD) had not been realized. This presentation describes a case of sudden death in the setting of DMD complicated by dilated cardiomyopathy (DCM) in which autopsy revealed a prominent finding of NVM; in doing so, this study attempts to explore a potential causal relationship between the DCM and NVM.

The deceased was a 21-year-old African-American man with DMD (wheelchair-bound) and DCM; a recent echocardiogram documented global hypokinesis with a left ventricular ejection fraction ranging from 20-30%. Five days before his death, he presented with an acute exacerbation of congestive heart failure and tricuspid regurgitation. On the day of his death, his caregiver called 911 for complaints of profound weakness; paramedics recorded a mean blood pressure of 65 mm Hg. He was transported to the Emergency Department and was administered crystalloid intravenous fluids, which restored his blood pressure to 91/51. However, despite being stable for the next few hours, he experienced a witnessed seizure that was followed by a thready carotid pulse, and shortly after, by pulseless electrical activity (PEA). Resuscitative efforts were initiated and were carried out for approximately 10-15 minutes but were unsuccessful and he was pronounced dead.

At autopsy, the deceased exhibited marked flexion contractures of the hips and knees and there was extensive fatty replacement of the calf and psoas muscles. There were unequivocal features of DCM, including a 550-g heart (expected for body weight: 223 g), moderate to marked left ventricular dilatation and patchy but focally confluent areas of dense white fibrosis, individually up to 0.6 cm, involving the posterior and lateral left ventricular walls. In addition, there was marked exaggeration of the trabeculae carnae within the left ventricular chamber, with numerous anastomosing trabeculae that imparted a distinctly "spongy" appearance, particularly at the left ventricular apex. Microscopic cardiac examination

revealed confluent replacement fibrosis and fatty ingrowth within the compact outer myocardial half, while the inner half consisted of an anastomosing network of trabeculae forming irregular "staghorn"-like spaces. The cause of death was certified as complications of DCM (associated with NVM) due to DMD.

In late 2005, NVM was described for the first time in a patient with DMD by a group of investigators in Vienna, Austria. They proposed that in the setting of DMD, replacement fibrosis of the compact myocardium following myocyte loss is the principal pathologic finding and accounts for the clinical spectrum of ventricular dysfunction in these patients, while NVM represents a compensatory response generated by a failing heart to regenerate its nonfunctional myocardium. The case presented case represents the second reported association between NVM and DMD. This study proposes that the precise molecular signals governing the events in embryonic myocardiogenesis may be recapitulated in certain clinical settings, such as this one; identification and isolation of such signals would corroborate this hypothesis and enhance the understanding of such events.

Noncompaction of the Ventricular Myocardium, Dilated Cardiomyopathy, Duchenne Muscular Dystrophy

G57 Death By Giant Cells: Report of Two Cases of Sudden Cardiac Death Due to Giant Cell Inflammatory Processes

Rebecca A. Hamilton, MD, Office of the District 21 Medical Examiner, 70 Danley Drive, Fort Myers, FL 33907; Linda Sullivan, BS, Wuesthoff Reference Laboratory, 6800 Spyglass Court, Melbourne, FL 32940; and Barbara C. Wolf, MD, Office of the District 21 Medical Examiner, 70 Danley Drive, Fort Myers, FL 33907*

After attending this presentation, attendees will be familiar with the differential diagnosis in cases of sudden cardiac death due to giant cell inflammatory processes involving the myocardium and will understand the roles of histologic examination and immunohistologic studies in arriving at the correct diagnosis.

This presentation will impact the forensic community and/or humanity by elucidating the clinical and pathologic issues involved in distinguishing the subgroup of sudden cardiac deaths resulting from inflammatory processes with giant cells that affect the heart.

The medical examiner or coroner usually investigates sudden and unexpected deaths in individuals without documented disease processes that would provide reasonable explanations for the deaths. These include the unexpected deaths of individuals who have been diagnosed with a known chronic natural disease that was not expected to cause death at that point in time as well as those cases in which the deceased had no known pre-existing natural disease at the time of death. Cardiovascular disorders, most notably arteriosclerotic and/or hypertensive cardiovascular disease, account for the majority of sudden and unexpected natural deaths. Less commonly documented are disease processes directly affecting the myocardium. In these cases, histologic examination of the myocardium is often essential in reaching a diagnosis.

Granulomatous inflammation of the myocardium can occur in the course of a number of systemic disease processes including infectious etiologies such as fungal, mycobacterial and parasitic infections, as well as hypersensitivity reactions and rarely autoimmune disorders. In many of these disorders giant cells comprise a component of the inflammatory infiltrate. Systemic granulomatous processes of unknown pathogenesis, most notably sarcoidosis, may also be associated with involvement of the myocardium. In contrast, giant cell myocarditis, also known as idiopathic myocarditis, a rare, frequently fulminant, and fatal disorder of unknown etiology, is isolated to the heart and lacks systemic involvement.

The majority of systemic granulomatous disorders that involve the heart are diagnosed prior to death due to their protracted clinical course and symptomatology related to the involvement of other organs.

Occasionally, however, these disorders are associated with sudden death due to pathologic involvement of the heart. These cases are likely to be investigated by a forensic pathologist, particularly if the individuals do not have antemortem diagnoses. Because of its isolation to the heart and rapid clinical course, giant cell myocarditis is most likely to be diagnosed at the time of autopsy. Indeed, an individual may be asymptomatic and sudden death may be the presenting manifestation of the disease.

This study reports two cases in which sudden death resulted from giant cell inflammatory processes affecting the myocardium. Both individuals lacked antemortem diagnoses. In one case an 18-year-old man who had been asymptomatic except for a 2 ½ month history of vague abdominal pain was found dead at work. Postmortem examination revealed a semigranulomatous, mixed inflammatory cell process involving the left ventricle that was associated with giant cells and lacked myocardial fiber necrosis and tissue eosinophilia. Numerous well-formed, noncaseating granulomas were found in the lungs, pulmonary hilar lymph nodes and kidneys. The diagnosis of sarcoidosis was rendered. The second case involved a 43-year-old man with a ten year history of intermittent chest pressure and cardiac arrhythmias who collapsed at work. The heart showed a similar mixed inflammatory cell infiltrate that included giant cells, although focal myocardial fiber necrosis and eosinophils were also present. Thorough gross and microscopic examination revealed no involvement of other visceral organs or lymph nodes and the diagnosis of giant cell myocarditis was rendered.

Giant, Cell, Myocarditis

G58 Sudden Death and Keratoderma Associated Cardiomyopathy: An "Affray" of the Heart

Christopher M. Milroy, MD, LLB, and Sacha Kolar, MBChB, Forensic Science Service, The Medico-Legal Center, Watery Street, Sheffield, South Yorkshire S3 7ES, United Kingdom; and Kim Survana, MBChB, Sheffield Teaching Hospitals, Northern General Hospital, Herries Road, Sheffield, South Yorkshire S5 7AU, United Kingdom*

After attending this presentation, attendees will have knowledge of cardiomyopathy associated sudden death and keratoderma as well as the law regarding manslaughter in England.

This presentation will impact the forensic community and/or humanity by discussing issues of interaction of sudden "natural" death and the law pertaining to homicide in England.

A 15-year-old girl was involved in an incident in which she was subject to threats, then blows before running away from the incident. She ran uphill away from the incident, collapsed and died. At autopsy a history was given that she suffered from the skin disorder Erythrokeratoderma Variabilis or possibly Papillon-Lefèvre syndrome and was on antihistamines. At autopsy there was significant thickening of the skin, most obvious of the palms and soles of the feet. The hair was abnormal as were the teeth. On internal examination the heart was clearly abnormal. There was a degree of dilatation of the ventricles and on microscopic examination there was obvious fibrosis, with no evidence of acute infarction or inflammation. A diagnosis of Plantopalmer Keratosis associated cardiomyopathy was made.

There are a number of genetic abnormalities associated with Plantopalmer keratosis. A number of heart conditions may be found including Naxos syndrome and Caravajal syndrome.

A charge of manslaughter, with an additional charge of affray was laid against four teenage defendants. The basis of the manslaughter charge was the charge of affray, except for brain edema and generalized haemostasis. Three of the defendants were convicted of manslaughter and affray. The fourth defendant was acquitted.

On appeal, the convictions for manslaughter were overturned. The convictions for affray were upheld. As well as the unique pathologic features, this case has clarified the law of manslaughter in the English legal system, limiting its extent to an act that is dangerous in the sense that sober and reasonable persons would recognize it as foreseeable.

Cardiomyopathy, Homicide, Keratoderma

G59 Correlations for Expected Heart Weight

William T. Gormley, MD, PhD, Deborah Kay, MD, and Anna Noller, PhD*, Office of the Chief Medical Examiner, Commonwealth of Virginia, 400 East Jackson Street, Richmond, VA 23219*

After attending this presentation, attendees will understand the use of correlations with height, weight, and Body Mass Index (BMI) to determine expected normal autopsy heart weight as well as variations in expected heart weight by sex and appreciates the deviation from expected heart weight as an indicator of heart disease.

This presentation will impact the forensic community and/or humanity helping to define abnormal heart weight in sudden and unexpected deaths and will explore the epidemiology of heart disease and the effect of BMI on heart weight.

After attending this presentation attendees will understand that the correlation of height, weight and Body Mass Estimation with expected normal heart weight is important to identify subtle hypertrophy, especially in the analysis of sudden and unexpected deaths with minimal disease. Standard references define normal ranges for heart weight at autopsy and there are published correlations of autopsy heart weight with body weight and body length. Body Mass Index (BMI) is commonly used as an indicator of obesity and obesity has been correlated with heart disease. This study explores the relationship of heart weight at autopsy to BMI as calculated from length and body weight data measured as part of the routine autopsy procedure.

This study reviewed reports of all autopsies performed in 2004 at the Richmond District Office of the Chief Medical Examiner. Data collected from each case included age, sex, race, height, weight, heart weight, and presence or absence of anatomically identifiable heart disease. Cases were excluded where there was extensive decomposition, burning, or other body destruction that could invalidate the height, body weight or heart weight data. While the collected data contained decedents of all ages, the study focused on adults between 18 and 65 years of age.

Correlations of heart weight with body weight in patients without identifiable heart disease were generally good and in agreement with previously published data. Similar correlation lines for patients with heart disease were significantly different with the expected bias toward increased heart weight. Comparison of correlations for men and women also produced significant and expected differences. Surprisingly, correlations of heart weight with BMI were much worse than the correlations with body weight.

Body Mass Index (BMI), Heart Disease, Heart Weight

G60 Gagging, Strangulation By Single/ Double Ligature ...or Incaprettamento?

João Pinheiro, MD, MSci, and Duarte Nuno Vieira, PhD, Instituto Nacional de Medicina Legal, Largo Sé Nova, Coimbra, 3000 213, Portugal*

After attending this presentation, attendees will learn that some apparent simple cases of strangulation turn out to be complex ones, with more than one form of mechanical asphyxia involved. This presentation

will also point out how important is to know the mechanism of death in these cases to be able to reconstitute the story.

This presentation will impact the forensic community and/or humanity through the familiarization with this particular ritualistic way of committing homicide – the incaprettamento - practiced not only within the community where it was originally described. Additionally the presentation will emphasize the importance of the differential diagnose between the diverse forms of mechanical asphyxia used in a single victim.

Incaprettamento is a typical homicide ritual used by the Italian Mafia as an admonitory significance to traitors and considered a form of vendetta. A rope is tied in a noose around the victim's neck. The other end of the rope is used to tie both hands and feet behind the back. Death is attributed to self-strangulation when, by exhaustion, the victim will no longer be able to support the legs in that forced position. Some authors point out that sometimes, the binding is done postmortem, to facilitate transportation and disposal of the victim.

This research presents a case of a man partially naked, who had been apparently gagged and strangled, with the hands and feet tied at the back, seeming to be a case of *incaprettamento*. He was found in a forest, some meters away from the local road, in a prone position with the head lower than the rest of the body.

The autopsy showed that the victim had been gagged, apart from having two constrictor items around the neck: a ladder belt (which tied simultaneously both hands behind the back, with a twisting device made of a metal part of a bicycle inserted between the rope and the skin) and, underneath it, a synthetic rope. The feet were bound with an electric wire, separately from the hands. Typical ligature injuries were observed, such as asphyxic exuberant signals, osteo-cartilagenous fractures, intimal tear of the carotid artery and bleeding into the muscles and mucosa. A sexual assault was ruled out using a standard protocol for collection and evaluation of the usual specimens.

Taking into account the autopsy diagnoses – gagging and/or a single/double ligature – this paper discusses the real cause of death, and its relation with a case of *incaprettamento*. Finally, this presentation will debate whether this could be considered a real *incaprettamento*, since, contrary to the typical procedure involved in this type of homicide; the feet were bind independently, without being attached to the hands and neck.

Incaprettamento, Strangulation, Gagging

G61 A Case Report of an Unexpected Accidental Electrocution

Christopher K. Poulos, MD, Indiana University Department of Pathology and Laboratory Medicine, 521 West McCarty Street, Indianapolis, IN 46225; Michele Catellier, MD, Forensic Pathology Associates of Indiana, 521 West McCarty Street, Indianapolis, IN 46225; Elena F. Bishop, MD, Indiana University Department of Pathology and Laboratory Medicine, Clarian Pathology Laboratory, 350 West 11th Street, Indianapolis, IN 46225; and Stephen S. Radentz, MD, Forensic Pathology Associates of Indiana, 521 West McCarty Street, Indianapolis, IN 46225*

After attending this presentation, attendees will understand basic principals of investigating accidental electrocutions and will also have an increased index of suspicion for electrocution in certain cases of sudden, unexpected death.

This presentation will impact the forensic community and/or humanity by increasing awareness of electrocution as a differential diagnosis in certain circumstances and by emphasizing the importance of a multidisciplinary approach to complete scene investigation in cases of possible electrocution. By increasing the detection of cases of electrocution, particularly those taking place in public areas, potentially hazardous or fatal electrical malfunctions, and situations can be detected and corrected before causing death or harm to additional individuals, including the investigators.

Fatal electrocutions are reported to account for a death rate of approximately 0.54 per 100,000, occur most commonly in men, and are mostly accidents (though suicides and homicides by electrocution do occur). The mechanism of death during electrocution varies, but is often due to ventricular fibrillation. Electrocutions can be categorized into direct current and alternating current types, and alternating current is generally regarded as more dangerous than direct current. Electrocutions can also be divided into high and low-voltage varieties (based on voltage greater than or less than 1000 volts), and, though the exact ratio of high versus low-voltage electrocution varies with the study, up to 83% of electrocutions are with low-voltage current. While high-voltage electrocutions are often accompanied by characteristic electrical burns, nearly 50% of low-voltage electrocutions are not accompanied by these burns or other physical evidence, which renders postmortem diagnosis potentially difficult. Indeed, even some characteristic features of high voltage electrocutions, such as the arborescent patterns seen in fatal lightning strikes, may be transient. This lack of specific pathologic findings makes a high index of clinical suspicion very important in certain circumstances, such when a person is grounded and near a source of electricity. Additionally, examination of the victim's clothing for burns and death scene investigation are of critical importance in detecting electrocution. Numerous authors have also stressed both the critical importance of scene safety and of a multidisciplinary approach during the investigations of potential electrocutions. Specifically, electrical engineers or representatives of a local power company are often called upon to examine electrical devices that potentially caused the electrocution.

To illustrate these points, this presentation will describe a case of accidental low-voltage electrocution that occurred in their practice. In this case, a 28-year-old male was found dead in a publicly accessible restroom. The initial report, accompanying the decedent to the county coroner's office, stated the death was believed to be a natural death; however, examination of the decedent revealed burns on the skin and clothing. Based upon these burns, which were believed to be electrical, additional scene investigation was requested by the forensic pathologist. This supplemental investigation disclosed that another individual had complained of receiving a "shock" in that restroom. Also, a representative of the local power company went to the scene and discovered two separate electrical devices that were defective and could have exposed the decedent, or other users of this restroom to low-voltage current, a risk that was heightened by a wet floor with a metal drain. A subsequent report that correlated the scene findings with the pattern of electrical burns on the victim's skin, suggest that both pieces of equipment contributed to the death of the decedent. This case serves to illustrate the potentially occult nature of low-voltage electrocutions and how a multidisciplinary scene investigation as well as expert examination of involved electrical equipment can greatly aid in the detection of such electrocutions, which can have an impact on public safety.

Electrocution, Fatal, Accidental

G62 Death From Truck Tire Servicing: A Report of Three Cases and Review of the Literature

Patrick Cho, MD, Aldo Fusaro, DO, and Richard C. Harruff, MD, PhD,
King County Medical Examiner's Office, 325 Ninth Avenue, Seattle,
WA 98104*

After attending this presentation, attendees will recognize different blunt force and blast type injuries associated with truck tire servicing accidents.

This presentation will impact the forensic community and/or humanity by helping in the recognition of the different blunt force and blast type injury patterns; and helping the attendee to be better aware of

OSHA regulations and manufacturers' recommendations for proper tire servicing.

Three cases of death from injuries related to truck tire repair and/or handling were identified between 1995 and 2006 at the King County Medical Examiner's Office in Seattle, WA. The decedents, all male, ranged in age from 30 years to 40 years old and had no significant medical conditions. Injuries ranged from blunt force trauma to the head, torso and extremities to blast injuries of the upper airways and lungs.

In the first case, the decedent made an unwitnessed service call to change a tire on a tractor-trailer truck parked in a lot. Evidence suggested the individual had changed the tire and was inflating the new tire when the sidewall blew out. The decedent was struck in the face and fell backward. Autopsy showed contusions to the lungs, esophagus, posterior pharynx, and superior larynx.

In the second case, a warehouse worker was rolling semi-truck wheels and tires onto metal racks. A supervisor witnessed a tire explode projecting the wheel upward into the decedent's head, chest and arms, projecting him backwards. Autopsy showed comminuted skull fractures, cerebral lacerations, multiple rib fractures, and pulmonary contusions.

In the third case, the decedent made an unwitnessed roadside service call to change a dump truck tire on an access road. He was found supine on the ground with the tire and wheel resting across his legs. Examination of the injuries and scene reconstruction demonstrated tire explosion during inflation and upward projection of the wheel. Autopsy revealed a depressed frontal skull fracture and parietal and frontal scalp lacerations with associated cortical contusions and subarachnoid hemorrhage.

Review of the literature revealed well documented patterns of injury and death associated with explosions during tire servicing and handling. The vast majority of fatalities from all tire servicing accidents involve service work on truck tires. Blunt force injuries to the head accounted for the majority of these fatalities, while other common injuries include broken facial and upper extremity bones. Other documented injuries included "blast" or concussive injuries to air-filled organs such as bowel, lung, and tympanic membranes. This study reviewed several manufacturers' standard safety procedures as well as OSHA regulations and found a general concordance on the proper equipment needed when changing a truck tire and on the proper procedure. These include using protective gear and using safety equipment. Proper tire changing procedure was outlined as a multi-step process with clear check points to be met before proceeding onward. The prevention of these types of injuries can best be accomplished by adherence to the tire manufacturers' warnings and recommendations as well as to OSHA's tire service regulations. There is precedent for the levying of fines against businesses not in compliance with OSHA workplace safety standards.

When investigating these frequently unwitnessed deaths, particular attention needs to be paid to scene investigation, noting if proper procedures and equipment were being employed. This is important not only to rule out foul play, but for ease of reconstruction of events leading to death when correlated to injuries found at autopsy.

Blunt and Blast Force Injuries, Truck Tire Servicing Accidents, OSHA

G63 A Rare Injuring Tool in a Dyadic Death

Sabina Di Donato, MD, Giovanni Paolo Di Peri, MD, and Carmina Dambra, MD, Institute of Forensic Pathology, University of Foggia - Italy, Ospedali Riuniti, Viale L. Pinto n. 1 - 71100 Foggia - Italy, Foggia, 71100, Italy*

After attending this presentation, attendees will have a better understanding of cases involving a homicide and suicide (HS). Only few cases of homicide-suicide by carpenter axe are reported in forensic literature. Sometimes it may be difficult for the forensic pathologist to distinguish between a real HS and a double murder. The importance of a thorough forensic investigation, including crime scene evaluation,

analysis of circumstantial data, autopsy findings, toxicological analysis, histological and immunohistochemical studies is emphasized.

This presentation will impact the forensic community and/or humanity by presenting the case of a homicide-suicide, where the murderer chopped his wife with a carpenter axe, and then he hanged himself. The unusual injuring tool and the relevant injuries were studied and analyzed to approach the case of dyadic death. The confocal microscope was utilized to verify the three dimensional appearance of the cutaneous lesions

Homicide-suicide (HS) is defined as that lethal event in which an individual kills another and subsequently commits suicide within one week. International studies report a highly variable proportion of HS in all homicides (from 1.5% of all recorded homicides in USA, to 42% of Denmark). Some authors proposed that the higher is the homicide rate in a population; the lower is the rate of HS. Per capita rates of HS, instead, appears quite constant across different countries and through time, in fact the annual incidence varies from the 0.2-0.6/100,000 in US, 0.07/100,000 in England and Wales, 0.18/100,000 in Finland, and 0.22/100,000 in Hong Kong. In Italy, in an observational period of 15 years, 1985 – 1999 it has been observed that the higher rates concern the Northern Italy (0.85/100,000), followed by the Central Italy (0.68) and the Southern region (0.38). Previous studies have outlined that the HS perpetrators show more similarities with those who commit suicide rather than with those who commit homicide. The vast majority of offenders are male (75-97%), aged 35-51 years, while the victims are generally female (60-85%), aged 30-35 years. Offenders are often apparently free of mental disorders, but some are regarded by relatives and friends as “hot tempered”; a low percentage have a diagnosis of major depression or psychotic disorder. The great majority of HS occurs between intimates (spouses and cohabitant) and family members. The largest group comprises the spousal or lover killing, followed by the homicide of children, and than of other family members. Male offenders usually kill spouses, while female perpetrators generally commit child homicide. The most frequent trigger is represented by the imminent separation or ending of an intimate relationship. Many modes of killing are described like shooting, strangling, stabbing, chopping, gassing, or poisoning, beating, etc. There exists a significant difference between male and female offenders in the method chosen to kill: in fact, while men are more prone to adopt active methods, women tend to use passive methods.

Here is a case of HS, where the husband chopped his wife at the back of the neck, resulting in a complete transection of the cervical spinal cord, and than hanged himself. A boy with a friend came back home and found the lifeless body of his mother lying face down in a large pool of blood. At a distance of two m, they saw the body of the father hanged by a strong nylon rope to the banisters of the mezzanine. Immediately they tried to help him, releasing his head from the slip knot, and called the ambulance, but they were both pronounced dead. In the adjacent room, policemen found a carpenter axe on a table, stained with blood and locks of hair. On the floor beneath the axe a large pool of blood was evident, with extensive blood spatter on the surface of the door and the adjacent wall. This pool of blood started a trail of blood terminating at the woman's body. The postmortem examination of the female deceased showed a deep linear cutaneous wound on the back of the neck, 6.5 cm in length, slightly oblique, with clear-cut divergent margins, exposing the underlying structures, with soft tissue bleeding underneath. A red colored area, 7.5 x 2.5 cm in diameter, surrounded this wound. The body of the second cervical vertebra showed a transverse fracture, passing underneath the dens and the right superior articular facet. The spinal cord was completely transected at the level of C₂. Also a complete section of the left vertebral artery was visible. No relevant injuries were detected on the remained of the body. Autopsy of the male revealed a ligature mark on the neck. In both cases, the histological investigation revealed massive hemorrhages in the cutaneous and subcutaneous tissues. Infiltration of erythrocytes in the dural layers and in the spinal cord was evident, at the level of transaction of the spinal cord in the female victim. Immunohistochemical studies

were performed on the cutaneous specimens collected from the neck lesions for the determination of the vitality. The evaluation of skin samples with confocal microscope allowed researchers to observe the three-dimensional model of the strangulation mark and the chopping wound. Toxicological analyses were negative.

Homicide Suicide, Chopping Wound, Immunohistochemical Study

G64 Independence Day Explosion on Lovers Key

Brett E. Harding, MBA, and Barbara C. Wolf, MD, Office of the District 21 Medical Examiner; 70 Danley Drive, Fort Myers, FL 33907*

After attending this presentation, attendees will have an understanding of the unique aspects and hazards involved in the investigation of the scene of a pyrotechnics explosion and in the postmortem examinations of the victims.

This presentation will impact the forensic community and/or humanity by providing an understanding of the unique considerations and hazards that should be taken into account by medicolegal death investigators and forensic pathologists involved in the investigation of deaths due to fireworks-related incidents.

Fireworks, generally recognized as having originated in China, have been popular in the United States since the mid-19th century. They are traditionally used in the celebration of Independence Day on Fourth of July, as well as other holidays. Because injuries due to recreational fireworks-related incidents among consumers are relatively common, the sale of fireworks is regulated by federal law and is also limited by state and local laws. Most injuries occur in children and in individuals actively handling the fireworks and most commonly involve the hands, face and eyes. In contrast, because fireworks display companies are under tight safety regulations, explosions in the professional pyrotechnics industry are rare.

This study investigated the scene and postmortem examinations of the victims of an explosion and resulting fire that occurred on Lovers Key in southwest Florida while a pyrotechnics crew was transferring fireworks from a semitrailer to a smaller truck in preparation for a Fourth of July display. The company had planned to use 853 fireworks shells ranging 3- to 12-inch in diameter and up to 4 feet long. The scene investigation involved eight teams of 80 people from multiple agencies, including the local fire department, the State Fire Marshall's Office, the Sheriff's Office, the Regional Bomb Squad, the Bureau of Alcohol, Tobacco, Firearms and Explosives, OSHA and the Medical Examiner's Office. The 40 hour investigation of the scene presented unique hazards because of flare-ups of the fire, a secondary explosion and because the debris included live firework shells. The potential detonation of live ordnance necessitated leaving the bodies at the scene until a thorough search was performed. The live rounds were marked and left in place until they were later secured in wet sand for removal and destruction. The investigation subsequently determined that the explosion was due to the accidental ignition of the fireworks, although the exact cause was never identified.

Four of the six members of the fireworks crew died at the scene, and later another later succumbed to thermal injuries. Two of the bodies at the scene were relatively intact, while the other two were fragmented. The sixth worker, a woman who was the farthest away from the trucks, jumped into a nearby body of water and survived although she suffered burn injuries and smoke inhalation. The identification of the decedents was made either by dental comparison and/or the comparison of pre- and postmortem radiographs of the axial skeletons. The autopsies also involved unique considerations due to the possible presence of unexploded ordnance in the bodies, necessitating total body radiographs prior to the examinations, because of the possibility of friction causing the detonation of these rounds. Injuries included thermal injuries resulting from the fire as well as blunt force injuries caused by the exploding fireworks and by structural materials from the destroyed vehicles. The

two relatively intact bodies showed penetrating wounds, predominately superficial, containing fireworks pellets and dark burning soot. There were no characteristic injuries to air-containing hollow viscera due to shock wave effects.

Fireworks, Explosion, Fatality

G65 Identifying the “Iceman”

Sarah L. Bettinger, MSFS, Devon R. Pierce, BS, and Suzanne M. Barritt, MS, Armed Forces DNA Identification Laboratory, 1413 Research Boulevard, Building 101, Rockville, MD 20850; Alexander F. Christensen, PhD, Joint POW/MIA Accounting Command, Central Identification Laboratory, 310 Winchester Avenue, Hickam AFB, HI 96853; and Louis N. Finelli, DO, Armed Forces DNA Identification Laboratory, 1413 Research Boulevard, Building 101, Rockville, MD 20850*

After attending this presentation, attendees will understand how the use of mtDNA can aid in the identification of missing service members from decades-old skeletal remains.

This presentation will impact the forensic community and/or humanity by providing the attendees with an example of the uses of mtDNA for the identification of human remains exposed to harsh environmental conditions.

The Armed Forces DNA Identification Laboratory (AFDIL) and the Joint POW/MIA Accounting Command-Central Identification Laboratory (JPAC-CIL) work in a combined effort to identify missing or unidentified personnel from past military conflicts. With the use of mitochondrial DNA (mtDNA) testing, skeletal remains are analyzed and compared to references from associated family members in order to make identifications. The following case study from World War II shows how the use of mtDNA can aid in the identification of missing service members from decades-old skeletal remains.

On November 18, 1942, 2d Lt. William Gamber and student Aviation Cadets John Mortenson, Ernest Munn and Leo Mustonen of the 41st School Squadron, departed Mather Field, California, for a 4-hour navigational training flight. Five hours after their departure, and with no communication from the AT-7 aircraft, search crews were sent out to locate the flight team. However, with no position reports during the flight, search crews did not know where to look in the mountainous terrain of the flight's route. After search parties found no remnants of the aircraft or its crew, the United States Army Air Forces (USAAF) abandoned it search. On November 9, 1943, the War Department officially declared all four men as dead.

Almost five years later, on September 24, 1947, two students found portions of an aircraft approximately 120 miles east of Los Banos, California. Search parties came upon widely scattered wreckage, including two engines, embedded in the ice. A data plate from one of the engines matched that from the missing AT-7 aircraft. Remains found at the site could not be identified and were interred in a group burial in the Golden Gate National Cemetery, San Bruno, California.

Decades later, on October 15, 2005, two hikers came upon a body, partially encased in ice in Mendel Glacier in Kings Canyon National Park. No evidence was found to immediately identify the body, but an undeployed U.S. Army parachute was strapped to the body, indicating that of a military service member. The National Park Service then contacted the JPAC-CIL to assist in the recovery. JPAC-CIL removed the remains as well as some material evidence from the body. Historical evidence associated with the loss of the AT-7, and evidence recovered in 1947 and 2005, suggested that these remains were likely one of the four men aboard this aircraft when it was reported missing on November 18, 1942.

The remains arrived at the CIL in Honolulu, Hawaii where a thorough anthropological analysis was made. On November 3, 2005, a small portion of the left tibia was sent to the AFDIL, in Rockville, Maryland, for mtDNA analysis. Blood references from family members

of missing service members were obtained and compared to the data obtained from the left tibia. Exclusionary results, along with evidence obtained from the site, concluded that the missing individual was Air Cadet Leo Mustonen from Brainerd, Minnesota.

The views expressed herein are those of the authors and not necessarily those of the Armed Forces Institute of Pathology, the U.S. Army Surgeon General, nor the U.S. Department of Defense.

Identification, mtDNA Analysis, Frozen Remains

G66 Caddisfly Cases Assist Homicide Case: Determining a Postmortem Submersion Interval (PMSI) Using Aquatic Insects

John R. Wallace, PhD, Millersville University, Department of Biology, Millersville, PA 17551; Richard W. Merritt, PhD, Ryan K. Kimbaraskas, MS, Mark E. Benbow, PhD, and Mollie McIntosh, PhD, Michigan State University, Department of Entomology, 243 Natural Science, East Lansing, MI 48824-1115; and Joyce DeJong, MD, Sparrow Hospital, Forensic Pathology Department, Lansing, MI 48824*

The goal of this presentation is to discuss a particular case study that exemplifies the importance of understanding aquatic insect biology to help determine a postmortem submersion interval (PMSI) in streams, rivers, and possibly lakes. This study demonstrates how certain aquatic insects, e.g., caddisflies (Order: Trichoptera, Family: Limnephilidae) can be useful in estimating the time period from a body is submerged to the point of discovery. The attendee will learn that some aspects of aquatic entomology can be useful in criminal investigations by learning how to incorporate life history aspects of aquatic insect biology to estimate a PMSI.

This presentation will impact the forensic community and/or humanity by demonstrating that there are aspects of aquatic entomology valuable to forensic investigations involving bodies recovered from aquatic systems. To date, very little research exists on the use of aquatic organisms to estimate a postmortem submersion interval; this particular case illustrates how aquatic insect evidence can augment traditional techniques used in criminal investigations to develop a PMSI time line.

The determination of a postmortem interval using entomological evidence collected from terrestrial crime scenes has been well documented. A review of the literature found that approximately 85% of studies pertained to terrestrial organisms, while only 15% pertained to aquatic organisms. This dichotomy can be explained simply because terrestrial insects have evolved to feed on carrion while aquatic insects have not. Therefore, because the biology of some terrestrial insects is intimately tied to decomposing animal flesh, where aquatic insect biology does not, this biological difference has facilitated the use of terrestrial insects in criminal investigations. Consequently, many times aquatic insect evidence is ignored from crime scenes in aqueous environments. Since remains are often found in aquatic environments, it is important that forensic scientists and law enforcement personnel visiting such crime scenes have an increased knowledge of the aquatic organisms that could potentially colonize human remains.

Although few indicators of time since death for remains found in aquatic ecosystems are comparable in precision to the insect indicators used in terrestrial cases, there are observations that can be useful in suggesting or ruling out an approximate PMSI. For example, the time intervals needed for certain growth phases of aquatic insects such as caddisflies that may attach themselves to the remains can be used to estimate a minimum PMSI. Approximately eight of the 13 orders of insects containing species with aquatic or semi-aquatic stages are likely to be associated with carrion or remains in aquatic habitats. The evolution of a vast array of physiological and behavioral adaptations in aquatic insects enables these organisms to inhabit virtually all bodies of water.

Portions of a body from an adult male were discovered in a south central Michigan stream. The body was dismembered and portions were recovered from plastic bags floating in the stream. Insects specimens collected from the plastic bags containing body parts consisted of one fly larva (Diptera) belonging to the family Muscidae, and caddisfly larvae (Trichoptera) belong to two families, the Limnephilidae or case-makers and the Hydropsychidae, net spinners. Because of case material type, size of mineral pieces used in the case, and the size of the stream from where they were collected, larvae belonging to the family Limnephilidae were separated into two different species, as well as placed in specific larval instars (or larval stage of development) which helped to age them. Based on the similarities of the behavior, life histories and occurrence of these two species throughout the year, two caddisfly species belonging to the genus *Pycnopsyche* were present, mainly the last developmental larval stage of *Pycnopsyche lepida* and *Pycnopsyche guttifer* were identified. Unique case-building behaviors of these Limnephilid caddisflies found on the remains were used to elucidate a PMSI range consistent with the disappearance of the victim. It is important for forensic investigators to understand that although some precision is lost in estimating a PMSI with aquatic insects, these organisms should not be ignored in gathering evidence from aquatic crime scenes, that in fact, they can provide valuable details in estimating a PMSI.

Aquatic Insects, Caddisflies, Postmortem Submersion Interval

G67 A Standardized Field Protocol for Experimentally Investigating Variability in Entomology-Based Postmortem Intervals Over Multiple Sites and Years: A Proposal

Kenneth G. Schoenly, PhD*, California State University, Stanislaus, Department of Biological Sciences, 801 West Monte Vista Avenue, Turlock, CA 95382; Jeffery K. Tomberlin, PhD, Texas A&M University, Texas Cooperative Extension, 1229 North U.S. Highway 281, Stephenville, TX 76401; John R. Wallace, PhD, Millersville University, Department of Biology, Millersville, PA 17551; M. Lee Goff, PhD, Chaminade University, 3140 Waialae Avenue, Honolulu, HI 96816; Jeffrey D. Wells, PhD, West Virginia University, Biological Sciences, Morgantown, WV 26506; and Richard W. Merritt, PhD, Michigan State University, Department of Entomology, 243 Natural Science Building, East Lansing, MI 48824

After attending this presentation, attendees will gain understanding of the key factors that influence variability of entomology-based PMI estimates and the need for forensic entomologists to devise standardized field experiments at multiple sites over several years. Such a protocol will disentangle the combined and interactive effects of these key factors on carcass decay rates and carrion-arthropod colonization, development and succession.

This presentation will impact the forensic community and/or humanity by through the introduction of this collaborative framework and call for a standardized field protocol, the authors will provide the forensic science community several scientific examples, gleaned from the entomological literature, of the need to better understand spatio-temporal variability of entomology-based PMI estimates through the establishment of a small network of field sites.

A multi-site field protocol, modeled after the U.S. Long-Term Ecological Research Network, is proposed for investigating the major

biotic and abiotic factors that influence entomology-based postmortem intervals (PMI), i.e., the time period between insect colonization and body discovery. The study proposes that this goal can only be achieved by a multi-investigator group studying forensically-important (FI) arthropods year-round over several years. Investigators and sites will be chosen from a subset of active and willing researchers (with established track records) whose institutions bracket more latitudes than longitudes in order to reflect the widest range of climates and vegetation types.

The central features of this protocol, which the authors have embraced in their own research and training programs, include the use of pig carcasses as surrogate corpses, fixed sampling stations as mock crime scenes, comparative tests of different field methods, and the integration of photographic, climatic, and arthropod records. The domestic pig (*Sus scrofa* Linnaeus) (of roughly 23-27 kg starting weight) closely resembles a human in its fat distribution, chest cavity, lack of heavy fur, and omnivorous diet. Advantages to using pigs include ease of procurement, reasonable cost, and a low propensity to incite public objection. The pig-as-surrogate claim was recently validated in field trials conducted inside the Forensic Anthropology Center (formerly ARF) at the University of Tennessee, Knoxville, TN, using simultaneously placed human and porcine subjects studied over a 35-day summer period. In that study, exceptionally high overlap in arthropod abundances (>99%) was reported from three subjects (one human, two pigs), indicating that only a few very rare FI taxa were associated with one subject or the other.

Within each site, the initial study design will feature replicated pig carcasses representing the “background” condition (i.e., surface-exposed, unclothed, and vertebrate unscavenged) against which other replicated treatments could be compared in the future (e.g., buried, burned, submerged, clothed, and/or vertebrate scavenged remains). Recent research has shown that when different sampling methods are used to inventory the carrion-arthropod fauna (i.e., aerial nets, hand collections, pitfall traps, sticky traps), results are often species-selective leading to catches of variable species composition which have the potential for affecting PMI estimates. Many other studies have established that carrion-arthropod succession and carcass decay rates are affected by season, temperature, elevation, exposure mode (e.g., buried, burned, submersed, wrapped), presence/absence of predators, and other factors.

Through this protocol, it is hoped to achieve a better understanding of variability and uncertainty in PMI estimates by holding constant both investigator error and exposure conditions. To further this goal this study will work to disentangle the combined and interactive effects of climate, season, and geography on carcass decay rates and arthropod colonization, development, succession, and species composition. To further reduce inter-investigator error, the study will require that each researcher channel his/her voucher specimens to the same taxonomic specialists to insure uniformity and accuracy of identifications across sites. Statistical analysis will focus on testing whether the order and timing of different species of colonizing insects used in both development and succession-based PMI estimates are comparable (i.e., repeatable) across different sites, seasons, and years. Given the critical need to separate pattern from “noise” in forensic entomology and to accurately and precisely estimate time-of-death, which the Law requires to be ascertained, the need for a standardized field protocol that can function at multiple sites for several years becomes clear.

Through the introduction of this collaborative framework and call for a standardized field protocol, the authors will provide the forensic science community several scientific examples, gleaned from the entomological literature, for the need to better understand spatio-temporal variability of entomology-based PMI estimates through the establishment of a small network of field sites.

Forensic Entomology, Postmortem Interval, Field Protocols

G68 Characteristics of Fatal All Terrain Vehicle (ATV) Accidents

Michele Eichenmiller, MS, James A. Kaplan, MD*, David J. Clay, BA, Myron A. Gebhardt, MS, Brandon Lewis, BS, Nabila A. Haikal, MD, James C. Kraner, PhD, Office of the Chief Medical Examiner, 619 Virginia Street West, Charleston, WV 25302

After attending this presentation, attendees will learn of particular concerns to be considered when investigating fatal ATV accidents.

This presentation will impact the forensic community and/or humanity by focusing attention on the circumstances of fatal All Terrain Vehicle (ATV) accidents, particularly the role of alcohol impairment.

The goal of this presentation is to highlight some of the forensically relevant circumstances surrounding deaths that result from ATV accidents. Emphasizing the factors that are common to these cases will enhance the attendee's attention to pertinent issues to be considered when investigating ATV related deaths.

An all-terrain vehicle or "ATV" is defined as any vehicle fifty-two inches or less in width, having an unladen weight of 800 pounds or less, traveling on three or more low pressure tires with a seat designed to be straddled by the rider, intended for, or capable of travel over unimproved terrain. Using national data from 2002-2004, West Virginia leads the nation with an annual average of 1.7 fatalities per 100,000 people; followed by Kentucky at 0.85. The national average for the same period is 0.17 deaths per 100,000 citizens.

The West Virginia Office of the Chief Medical Examiner investigated the fatalities reviewed in this report. Biological samples were obtained from each of the cases during either internal autopsy or external examination of the body. Over a three-year period (2003-2005), a total of 99 fatal ATV-related accidents occurred in West Virginia. Of the fatalities reviewed, 85 were male and 14 were female. The decedents ranged from 7-80 years of age, with 36 being the average age. Overall, October was the month with the highest incidence (14 cases), followed by May and July with 13 fatalities occurring during each. Toxicological testing included blood alcohol analysis by direct injection GC-FID using *t*-butanol as an internal standard. Samples were also tested for drugs of abuse. However, only alcohol findings are included in this presentation. Other significant observations include the following:

- Fifty-eight percent of the accidents occurred on unpaved roads, with 28% on paved roads. The road surface was not specified in the records available for review in the remaining cases.
- Eighty-four of the fatalities were drivers, while ten were passengers. The position of the decedent was not ascertained in five of the deaths.
- There were ten multi-vehicle and 75 single-vehicle accidents. In fourteen collisions, the number of vehicles involved was not specified.
- Only thirteen individuals were wearing a helmet whereas 51 were not; and of the latter, seven were under the age of 18.
- Excessive speed was documented in the investigative reports of 14 fatalities and was not named as a factor or unknown in the remaining 85 cases.
- Forty-nine percent of the fatalities had blood alcohol concentrations exceeding 0.08%.
- The average blood alcohol concentration was $0.19\% \pm 0.09\%$.

Through the first seven months of 2006, 39 ATV-related deaths had already occurred in West Virginia, underscoring the need for addressing the problem of ATV safety by state government.

In conclusion, high blood alcohol concentration is a frequent factor in fatal ATV accidents. It is also important to note that the generally steep terrain of West Virginia is an additional concern when operating vehicles with a high center of gravity, such as an ATV. Other ATV-specific accident factors obtained from police and injury-prevention sources will also be presented.

ATV, Fatality, Accident

G69 Using Ninhydrin to Detect Grave Soil

David O. Carter, PhD*, Department of Entomology, University of Nebraska-Lincoln, 202 Plant Industry Building, Lincoln, NE 68583-0816; David Yellowlees, PhD, School of Pharmacy and Molecular Sciences, James Cook University, Townsville, QLD 4811, Australia; and Mark Tibbett, PhD, Centre for Land Rehabilitation, School of Earth and Geographical Sciences, University of Western Australia, Crawley, WA 6009, Australia

After attending this presentation, attendees will understand fundamental effects of cadaver decomposition on associated soil (grave soil) and the methodology required to analyze grave soils for the presence of ninhydrin-reactive nitrogen.

This presentation will impact the forensic community and/or humanity by providing a method to rapidly locate clandestine graves and cadaver decomposition sites.

After this presentation, attendees will understand fundamental effects of cadaver decomposition on associated soil (grave soil) and the methodology required to analyze grave soils for the presence of ninhydrin-reactive nitrogen. This presentation will impact the forensic community by providing a method to rapidly locate clandestine graves and cadaver decomposition sites.

Some death investigations commence without knowledge of the location of a body and/or decomposition site. In these cases it is necessary to locate the remains or the site where the body decomposed prior to relocation. Ideally, the location of these sites would be rapid and require little destruction of the scene, such as that achieved with cadaver dogs. However, few options remain if cadaver dogs are unavailable or prove unsuccessful.

Ninhydrin is a compound that is readily available to most investigative agencies, as it can be used to locate latent fingerprints. This use relies on the color change that occurs when ninhydrin reacts with protein-, peptide-, amino-, and ammonium-nitrogen (collectively known as ninhydrin-reactive nitrogen: NRN) left on a surface contacted by skin. Similarly, the decomposition of an organic resource results in the release of NRN into the soil. Considering that a cadaver can comprise as much as 3% nitrogen, there is great potential for NRN to be detected in grave soils. As a consequence, this study hypothesizes that the decomposition of a body would result in a significant increase in NRN in soil.

A field experiment was conducted at two disparate field sites during the dry season (March 2003). Site 1 was comprised of a loamy sand soil (84% sand, 11.1% silt, 4.9% clay) and was located in Yabulu, Queensland, Australia. Site 1 receives an average rainfall of 140 mm during the dry season (March-October) and average maximum/minimum temperature equals 22.9 °C/16.7 °C. Site 2 was comprised of a sandy soil (97.7% sand, 1.3% silt, 1% clay) and was located in Pallarenda, Queensland, Australia. On average, site 2 receives 120 mm of rainfall during the dry season and the average maximum/minimum temperature is 26.9 °C/16.4 °C. Grasses with scattered trees dominated the resulting vegetation at the two sites, as is typical of a tropical savanna ecosystem. Juvenile rat (*Rattus rattus*: ~18 g) cadavers were buried (2.5 cm) in the centre of a 2 m² plot. Grave soil was collected at 7, 14, 21, and 28 days following burial.

To measure NRN, 2 g soil (dry weight) was amended with 8 ml KCl (2 M) and shaken (150 rpm) for 30 minutes. Following shaking, the solution was filtered through a filter paper (#42) into a culture tube. To 1 ml of filtrate, 0.5 ml ninhydrin reagent [0.8 g ninhydrin, 0.12 g hydridantin, 30 ml dimethyl sulfoxide, 10 ml lithium acetate] was added, mixed, and incubated at 100 °C for 25 minutes. The reaction was stopped with 10 ml 50% ethanol-water (v/v) and absorbance was read at 570 nm. The concentration of NRN was calculated against a leucine standard. To make leucine standard, 0.469 g leucine was dissolved into 1 l distilled water. This contained 50 mcg nitrogen ml⁻¹. Separate 100 ml volumetric flasks were amended with 0, 5, 10, 15, 20 and 30 ml leucine solution, 50 ml of 4 M KCl, and water to make up to 100 ml. These standards contained 0, 250, 500, 750, 1000 and 1500 mcg nitrogen.

Cadaver burial resulted in a 4-6 fold increase in the concentration of NRN in grave soil. This increase was observed within seven days of burial and remained constant until the end of the experiment (day 28), by which time the cadaver had been skeletonized for a minimum of 14 days. This rapid and stable increase in NRN has great potential to become a standard investigative tool, considering that the analysis of NRN in grave soil can be conducted in less than one hour.

Forensic Taphonomy, Decomposition, Nitrogen

G70 Insects and Time Since Death: What Do We Really Estimate?

M. Lee Goff, PhD, Division of Natural Sciences and Mathematics,
Chaminade University of Honolulu, 3140 Waialae Avenue, Honolulu, HI
96816-1578*

After attending this presentation, attendees will gain an understanding of some of the limitations and constraints of time of death estimates based on entomological evidence

This presentation will impact the forensic community and/or humanity by making attendees aware of the problems and constraints associated with time since death estimates based on entomological evidence, the participants will be better able to evaluate the significance of these estimates to their investigations.

Forensic entomology is a powerful tool for use in the estimation of the minimum period of time since death in many cases. There are, however, certain constraints in its application that must be kept in mind. First, what is provided is primarily an estimate of the period of insect activity on the body, rather than an estimate of the actual period of time since death. While these periods are frequently quite similar and the estimate provided is close to the actual time since death, they are not identical. There also exist a number of confounding factors beyond the control of the entomologist and/or crime scene personnel that will further serve to reduce the similarity between the estimate and the actual postmortem interval. These include: concealment of the body, incomplete collection of relevant materials by scene personnel, presence of chemicals on or around remains, seasonal and geographic variations in insect distribution, microclimatic factors, and lack of common sense. Additional problems lie in approaches to interpretations of data, often resulting in estimates produced that can not be supported by the current state of the sciences involved.

Postmortem Interval, Insects, Entomology

G71 Dying of the Cold in a Warm Climate - Hypothermia Deaths in Sydney, Australia

Johan A. Dufou, MMed, and Cathy Lim, MBBS, Department of
Forensic Medicine, 42-50 Parramatta Road, Glebe, NSW 2037,
Australia*

The goal of this presentation is to describe the features of hypothermia related deaths in Sydney, Australia, a geographic location generally viewed as having a temperate to hot climate.

This presentation will impact the forensic community and/or humanity by highlighting the dangers of hypothermia in the elderly, even in temperate climates. Attendees will be informed of the social circumstances, the death scene and pathological findings at autopsy in this series of cases.

Death due to hypothermia is well known as a significant public health problem in cold climates, affecting predominantly homeless people, drug dependent persons, and the elderly. Hypothermia is generally considered very rare in more temperate climates and there is a general lack of awareness of the problem by both the medical fraternity and the general public. This study examines the problem of fatal hypothermia in Sydney Australia, a city with a reputation of having a year round temperate to hot climate.

There were 24 cases of fatal hypothermia in a five-year period between January 2001 and December 2005. For the purposes of this study, the diagnosis of hypothermia was made by either a temperature measurement at hospital (17%), suggestive autopsy findings (33%), a suggestive history (4%), or a combination of autopsy findings and a suggestive history (46%). The majority of the deaths occurred in winter (46%) as expected, whilst equal numbers occurred in the seasons on either side of winter - spring (25%) and fall (25%). Despite generally hot summer temperatures, one death occurred during summer. This person had become lost in bushland and was found in a state of extreme dehydration.

The mean age was 76 years (range 56 – 92), with a female predominance (63%). Risk factors for hypothermia were identified in 58%, and these included alcoholism mental illness (schizophrenia, bipolar disorder) and developmental delay. All but two decedents lived alone. Nine decedents were underweight (body mass index < 20 kg/m²).

Nineteen cases (79%) were found in a building, a house, apartment, or other premises. Of those, 46% were dead at the scene, while the remainder died either on the way to or in hospital. In the remaining five cases, the decedent was found outside. Three in this group were dead at the scene, while two died subsequently in hospital. This indicates that despite rewarming and supportive care, hypothermia past a certain point is irreversible and fatal.

Four decedents were found naked, four were dressed in minimal amounts of clothing and the decedent was adequately dressed in a further three cases. There was evidence of paradoxical undressing in seven cases. In the remaining six cases, the presence or absence of clothing was not given.

Pathological findings in fatal cases of hypothermia are generally considered non-specific. Gastric erosions were found in 79%. There was one case with acute pancreatitis, and a single case with rhabdomyolysis. The characteristic cutaneous lesions in hypothermia, reddening and abrasion over the large joints of the limbs were present in 16 (75%) cases. In four cases (17%), there were no autopsy findings to suggest hypothermia, although either hospital or environmental features strongly supported the diagnosis. Other significant autopsy findings included atherosclerotic cardiovascular disease (50%), pneumonia (17%), pulmonary congestion and edema (17%), chronic airways limitation (13%) and single cases of glioblastoma multiforme and metastatic bowel cancer. With the exception of two cases where only a raised blood alcohol was detected, all cases had significant pre-existing natural disease processes. Toxicology was performed in 18 cases – alcohol was detected in four cases, and other psychotropic agents were present in four deaths. No illicit drugs were detected.

This study highlights a significant public health problem that is not limited to cold climates. There is little awareness of the hazards of hypothermia in the elderly in Australia and probably other temperate parts of the world. Life-threatening hypothermia does not occur at any one particular temperature, as other factors such as wind movement, clothing, dampness of the environment, and vulnerability of the individual all play a role. Forensic pathologists and other death investigators who have the good fortune of living in warm climates need to remain vigilant of this condition, and not misattribute the death to natural disease processes such as atherosclerotic cardiovascular disease or pneumonia.

Autopsy Pathology, Hypothermia, Environmental Medicine

G72 The Postmortem Picnic

Kathryn Haden-Pinneri, MD*, Mary Lynn Anzalone, MD, and Luis A. Sanchez, MD, Office of the Medical Examiner of Harris County, Joseph A. Jachimczyk Forensic Center, 1885 Old Spanish Trail, Houston, TX 77054

After attending this presentation, attendees will understand a potentially confusing postmortem artifact caused by the Red Imported Fire Ant (RIFA) and stress the importance of good photographic scene documentation.

This presentation will impact the forensic community and/or humanity by educating forensic scientists about alterations in wounds caused by *Solenopsis invicta*, the Red Imported Fire Ant, which may affect wound interpretation.

Postmortem alteration of wounds by insects is a fairly common phenomenon, especially in decomposed bodies where maggots are frequently encountered. The destruction they produce can be significant, even to the point of complete obliteration of the wound and the underlying wound track. Without damage to the skeletal elements, the trauma may not be discernible. Alterations of wounds in the "fresh" state are not as common; however it is being seen with increasing frequency in the Southern United States, where fire ants have invaded.

Solenopsis invicta (S. wagneri), the Red Imported Fire Ant (RIFA), has infested large parts of the United States, concentrating mainly in the warmer Southern region. States from California to Maryland have documented their presence and the destruction they cause. Lacking predators and parasites, these ants have become a major pest, destroying plants, crops, trees, and even small animals. They are also attracted to electrical currents and subsequently damage electrical boxes, air conditioners and other equipment.

First introduced into the U.S. from its native South America, the RIFA arrived in cargo from Brazil at the port of Mobile, AL in the 1930s. This species has spread rapidly throughout the Southeastern United States and has recently been identified in Australia, the Philippines, Taiwan, and China.

Fire ants are omnivores, feeding on almost any plant or animal. Other insects are their preferred food. Humans become affected by the RIFA when it bites and stings. In response to vibration or movement, RIFAs react quickly and aggressively to disturbances of their colony or mound. A single ant will sting repeatedly, even when out of venom. The RIFA bites with its mandibles to attach itself to the skin, and then it stings with its abdomen, injecting toxic venom. A pustule forms in 24-48 hours, which may get secondarily infected. Some individuals are allergic to the venom, and anaphylaxis may ensue.

For forensic pathologists, RIFAs are creating problems by their rapid appearance on bodies found outdoors. Within minutes, 10-20 ants will arrive at the body, and many more will come after that. Rather than biting and stinging in an aggressive manner, the RIFA just bites, gaining sustenance from the body instead of injecting venom. In contrast to maggots, which prefer open wounds, moist mucous membranes and dark environments, RIFAs will readily eat intact exposed skin. They tend to concentrate at clothing/skin interfaces and prefer the outer surface of the body, rarely entering the body cavities or altering the wound tracks.

Increasingly, RIFAs are being encountered in open wounds, and the changes they leave behind can be troublesome. In general, postmortem artifacts caused by insects are easily distinguished from antemortem trauma. When a wound is involved, however, the changes are not as straightforward. The yellowing, seen with postmortem insect activity is usually lacking or is camouflaged by the actual wound characteristics.

Firearm wounds, in particular, can have a very puzzling appearance when altered by RIFAs. If only a few bites occur around the wound, it may be mistaken for stippling, thereby altering the interpretation of range of fire. On the other hand, if a large number of RIFAs are present and they have been there long enough, determination of entrance versus exit may be completely obscured.

Scene photographs are key in order to verify or deny the presence of RIFA activity. A small number of RIFAs will usually get transported with the body and/or in the body bag. Without scene photographs to review, you may not realize the extent of their involvement in wound alteration. In one case, the edges of a gunshot wound were very irregular, simulating an atypical entrance or possible intermediary target. Scattered areas of postmortem insect activity elsewhere on the body indicated the presence of RIFAs; however, it wasn't until the scene photos were reviewed that it was apparent to what extent they had altered the gunshot wound. In one photo, RIFAs are seen completely filling the wound, something typically associated with maggots, not ants. This large concentration of RIFAs imparted an atypical appearance to the gunshot wound.

In addition to the many other variables that cause alterations of wounds in the postmortem setting, changes induced by RIFAs must be considered, particularly in bodies found outdoors. RIFAs pose an additional hazard at the time of autopsy. Care must be taken when manipulating bodies or clothing containing RIFAs because the ants will act aggressively, biting and stinging those that have disturbed them, possibly inciting an allergic reaction in susceptible individuals. As RIFAs continue to invade the United States, more and more forensic investigators will be left to interpret the trauma they leave behind.

Solenopsis Invicta, Fire Ant, Postmortem Artifact

G73 Applying Statistical Principles to the Entomological Estimation of Postmortem Interval

Bart J. Harvey, MD, PhD, MEd*, University of Toronto, 407-263 McCaul Street, Toronto, Ontario M5T 1W7, Canada; Sherah L. VanLaerhoven, PhD, University of Windsor, Room 23, Biology Building, 401 Sunset Avenue, Windsor, Ontario N9B 3P4, Canada; and Paul N. Corey, PhD, University of Toronto, Department of Public Health Sciences, 6th Floor, 155 College Street, Toronto, Ontario M5T 3M7, Canada

After attending this presentation, attendees will understand how four statistical principles apply to the estimation of ambient temperature necessary to enable the entomological estimation of postmortem interval. Specifically, attendees will understand how estimate precision, random variation, sufficient sample size and sampling breadth, and the choice of estimation model (e.g., linear, non-linear) should be considered and taken into account when postmortem interval ambient temperatures are estimated.

This presentation will impact the forensic community and/or humanity by highlighting how the consideration of four statistical principles can inform the estimation, accuracy, and precision of the postmortem interval, as made through entomological techniques.

After attending this presentation, attendees will understand how four statistical principles apply to the estimation of ambient temperature, which is required for estimation of postmortem interval using entomological evidence. Specifically, attendees will understand how estimate precision, random variation, sufficient sample size and sampling breadth, and the choice of estimation model (e.g., linear, non-linear) should be considered when postmortem interval ambient temperatures are estimated.

This presentation will impact the forensic sciences community by highlighting how the consideration of four statistical principles can inform the estimation, accuracy, and precision of the postmortem interval, as made through entomological techniques.

By examining the type and developmental stage of insects found on remains, entomological techniques can provide an estimation of the time since death or the postmortem interval. Insect development is highly dependent on ambient temperature, therefore, estimate using insect evidence require determination of the temperatures that the remains were exposed to following death. While these exposure temperatures can be

readily determined in many cases, in others, when no temperature recordings are available, they must be indirectly estimated, often by examining the relationship between the temperatures at the site where the remains were found and those recorded at a nearby weather station. This relationship can be determined by taking temperature recordings at the site where the remains were found for an extended period of time following their recovery and comparing these with the temperatures recorded over the same period of time at the nearby weather station. Using the statistical techniques of regression, the relationship between these two measures can then be defined by a suitable mathematical equation that, for a given weather station temperature, can provide an estimate of the corresponding temperature at the site where the remains were found.

However, because these temperature estimations are obtained by the mathematical regression modeling of the relationship between two sets of measured values, the application of four statistical principles can enhance the accuracy and precision of the estimated temperatures. First, because both sets of temperature measures are affected by random variation, the resulting regression model will be inherently imprecise—that is, single unique temperature values cannot be precisely predicted but, more realistically, a range of compatible temperature values can be determined. This range of compatible values is identified through the calculation of the “confidence interval for an observation” [1: 275-278] for each temperature estimated.

Second, because the precision of any given model will improve (i.e., the range of compatible values will narrow) according to the number of pairs of measurements available for model development, a sufficient number of temperature pairs should be included in the data collection used to develop the model. Third, it is also important to ensure that a sufficient number of comparative temperature pairs are collected over the full range of expected values (i.e., the range of temperatures that the remains were estimated to be exposed to prior to being found). If this is not done then ‘outlier’ temperatures will need to be estimated by extrapolating the model beyond the range of values that were used for its development. Because such extrapolated estimates assume that the relationship between the two sets of temperatures is the same beyond the measured values as it is within the measured range, erroneous temperature estimates will result when this assumption is not met. Of course, ensuring that the assumption applies in a given circumstance requires that actual temperature measures be collected across a sufficiently broad range of values.

Fourth, while a straight line (i.e., linear) relationship is often expected to best model the relationship between two measures, this is not always the case. As such, to enhance the accuracy of the temperature estimates, the type of relationship between the two sets of temperature measures should be appropriately studied so that the applicable mathematical model (i.e., linear or one of the many non-linear possibilities) for each set of temperature data can be accurately determined. In fact, it is possible that different models may be required for different parts of the same set of data (e.g., day versus night). For example, because of the characteristics of a setting where remains were found, temperatures at that site might be found to be generally higher during the day, but lower at night (in comparison to the corresponding weather station temperatures), thus necessitating the development of two distinct models to be used to estimate the applicable temperatures, according to the time of day.

During the presentation, examples illustrating each of these statistical principles, and their applicability and impact upon the entomological estimation of postmortem interval will be demonstrated and discussed.

Postmortem Interval, Statistics, Entomology

G74 The Validation of Gene Expression as a Means of Predicting the Age of the Blow Fly *Lucilia sericata*

Aaron M. Tarone, BS*, Department of Zoology, Michigan State University, 203 Natural Sciences, East Lansing, MI 48824; and David R. Foran, PhD, Forensic Science Program, Michigan State University, 560 Baker Hall, East Lansing, MI 48824

After attending this presentation, attendees will understand the use of gene expression in determining the age of forensically useful blow flies.

This presentation will impact the forensic community and/or humanity by helping the forensic community understand how to use gene expression and statistical analyses to better address the requirements of *Daubert* as it pertains to forensic entomology.

Forensic entomology is an established field, with a relatively good track record of predicting a postmortem interval (PMI) through an understanding of blow fly development. However, in the context of *Daubert*, all of the forensic sciences will be expected to provide techniques that have been adequately tested, have laboratory standard operating procedures (SOPs), have undergone publication in the peer-reviewed literature, are accepted by the relevant scientific community, and have known potential error rates. Though forensic entomology can meet most of these criteria, the field will likely be required to establish SOPs and provide information as to error rates and the precision of its methods.

In addition to not yet fully meeting *Daubert* requirements, blow fly based PMI estimates suffer from increasing error as the animal develops (Wells and Lamotte 1995). This stems from the fact that the durations of subsequent developmental stages increase, and the body size traits used by entomologists (larval length or weight) that help refine age estimates in the feeding stages become far less useful in the later stages of immature development. Thus, other characteristics that predictably change during these stages are potential sources of information that could be valuable to investigators attempting to age flies. Gene expression profiles are known to vary significantly throughout the development of all animals, and have been studied extensively in the dipteran *Drosophila melanogaster* (e.g., Arbeitman et al. 2002). To understand how gene expression might be utilized for more accurately aging a forensically useful blow fly, a gene expression profile data set for nine developmentally variable genes was created for the immature life cycle of ~700 individual *Lucilia sericata*. Three regional strains of flies were grown under controlled laboratory conditions and regularly sampled for both size and gene expression levels, creating a high-resolution developmental profile of these cohorts.

Following this, genetic profiles were used in conjunction with developmental stage and body size data to estimate the age of individual blow flies. However, body size and gene expression levels are not easily explained by a simple mathematical function (they are non-parametric) and statistical endeavors that can help investigators (and triers of fact) understand such multivariate and non-linear data must be employed to make predictions of age. To this end, statistical models of developmental age in terms of genetic and phenotypic profiles have been produced. The two most promising forms are principle component analysis and generalized additive models. The former has been used in other forensic sciences to make predictions of class evidence and may be useful with entomological data. With generalized additive models, it is possible to define the percent of development explained by the data, and to deduce the usefulness of different models (and variables within models) through a comparison of generalized cross validation (GCV) scores (Wood 2006). Currently, predictions of age incorporating standard data and gene expression can describe up to 97% of the variation in development, which is an increase of ~10% compared to using developmental stage and body size alone.

However, no mathematical model is useful based solely on its theoretical ability to predict age, thus the models need to be validated on different data sets. To accomplish this, a blind study was conducted with

flies grown under both experimental (in the laboratory using the same conditions as the original experiment) and natural (out of doors) environments. Gene expression and body size profiles of the juvenile flies collected were used to predict the age of the individuals employing the models generated from the aforementioned data set. The validation of the age models and their importance in helping the field of forensic entomology increase precision and meet the requirements of *Daubert* will be discussed.

Forensic Entomology, Postmortem Interval, Generalized Additive Model

G75 Have I Eaten Here Before? Considering Multigenerational Colonization of Remains by Blow Flies

Timothy E. Huntington, MS*, and Leon G. Higley, PhD, University of Nebraska, Department of Entomology, 202 Plant Industry Building, Lincoln, NE 68583

After attending this presentation, attendees will understand that there is little potential for multiple generations of blow flies arising from the same corpse.

This presentation will impact the forensic community and/or humanity by demonstrating a substrate limitation to blow fly colonization of decomposing remains.

Forensic (or medicocriminal) entomology, the use of arthropods in legal investigations, is most frequently employed to estimate the postmortem interval (PMI) of victims of violent crimes or suspicious deaths. The most commonly used method of PMI estimation employs temperature-dependent developmental rates of blow fly larvae (Diptera: Calliphoridae). Retrospective scene temperatures, those temperatures that the insects experienced during development, are used in combination with known developmental rates of the species involved to estimate the age of the insects, which often correspond closely with the time of death of the victim.

One key element entomological analysis is the use of the oldest insects associated with the body, as these represent the closest estimate of the minimum time since death. This facet of forensic entomology consequently leads to questions by investigators and attorneys regarding the potential for multiple generations of blow flies arising from the same corpse. While blow flies continue to be attracted to the carrion well into the later stages of decomposition, the carcass is no longer attractive as an oviposition medium after some point, and it is widely held that the maggots which fed on a set of remains will not normally eclose as adults and oviposit on the same body. Flies in abnormal conditions, however, have been known to alter their behavior as a response to their circumstances. The goal of this study was to investigate whether adult blow flies eclosing into a situation where there is no carrion source other than their larval host would oviposit on this carcass or die without reproducing.

Six freshly killed pig (*Sus scrofa* L.) cadavers (~53 kg) were placed on the soil surface and left undisturbed for approximately 45 hours (75 ADD-B0) to allow for extensive insect colonization. After this time, Lumite® (18 x 14 mesh) exclusion cages (6 ft³) were erected over each pig. After placement of the cage, adult blow flies were physically killed or removed from the cage. Subsequent maggot development into adult blow flies occurred within each cage, resulting in high populations of adult flies that represented the first generation of fly development on the cadaver. Following the emergence of adult flies within each cage, a 'choice'/'no choice' study was conducted by placing a freshly killed pig (~47 kg) in three of the cages and observing for colonization of each carcass.

In this study, each of the fresh pig cadavers in the 'choice' portion of the experiment were colonized readily by blow flies, but none of the

decomposed remains (in either the 'choice' or 'no choice' scenarios) were colonized. This result is not unexpected, but confirms the conventionally held understanding of a single generation of blow flies emerging from a single corpse, even under extenuating circumstances. The fact that blow flies under these conditions die without reproducing indicates the unsuitable nature of a body that has undergone advanced decomposition as larval substrate.

Forensic Entomology, Decomposition, Taphonomy

G76 The Investigation of Animal Tissue as an Analogue for Human Tissue in Decomposition Studies in Soil

Kathryn L. Stokes, BSc*, Centre for Forensic Science, University of Western Australia, 35 Stirling Highway, Nedlands, Perth, Western Australia 6009, Australia; Shari Forbes, PhD, University of Ontario Institute of Technology, Faculty of Science, University of Ontario Institute of Technology, 2000 Simcoe Street North, Oshawa, ON L1H 7K4, Canada; and Mark Tibbett, PhD, Centre for Land Rehabilitation, School of Earth and Geographical Sciences, Faculty of Natural and Agricultural Sciences, University of Western Australia, 35 Stirling Highway, Nedlands, Perth, Western Australia 6009, Australia

After attending this presentation, attendees will understand the chemical process of decomposition, the compounds released during the decomposition of muscle tissue of different species, and their interaction with the soil environment. The aim of this presentation is to compare the use of animal tissue as an accepted model for human tissue in decomposition trials.

This presentation will impact the forensic community and/or humanity by showing direct comparisons between the decomposition chemistry of human and various animal tissues in a soil environment. The identification of both similarities and differences between the different tissue types will help identify the best animal analogue for future decomposition studies.

Pig (*Sus scrofa*) carcasses are currently accepted as the closest model to human decomposition due to their physiological similarities to humans. For this reason they are commonly used in a range of decomposition studies involving microbial activity and entomology. However from a chemical perspective there are limitations with this model due to variations in the decomposition compounds produced by humans and animals. Furthermore, the behavior of these compounds in soil is unknown with respect to the subsequent nutrient dynamics. The current study was therefore conducted to investigate the chemical decomposition of skeletal muscle tissue in soil and to compare similarities and/or differences between human and animal tissue. The results will assist in determining the most useful animal model in chemical decomposition studies. The research may benefit forensic investigations involving decomposed remains whereby the species determination is in question.

A laboratory incubation method was used to monitor chemical changes during decomposition. The soil in each microcosm was a sand texture adjusted to 50% water holding capacity to provide optimal conditions for microbial activity. Cuboid pieces of skeletal muscle tissue from four different species, namely porcine, bovine, ovine and human, were interred at 1 cm depth in the soil and incubated at 25°C for 37 days. Carbon dioxide evolution was used as an index of soil microbial activity. Aerobic conditions were maintained by opening the microcosms daily to replace oxygen depleted air from the container. The microcosms were destructively harvested at periods of 2, 4, 6, 8, 12, 16, 23, 30 and 37 days. Any remaining skeletal muscle tissue was removed, weighed, and dried to ascertain mass loss. The soil immediately surrounding the site of muscle tissue decomposition (detritosphere) was collected and analysed. The mineralization of nutrients was monitored by analyzing inorganic molecules within the soil using colorimetric methods for ammonium,

nitrate and phosphate, and atomic absorption spectroscopy for potassium levels. The release of long chain fatty acids into the soil was also monitored using GC-MS.

Results have demonstrated that for all skeletal muscle tissues there is an observed increase in pH before a decrease back to the starting pH measured prior to muscle tissue interment. Electrical conductivity also increases for all different types of skeletal muscle tissue. Further results from organic and inorganic chemical analyses will be discussed in the presentation.

Animal models are commonly used for decomposition studies due to restrictions on the use of human cadavers. The results from this study will impact the forensic community by showing direct comparisons between the decomposition chemistry of human and various animal tissues in a soil environment. The identification of both similarities and differences between the different tissue types will help identify the best animal analogue for future decomposition studies.

Animal Tissue, Human Models, Decomposition

G77 ‘Ndrangheta’ Homicide (Executions)!

Cristoforo Pomara, MD, Department of Forensic Pathology, University of Foggia, Ospedali Riuniti, via L. Pinto 1, Foggia, 71100, Italy; Floriana Monciotti, MD, Department of Forensic Pathology, University of Siena, Policlinico Le Scotte, Siena, 53100, Italy; and Marianna Di Padua, MD, and Carmela Fiore, MD, Department of Forensic Pathology, University of Foggia, Ospedali Riuniti, via L.Pinto 1, Foggia, 71100, Italy

After attending this presentation, attendees will learn about ‘Ndrangheta,’ one of the famous “four mafias” a criminal organization from the southern part of Italy. A unique case of ‘ndrangheta’-related homicide/double execution is presented. A detailed scene investigation and a complete postmortem examination were performed; the surface aspects of gunshot wounds were also analyzed by means of confocal laser scanning microscopy.

This presentation will impact the forensic community and/or humanity by demonstrating the rarity of the modalities of this execution makes it peculiar and a complete pathologic investigation (death scene investigation, autopsy performing, and toxicological screening) is strongly recommended to completely investigate this type of homicide.

This unique case of double simultaneous “‘ndrangheta’-related homicide, or execution was discovered in the Tuscan countryside. In the morning of April 10, a farmer noted the presence of bloodstains near the road on his property. The bloodstain course ended in a wooded area where a gun case was detected. He immediately alerted the authorities. An unusual arrangement of the leaves next to the road caught the attention of those searching the area. A few centimeters under these leaves and soil, hands and feet surfaced; at the end of excavations, 160 cm underground, two lifeless bodies were present. They were found kneeling, beside each other. The two bodies were covered with burnt lime, which was cautiously removed. They were dressed only underpants and wore a pair of gloves. Clothes belonging to the deceased were found next to the bodies. Core temperature of the remains, measured by means of bulb thermometer, was 14°C. The external temperature was 17°C. Rigor mortis was partially present and livor mortis was represented by fixed reddish-purple coloration localized on anterior part of the bodies. At external examination the caustic effect of burnt lime on the face and the trunk was observed. A round wound on the left occipital region was detected on each body. A second round wound on the right dorsal region was observed in one of the deceased. Forty-eight hours after discovery, a complete autopsy was performed. A total body CT study confirmed in one case the presence of a metallic foreign body in the first cervical segment while in the second case foreign metallic bodies were observed in the right orbital region and at the mandibular angle. Postmortem examination of the spinal cord was performed according to the Adam’s technique and the deformed bullets

were recovered. A complete histological study was performed. Cutaneous gunshot wounds were also studied by means of confocal laser scanning microscopy. Few days after the examination, a positive identification was made by fingerprint comparison. The victims were two brothers belonging to the criminal association ‘ndrangheta’ under probation in Tuscan countryside. It is well known all over the world of the existence of the “four Italian mafias” that are referred to the “Cosa Nostra” in Sicily, the “Camorra” in Campania, the “Sacra Corona Unita” in Puglia and the ‘Ndrangheta’ in Calabria. The last one is estimated to be Italy’s most powerful organized crime association, surpassing the Sicilian Mafia. Their moneymaking schemes include racketeering, extortion, loan sharking, illegal immigration, money laundering, cigarette smuggling, and arms and narcotic trafficking. In homicides committed by criminal organization the method employed as well as the positioning of the body follow a macabre ritual laden with significance and intending to be a warning to others who interfere with the activities of these organizations.

Ndrangheta Homicide Execution, Burnt Lime, Confocal Microscopy

G78 Pig-Mentation: Postmortem Iris Color Change in the Eyes of Sus Scrofa

Elizabeth J. Abraham, MA, MSc, University Health Network, MedWest, 750 Dundas Street West, 2nd Floor, Suite 279, Toronto, Ontario M6J 3S3, Canada; Margaret Cox, PhD, Inforce Foundation, Melbury House, 1-3 Oxford Road, Bournemouth, Dorset BH8 8ES, United Kingdom; and David Quincey, MSc, Bournemouth University, Institute of Health and Community Studies, Royal London House, 1st Floor, Christchurch Road, Bournemouth, Dorset BH1 3LH, United Kingdom*

After attending this presentation, attendees will learn that iris color of a deceased individual is not reliable for identification, and will have an appreciation of the implications of this phenomenon within the context of victim identification, particularly in mass fatality incidents.

This presentation will impact the forensic community and/or humanity by demonstrating the protocol for victim description, particularly in mass fatality incidents, should be modified in order to account for the taphonomic phenomenon of eye color change.

Eye color is one of the physical characteristics recorded in a missing person report and in a victim identification report. Software programs are employed, by law enforcement and disaster management agencies, to compare the two sets of data, searching for potential matches and eliminating individuals if the data are inconsistent.

A thorough review of the literature revealed that postmortem iris color change is mentioned in only two forensic pathology texts, by the same author. A study on the preservation of contact lenses using the eyes of *Sus scrofa* (domestic pig) also mentions the phenomenon of blue eyes changing to brown after death.

While experienced forensic pathologists should be familiar with the phenomenon of postmortem iris color change, it is not common knowledge among death investigators. Victim identification forms and disaster victim identification software currently in use in the United Kingdom, Canada and internationally contain a field for eye color. Moreover, recording eye color is standard routine in the external examination in an autopsy.

In order to determine whether Knight’s references (2004 and 1997) are anecdotal and/or whether Jackson (2001) observed an anomaly, a controlled experiment of postmortem changes to isolated *Sus scrofa* eyes was carried out. The eyes (n=137) were observed for three days postmortem at three different temperatures. In addition, a *Sus scrofa* head with *heterochromia iridum* (two different colored eyes) was obtained in order to observe decompositional changes of eyes *in situ*.

All isolated blue eyes in the experiment, at room temperature and higher, changed to brown/black within 48 hours. The *in situ* blue eye, at room temperature, turned brown/black within 72 hours. In fact, the *in situ*

blue eye was indistinguishable from the *in situ* brown eye, and the change occurred prior to decomposition of the eye itself.

Blue eyes kept at a cool temperature exhibited signs of iris color change, but all of the eyes were still recognizably blue after 72 hours.

Drying of the sclerae in isolated eyes also occurred, the result being that the entire globe turned black concomitantly with the iris color. The sclerae of the *in situ* eyes with open lids, however, remained white and fresh-looking, and the blue eye changed to brown/black within 72 hours.

The possible role of the vitreous humour, which also turned black postmortem, is explored. The quantity of free melanin granules in the vitreous increases with postmortem interval. This is likely a result of the degradation of melanocytes in the retinal and choroids layers of the posterior chamber, in a process driven by autolysis. Further histological studies are required, including quantified melanin granule counts of vitreous humor samples using scanning electron microscopy.

Most importantly, further studies are required on human eyes to explore the reliability of this phenomenon and the conditions driving it. If postmortem iris color change occurs consistently in humans, then this taphonomic artifact will have to be taken into account when recording eye color in victim identification reports. This is particularly relevant in cases of mass fatalities, when victims may exposed to the elements for up to several days, and a discrepancy such as eye color in antemortem and postmortem data may delay identification when processed by disaster victim identification software.

Iris Color Change, Postmortem, Taphonomy

G79 Child and Adolescent Victims in Forensic Autopsy: A Five Year Retrospective Study

Anny Sauvageau, MD*, and Stéphanie Racette, BSc, Laboratoire de Sciences Judiciaires ET de Médecine Légale, 1701, Parthenais Street, 12th Floor, Montreal, Quebec H2K 3S7, Canada

After attending this presentation, attendees will have a better understanding of the epidemiological features of child and adolescent victims in forensic autopsy and of the usual characteristics of homicide in the four to 19 years of age population.

Though literature on child abuse investigation of children less than three years of age is quite extensive, the data on forensic autopsy in the older population from four to 19 years of age is more limited. This presentation will impact the forensic community and/or humanity by providing data from a systematic five year retrospective study on this child and adolescent victim population in forensic autopsy.

In the province of Quebec (Canada), all forensic autopsies are performed at a centralized laboratory. During the five year period from 2000-2004, a total of 233 cases of children and adolescents deaths were autopsied in the four to 19 years of age population. Of those, the large majority of cases belonged to the 15-19 age group (139 cases), with the remaining cases equally distributed between the 4-9 and the 10-14 age groups (42 cases each).

Child and Adolescent Victims of Forensic Autopsy: Male victims were more frequently encountered than female ones (148 males for 75 females), this male predominance being more obvious in the 15-19 age group (male:female ratio of 23:19 in the 4-9 age group, 24:18 in the 10-14 and 101:38 in the 15-19). In this population, accident was the most frequent manner of death (44%), followed by homicide (24%), suicide (18%), undetermined (9%) and natural (4%). In the 4-9 age group, manner of death was mostly accident (57%) or homicide (37%). An important gender difference was noted in the manner of death. As a matter of fact, while male were more prone to die from accident (74%) than from homicide (17%), the opposite was observed for female (47% homicide compared to 37% accident). In the 10-14 age group, accident remained the most frequent manner of death (50%), followed by homicide (19%) and suicide (14%). Accidents are more frequent in males (58% of male victims

compared to 39% of female ones) while homicide is more frequent in females (28% of female victims compared to 12% of males). In the 15-19 age group, accident was once again the most frequent manner of death (38%), though less predominant in comparison with suicide (25%) and homicide (24%). In terms of gender, the relative incidences of each manner of death were more similar in this age group.

Homicide Victims: In a total of 54 homicide cases (24 females and 30 males), 13 cases belonged to the 4-9 age group, 8 to the 10-14 age group and 33 to the 15-19. The two most frequent methods of homicide found were firearm and sharp force, each at 27% of cases, followed by asphyxia (23%), blunt force (20%) and intoxication (3%). The gender distribution of homicide cases in the different age groups shows a strong female predominant ratio in the 4-9 and 10-14 age groups (9:4 and 5:3 respectively), while the opposite situation was observed in the 15-19 age group (10:23). An analysis of homicide methods by age group and gender will be presented. Overall, the results for the 4-9 age group are particularly interesting, clearly demonstrating predominance of sharp force in female victims compared to asphyxia in males.

In conclusion, this five year retrospective study gives new insight in the epidemiology of child and adolescent victims in forensic autopsy as well as a better description of homicide cases distribution.

Child Death Investigation, Adolescent Death Investigation, Forensic Pathology

G80 Hemoglobin SC Disease Presenting as Sickle Crisis After Outpatient Surgery: A Case Report

Wendy A. Lavezzi, MD*, and Mitra B. Kalekar, MD, Cook County Medical Examiner's Office, 2121 West Harrison Street, Chicago, IL 60612

After attending this presentation, attendees will learn the significant signs, symptoms, and sequelae of Hemoglobin SC disease, and implement the use of postmortem hemoglobin electrophoresis in indicated cases.

This presentation will impact the forensic community and/or humanity by providing information on the importance of recognizing an occult hemoglobinopathy and its possible contribution to the cause of death.

Hemoglobin SC (Hb SC) disease is a hemoglobinopathy with approximately the same incidence as that of Hemoglobin SS (Hb SS) disease in American blacks. The typical presentation of Hb SC disease includes fatigue, dyspnea on exertion, frequent upper respiratory infections, sporadic mild jaundice, and arthralgias. The onset of complications due to Hb SC disease is usually in childhood, but many do not present until the teens or later. Rare reports of aut splenectomy in Hb SC disease exist, but most patients with Hb SC disease have splenomegaly. Unlike Hb SS disease, painful crises in Hb SC disease occur more frequently in the muscles and joints than in the abdomen. Although Hb SC can present with the same manifestations as sickle cell anemia, it is generally characterized by a milder anemia and fewer vasoocclusive crises, with a severity that is intermediate to those of sickle cell disease or sickle cell trait.

A 33-year-old black male who underwent outpatient surgery for arthritis that developed following ankle and foot fractures sustained three years prior when he jumped off a roof while fleeing from an offender. His preoperative medical history and physical were within normal limits, and he had a history of sickle cell trait.

The surgery lasted 2½ hours, with two hours of tourniquet time, and consisted of a right subtalar fusion and arthroplasty of the 2nd-4th right toes, with application of a cast. There were no complications during surgery. Ketorolac and local bupivacaine were given, a dressing was applied, and the tourniquet was removed. His airway device was then removed, and on the way to the recovery room he suffered sudden

cardiopulmonary arrest and was intubated, but expired despite resuscitative measures.

At autopsy, he had a plaster cast on the right leg, beneath which were intact sutured incisions and orthopedic hardware. The lungs were heavy and congested, and the mucosa of the gastrointestinal tract was hemorrhagic and appeared ischemic. The heart, liver, kidneys, and brain displayed no abnormalities. The spleen weighed 4 grams and had light tan, fibrotic parenchyma. Based on the appearance of the spleen, the family was contacted, and they stated that the patient did have sickle cell trait, and not sickle cell anemia.

Postmortem hemoglobin electrophoresis, however, revealed the presence of Hb SC disease. Microscopy revealed pulmonary congestion with prominent sickling of red blood cells within vessels. Sickling of red blood cells was also prominent in the liver, heart, kidneys, meninges, adrenal glands, thyroid gland, and gastrointestinal tract. Sections of the spleen showed prominent fibrosis and calcification, consistent with autopsplenectomy. It is theorized that release of the tourniquet caused a large amount of partially deoxygenated blood to re-enter the circulation and cause a sickle crisis. The cause of death was determined as sickle cell crisis due to hemoglobin SC disease, with ankle surgery following a fall from height as a significant contributing condition. The manner of death was accidental.

Sickle cell crisis in Hb SC disease is rare. Despite the fact that this patient underwent autopsplenectomy, he had previously suffered no symptoms of Hb SC disease and believed throughout his life that he had sickle cell trait. The use of postmortem hemoglobin electrophoresis was invaluable in the determination of cause of death in this case.

Forensic Science, Hemoglobin SC Disease, Sickle Cell Crisis

G81 Hola Camp Massacre Kenya 1959

Maurice G. Rogev, MB ChB, MD*, Zamenhof St.11/1, Tel-Aviv-Jafo, 64373, Israel

The goal of this presentation is to demonstrate where in cases where either living victims of violence or the dead resulting from violent acts' it is important to investigate the medical history of the victim when conducting the clinical examination or the autopsy.

This presentation will impact the forensic community and/or humanity by drawing the attention of the forensic community to the fact that these cases do occur. The complete forensic evaluation that includes a review of the clinical record for all patients undergoing a full autopsy examination should become a routine procedure in such cases.

The "Hola Camp Massacre" occurred on 3 March 1959 in a detention camp run by the British Colonial Government of Kenya during the Mau Mau rebellion. The detention camp, established early in the Mau Mau Kikuyu rebellion that raged from 1952 to 1960 was situated in a remote area of the coastal province of Kenya.

The camp was staffed by Kenyan African warders and commanded by British Colonial prison officers with locally recruited Kenya European civil servants.

The following facts are beyond dispute.

The warders were authorized to use reasonable force to induce resisting camp detainees to work against their will. In the incident under consideration, warders used unauthorized excessive violence with clubs, sticks and body kicks.

Eleven men were killed and some sixty 60 injured. Of these, 26 men were admitted to the camp hospital in a state of surgical shock, with extensive bruising, subcutaneous hemorrhaging and hematoma in many areas of the body surfaces.

Clinical examination revealed signs of severe chronic deficiency of Vitamin C, (Ascorbic Acid).

The eleven bodies were flown to the Medical Research Laboratories in Nairobi, where the author performed autopsy examinations in his capacity as the Police Forensic Pathologist.

The autopsy examination revealed extensive subcutaneous hemorrhages, hematoma and laceration of muscles in the region of the head, neck, torso and the limbs. No serious fractures were found in the bodies, except for a linear fracture in the occipital skull bone in one case. All internal organs were anatomically intact. There were hemorrhages in the respiratory, the gastro-intestinal tracts and in the urinary bladder. There was severe pulmonary edema.

The cause of death in these cases was determined to be due to acute hemorrhagic shock; with complications resulting from their state of severe Vitamin C deficiency at the time they received the multiple beatings with a club-like weapon.

The patients in hospital were diagnosed as suffering from acute traumatic hemorrhagic shock and responded to therapeutic doses of Ascorbic Acid (Vitamin C) and to supportive medical treatment. The clinical diagnoses showed clearly that the detainees were suffering from Vitamin C deficiency or Scurvy when they were subjected to the beatings.

The important principle as illustrated by these cases is that the forensic scientist must evaluate both the complete clinical syndrome presented by the victim of an assault and the autopsy examination diagnosis as a whole concept.

The question arises whether similar blows inflicted on healthy detainees could have produced the acute hemorrhagic shock syndromes that were suffered by the beaten detainees?

This presentation will show that in terms of the above principle, the answer must be negative.

Hola Camp, Massacre, Kenya

G82 Comparison of Wound Severity Between Center-Fire Rifle Projectiles and Shotgun Slugs

Jennifer H. Park, DO*, Miami Dade County Medical Examiner Department, 1851 NW 10th Avenue, Miami, FL 33136-1133; and Richard C. Harruff, MD, PhD, King County Medical Examiner's Office, 325 Ninth Avenue, HMC, Box 359792, Seattle, WA 98104

After attending this presentation, attendees will understand how the kinetic energy and fragmentation properties of a missile affect the extent of firearm wounds in a human body.

This presentation will impact the forensic community and/or humanity by contributing to the understanding of the relationship of a missile's kinetic energy and its wounding pattern in actual firearm wounds.

Introduction: Contemporary understanding of wound ballistics relates the severity of wounds to the temporary cavity that a projectile creates as it passes through the body tissues. This cavity is felt to be proportional to the kinetic energy (KE) possessed by the projectile. KE is related to both the mass (m) and the velocity (v) by the well-known formula: $KE = \frac{1}{2} mv^2$. This concept generally fits with ballistic experiments using gelatin, and accords well with general practical experience of forensic pathologists. There is little literature; however, that analyzes this relationship in actual firearm wounds. This study sought to explore this hypothesis using scientific methods on examples from medical examiner cases. A comparison was made of wounds produced by high velocity, center-fire rifles projectiles (CFRP) with those produced by shotgun slugs (SGS). The basis for this comparison is that CFRP have a relatively small mass and extremely high velocity while SGS have a large mass and a relatively low velocity.

Methods: A search was performed of the records at the King County Medical Examiner Office, Washington, for SGS and CFRP wound cases over the last 12 years – from mid-1993 to mid-2005. For these cases, the caliber of the CFRP and gauge of the SGS were obtained from the investigator reports, along with an examination of the weapon, ammunition, and recovered projectile. Only head wounds were used to

compare wounds produced by CFRP and SGS. A grading scheme was developed based on head wounds documented in the autopsy reports, radiographs, diagrams and photographs. Grade I was limited to a skin laceration at the entry site, with minimal fractures or avulsion injuries. Grade II included complex skull fractures and limited avulsion of the scalp, skull, or brain. Grade III involved extensive avulsion of the scalp, skull, or brain.

Results: A total of 80 suicide and homicide SGS and CFR cases were evaluated, the majority of which were contact wounds of the head. In all the SGS cases, the slugs exited the body. Forty-two of 61 CFR cases showed fragmentation in the body. Overall, 64 cases were suicides and 16 were homicides. All of the contact head wounds resulted in extensive destruction of bony and soft tissue structures in the path of the wound with complete or near complete avulsion of the brain. For CFR, both high (e.g., .223, 3030, 30-06 caliber) and intermediate velocity (e.g., .45 caliber) ammunition were considered. Using the KE equation, it was calculated that the extent of the wound of a .223 should be approximately 90% that of a SGS wound. In the majority of SGS cases, slugs exit the body; therefore not all of the KE is transferred to the tissues. The majority of CFR projectiles fragment and remain in the body; however, resulting in the maximum transfer of KE to the tissues.

Conclusion: The results support the general observation that the extent of wounds of SGS is similar to that of CFR wounds. The objective of this study was not to compare the gauge and manufacturers of the weapons, but to provide the results of a general observation of wounding characteristics using scientific methods. CFR bullets fragment because of their high velocity and not because of hitting bone. The majority of the time, SGS do not fragment because of their lower velocities. Fragmentation allows for the dispersion of kinetic energy to the tissues. CFR projectiles possess approximately 90% of the energy of that of SGS; however, because most CFR bullets do not exit, there is more transfer of kinetic energy to the tissues than that of SGS bullets, where majority exit the body.

Firearm Wounds, Shotgun Slugs, High Velocity Center-Fire Rifles

G83 A Comparison of Penetration Distances for Five Ballistic Gelatins to a BB Gunshot Wound to a Live Human Forearm

David J. Porta, PhD, Drew H. Duerson, and Bill Tietjen, PhD, Bellarmine University, Department of Biology, 2001 Newburg Road, Louisville, KY 40205; and Tyler A. Kress, PhD, BEST Engineering, 2312 Craig Cove Road, Knoxville, TN 37919*

After attending this presentation, attendees will see the accidental result of a BB gunshot and learn how ballistic gelatin preparation methodology can affect penetration results.

This presentation will impact the forensic community and/or humanity by demonstrating the only documented case where precise BB gun firing distance is known for a wound to a live human forearm. The penetration distance was determined using X-Rays. This data was then compared with recreated BB gun firings into five (5) different ballistic gelatins to determine which average penetration distance is the closest to this single human case.

Misuse of BB guns causes a significant number of injuries each year. One of the authors was subjected to such misuse and the result was a penetrating wound to the proximal anteromedial aspect of the right forearm. The subject was a healthy, 37-year-old male with fairly well muscled forearms due to years of baseball playing. Fortunately, this accident occurred in a laboratory setting and all parameters were recorded. The gun was a Daisy-brand Powerline Model 1200. This carbon dioxide powered pistol can fire a standard steel BB at up to 420 feet/second. In this case, the muzzle was located precisely 126 cm from the subject's bare forearm and the gun was equipped with a fresh CO₂ cartridge.

Radiographs were made and the BB was noted to have penetrated just over 63 mm into the flesh (after magnification was taken into account). The BB was surgically removed under fluoroscopy. The surgeon noted no involvement of the radius, ulna or major neurovasculature. However, the BB did pierce the interosseous membrane. The wound was irrigated and sutured closed with no significant complications.

It is an extremely rare case when such precise data is known about an actual gunshot wound to a live human being. It afforded the authors an interesting opportunity to compare the BB penetration in this person to a laboratory-based series of experiments utilizing ballistic gelatins.

In order to perform better controlled studies on the damaging effects of various bullets passing through soft tissues, ballistic gelatin was created many years ago. The gelatin is said to simulate the density and viscosity of human and animal muscle tissues. A standard gelatin powder (250 Bloom Type A Ordinance Gelatin) was purchased from Kind & Knox Gelatine, Inc. (Sioux City, Iowa). There are a variety of methods published for the preparation of 10% gelatin blocks. Five were chosen for this study: 1) The manufacturer's directions; 2) The Vyse gelatin utilized by the FBI; 3) A technique in which the maximum temperature never exceeds 104 degrees F; 4) A technique in which the starting water is at 129 degrees F; and 5) A recipe published by Lewis et al. 1982. They appear to have relatively minor differences (mostly related to various temperatures and standing times).

Gels were poured into transparent hard plastic cups. Each cup was placed in a protective firing range and subjected to five BB shots from 126 cm away- using the same Daisy gun. A total of 25 shots were recorded for each of the five gelatin recipes and all penetration distances were measured with digital calipers. The data were stored in Microsoft Excel, then imported to Stata 8.0 (College Station, Texas) for analysis. The mean penetration distance for each recipe was: 1) 62.24 mm; 2) 43.25 mm; 3) 56.13 mm; 4) 64.22 mm, and 5) 40.98 mm. ANOVA testing was significant between all groups but the chi-squared analysis results were <0.05; therefore, variances were not equal and parametric testing was dropped. Kruskal-Wallis tests indicated statistically significant differences between the mean penetration distances for all the recipes. The Mann-Whitney test indicated significant differences between each recipe except when comparing one and four. Interestingly, the mean penetration distances for those recipes were the closest to the actual penetration depth in the live human subject (63 mm).

In summary, a live human subject was accidentally shot in a muscular area of his forearm with a BB gun. The penetration distance compared favorably with two of five ballistic gelatin preparations. Although the live human data consists of a population (n) of one, it appears to be the only such data in the medical literature. Based on this, it seems the preparation method for ballistic gelatin has significant affects on the penetration distance for BB gunshots.

BB Gunshot, Ballistic Gelatin, Live Human Forearm

G84 Suicidal and Homicidal Sharp Force Injury: A Five Year Retrospective Comparative Study of Hesitation Marks and Defense Wounds

Stéphanie Racette, BSc, Célia Kremer, MSc, and Anny Sauvageau, MD, Laboratoire de Sciences Judiciaires et de Médecine Légale, 1701, Parthenais Street, 12th floor, Montreal, Quebec H2K 3S7, Canada*

After attending this presentation, attendees will gain better knowledge of hesitation marks and defense wounds pattern in sharp force injury and its correlation to suicidal and homicidal manner of death.

This presentation will impact the forensic community and/or humanity by providing a systematic evaluation of hesitation marks and defense wounds in sharp force injury in the Quebec province (Canada) forensic laboratory from 2000-2004.

In sharp force injury cases, forensic pathologists often have to determine whether the injuries were self-inflicted or not. The presence of hesitation marks or defense wounds, respectively associated to suicide and homicide, has been accepted as useful characteristics in the evaluation of manner of death. However, very few studies in the forensic literature have systematically analyzed the features differentiating hesitation marks and defense wounds.

Over a five year period, in the Quebec province (Canada), all cases of suicidal and homicidal sharp force injury were retrospectively reviewed for the presence of hesitation marks and defense wounds. For each case, data on incidence, gender, age, hesitation marks/defense wounds localization, fatal wound(s) pattern and blood alcohol concentration (BAC) was compiled. Data was statistically analyzed in order to highlight differences between hesitation marks and defense wounds.

Hesitation marks: A total of 58 sharp force suicides (7 women; 51 men) were found, of which 74% (n=43) were positive for hesitation marks. Seventy-one percent of women and 74% of men presented hesitation marks and women showed a significantly higher amount of hesitation marks compared to men ($p<0.05$). Victims were aged from 23 to 83 years with an average age of 43 years for cases with hesitation marks. The three most frequent locations of hesitation marks were neck area in 46% of cases, followed by left thoracic area (44%) and wrists (39%). A positive correlation was found between the amount of fatal wounds and the amount of hesitation marks ($p<0.001$). When only one fatal wound was found, absence of hesitation marks was noted in 39% of cases. No correlation was found between BAC and presence of hesitation marks.

Defense wounds: A total of 149 sharp force homicides (59 women; 60 men) were found, of which 61% (n=91) were positive for defense wounds. A significant difference between male and female incidence was noted (71% compared to 54%; $p<0.05$) and women showed a significantly higher amount of defense wounds compared to men ($p<0.001$). Victims' age ranged from six months to 82 years with an average age of 42 years for cases with defense wounds. In terms of location, defense wounds were most frequently found on hands (78%), followed by arms (48%) and forearms (34%). Victims presenting with defense wounds showed a four times higher average amount of non-defense wounds. Absence of defense wounds was noted in 80% of cases showing only one fatal wound. A negative correlation was revealed between BAC and amount of defense wounds ($p<0.01$). Indeed, the highest amounts of defense wounds were noted in the absence of BAC, while the highest BACs were associated with the absence of defense wounds.

In conclusion, this retrospective study systematically compares features of hesitation marks and defense wounds and gives new insight on medicolegal expertise in sharp force injury cases.

Hesitation Marks, Defense Wounds, Sharp Force Injury

G85 Estimation of Postmortem Interval Using Bioelectrical Impedance of the Human Body

Beat Horisberger, MD, and Patrice Mangin, MD, PhD, Institute of Legal Medicine, University of Lausanne, 21, Rue du Bugnon, Lausanne, CH-1005, Switzerland*

After attending this presentation, attendees will understand the principles of a new tool for the estimation of postmortem interval, bioelectrical impedance of the human body, in addition to the traditional methods currently used.

The method of measurements using cutaneous bioelectrical impedance may impact the forensic community and/or humanity by becoming a valuable analytic tool for the estimation of the time of death in forensic medicine.

In medicolegal practice, being able to estimate the time of the death is of paramount importance. Particularly in cases of homicides (to accuse or exculpate an alleged criminal), the cases of postmortem manipulation of the remains (occurring especially in the cases of overdose), as well as in civil matters (for example succession rights). The interest to perform a technique to specify more precisely the time of the death in the first part of the postmortem interval lead to the development of a new method, based on the bioelectrical impedance of the human body.

Human body can be compared to an electrical complex circuit, containing water, electrolytes, and cellular membranes. A direct, or alternating low frequency (<5 KHz) current, applied to the body, was used to measure electrical resistance. The alternating current will reflect both the extracellular compartment (electric resistance) and the intracellular compartment (capacitive resistance).

Initially, measurements were made on 34 fresh bodies, with a known time of the death, less than five hours postmortem. Electrodes (patches) were applied on the skin with a distance between patches of 10 cm, on the chest, abdomen, arms and thighs. Bodies were placed in a room at constant ambient temperature (approximately 18 - 20 °C). Measurements were performed using an impedance meter that automatically recorded the values of resistance (R), impedance phase angle (theta), as well as the body temperature (rectal probe) and the ambient temperature. Measurements were recorded every ten minutes during the first 24 hours, then every 15 minutes. The available time for the measurements was dependent on the interval between death and the time of the postmortem examination.

The reactance (Xc) and the impedance (Z) were calculated using the recorded data. These results were compared with the postmortem interval. A variation was observed with the absolute values between the different bodies. On the other hand, with the relative values, a statistically significant arithmetic correlation, was noted between the values of reactance and impedance compared to the postmortem interval.

The method of measurements using cutaneous bioelectrical impedance may become a valuable analytic tool for the estimation of the time of death in forensic medicine.

Forensic Medicine, Postmortem Interval, Bioelectrical Impedance

G86 Postmortem Skeletal Survey Use in Pediatric Forensic Autopsies: A National Survey

Antoinette L. Laskey, MD, MPH, Children's Health Services Research, Indiana University School of Medicine, The Regenstrief Institute for Health Care, 1001 West 10th Street, Bryce 2112, Indianapolis, IN 46202; and Michele J. Catellier, MD, Forensic Pathology Associates of Indiana, LLC, 521 West McCarty Street, Indianapolis, IN 46225*

The goal of this presentation is to summarize a national survey of postmortem pediatric radiology practice, as reported by forensic pathologists. This will provide an understanding of current practice patterns and factors that may influence the type and extent of radiologic tools that are utilized in the postmortem evaluation of forensic pediatric cases, and introduce possible consideration for future practice including creative funding sources and community resources.

This presentation will impact the forensic community and/or humanity by assisting the forensic pathology community in analysis of how skeletal surveys are defined, and whether the current practices are providing adequate information in cases of unexpected pediatric death and/or suspected child abuse. In addition, it is anticipated that the results will provide suggestions for alternative techniques and resources, as well as creative funding sources in the area of postmortem radiography. Future research should include a cost-benefit analysis of various protocols.

Radiography is an essential tool in the evaluation of suspected physical abuse in the living child. Postmortem radiological evaluation is often included in the autopsy of a child or infant whose death is unexpected or suspicious for abuse. Just as in the living, discovery of subtle injury at autopsy may be dependent upon ancillary studies. Although the pathologist has the advantage of direct examination of the axial skeleton during the postmortem examination, a routine autopsy does not allow for examination of the appendicular skeleton. Dissection of distal extremities, for instance, may not be performed without radiologic studies that direct the pathologist to the location of potential injury. Previous studies have documented injuries such as metaphyseal fractures that were unsuspected on external examination.

According to the recently approved Forensic Autopsy Performance Standards of the National Association of Medical Examiners, "...The Forensic Pathologist or representative shall X-Ray all infants." In addition, in June 2004 a joint statement of the Society for Pediatric Radiology and the National Association of Medical Examiners was published, advocating the use of high quality radiographs in a postmortem child abuse investigation. The recommended appendicular postmortem survey includes a minimum of frontal views of each arm (two films), paired hands (one film), paired legs (one film) and paired feet (one film).

It has been recognized that the use of radiographs as an ancillary study in postmortem examinations is typically routine. The extent of such examinations, however, is not known. In the case of live children, recent studies suggest that in facilities with fewer numbers of pediatric cases, skeletal surveys are used less frequently and tend to include fewer images per study.

A mail survey of pathologist members of the American Academy of Forensic Sciences was distributed throughout the United States and its territories. The target population was pathologists who conduct autopsies on children \leq 36 months of age. There were a total of three mailings, and a \$2 incentive was included with each initial survey sent. The objective of the survey was to (1) assess adherence to the NAME recommendations for postmortem radiography among pathologists conducting forensic autopsies in children \leq 36 months of age, and (2) to describe the spectrum of postmortem skeletal survey practices in a national sample of pathologists. The response rate was 259/470 (55%). Data were analyzed utilizing univariate descriptive statistics.

Respondents reported handling one to approximately 2,000 pediatric cases per year in a given office. Nearly every respondent (99.96%) indicated that they obtained at least some imaging. The number of postmortem images obtained ranged from none to a "babygram" (i.e., one or two frontal films of the entire body) to a set of 19-30 individual films that include multiple views of the axial and appendicular skeleton, to full body MRI or CT scans. Most commonly, films were traditional X-Ray films although fluoroscopy and other techniques were also reported. Nearly one third of the surveyed pathologists reported routine use of the "babygram" as their sole postmortem radiographic tool.

Most surveys are performed on site, at the location of the autopsy laboratory, and most are funded at the expense of the office. Other funding sources included state budgets, grants and insurance billing.

Respondents reported using skeletal surveys most frequently when foul play or abuse is suspected. Not all pathologists utilize postmortem skeletal surveys in cases of presumed Sudden Infant Death Syndrome, or when foul play is not initially suspected.

Pediatric, Postmortem, Radiology

G87 Near Miss Incidents in Police Custody Suites in London, UK: A One Year Prospective Study

Jason Payne-James, MBBS*, Forensic Healthcare Services Ltd, 19 Speldhurst Road, London, E97EH, United Kingdom; Rebecca Teers, BA, Independent Police Complaints Commission, 90 High Holborn, London, WC1V 6BH, United Kingdom; Stefania Menin, MSc, Independent Police Complaints Commission, 90 High Holborn, London, WC1V 6BH, United Kingdom; and Margaret Stark, LLM, MBBS, Forensic Medicine Unit, St. George's Hospital, London, SW12, United Kingdom

After attending this presentation, attendees will be able to identify detainees at higher risk of harm while in police custody.

This presentation will impact the forensic community and/or humanity by reducing harm to detainees.

Background: Every year a number of deaths will occur in police custody within the UK. Potentially preventable deaths in police custody include those that involve illicit drugs, alcohol and deliberate self-harm. This study examined near miss incidents (NMI) that did not result in death in order to develop a better understanding of risk factors for detainees in custody. For the purposes of this research NMI have been defined as 'any incidents which resulted in, or could have resulted in, the serious illness, injury or self-harm of a detainee'.

Aims & Methods: A prospective study of NMI was undertaken for one year from May 2005 to 2006. Forensic physicians (FP) providing forensic medical services for the Metropolitan Police Service in London were asked to complete questionnaires on any incident that may have been considered an NMI. The questionnaire proforma was developed following a pilot study. Ethical Committee approval was given for this study. The aim of the study was to identify NMIs and to assess whether such incidents assisted in identifying indicators of increased risk within the police custodial setting. Data about all incidents were anonymised.

Results: 89 FPs voluntarily participated in this study. One hundred twenty-four proformas were returned in the 12 months study period. Ninety-six were returned identifying the FP and 28 were completed anonymously. 9 FPs returned $>$ 2 proformas. Incidents were classified according to a) type and b) whether they were very likely or fairly likely to result in a fatality. Each incident could have more than one type. Of 124 responses, 36% said that if there had been no intervention, the incident was very or fairly likely to result in a fatality. Of the 124 incidents reported, 60 (48%) were related to suicide/self harm [28% likely to result in fatality]; 41 (33%) were drug related [49% likely to result in fatality]; 29 (23%) were alcohol related [45% likely to result in fatality]; 23 (19%) related to a medical condition / existing injury [65% likely to result in a fatality]]; two (2%) were due to injuries sustained during arrest [both likely to result in a fatality]; eight (6%) were reported as being 'other' types of incidents [38% likely to result in a fatality].

Conclusion: This is the first prospective study examining risk factors for NMIs in police custody in the UK. The data will help identify particular groups of detainees at increased risk whilst in custody and will allow lessons to be learned in ensuring that care for such vulnerable individuals in custody is optimised.

Police, Near-Miss Incidents, Death in Custody

G88 Probability and Pathological Findings in Suicidal Versus Homicidal Hanging Deaths: A Case Study in Forensic Epidemiology

Michael D. Freeman, PhD*, Oregon Health and Science University School of Medicine, 205 Liberty Street, Northeast, Suite B, Salem, OR 97301

After attending this presentation, attendees will be introduced to the application of weighted probabilities to pertinent pathological or other evidence to forensic decision making in a criminal matter; in the presented case study, the determination in a hanging death of suicide versus homicide.

This presentation will impact the forensic community and/or humanity by demonstrating how probability plays an important yet frequently unrecognized and/or improperly applied role in forensic decision making. This and other concepts of Forensic Epidemiology will be introduced in this presentation, raising awareness for forensic pathologists and others who rely upon population-based data from which to draw conclusions.

Probability is in constant use in forensic settings as a means of weighing the accuracy of specific conclusions, and it is used nearly as often to give weight to conclusions. Opinions that include the terms "risk" or "likelihood," or the expressions "most often" or "would be expected (or not expected)" are all variations of probabilistic assessments. Such opinions imply both an underlying basis in population-based data as well as a methodologically sound synthesis of such data. When probabilistic opinions are proffered in a forensic setting they should be scrutinized carefully for their basis in epidemiologic data, as well as how the data has been interpreted to apply to the case in hand.

A case study is presented in which a 26-year-old Aboriginal man was found hanging from a sheet in a jail cell in Darwin, Australia in February of 1986. The postmortem examination revealed evidence of unilateral neck organ fracture (thyroid cartilage) and was ruled a suicide. The decedent's widow believed that the death was a homicide, and brought forth collateral evidence supporting the charge. An international panel of eight forensic scientists was convened to re-examine the evidence, and it was concluded that there was sufficient evidence to justify a disinterment of the decedent, in part due to the fact that the neck organ injury was thought to be unlikely given the circumstances of the hanging.

In 2004 a civil case was brought against several defendants, including the forensic pathologist who conducted the postmortem examination, charging them with a conspiracy to obscure the murder. One of the theories raised by the defense was that neck organ fractures were common in suicides resembling the circumstances of the death, a probabilistic determination. For this reason, a forensic epidemiologic review of the case was conducted, including a review and analysis of the relevant literature.

A comprehensive review of the published literature on observational studies of hanging deaths in which neck organ injury was the independent variable revealed four validated predictors for the presence of neck organ injury of varying strength (in nine studies describing 1342 cases): Age greater than 30 (strong), duration of suspension (moderate to strong), ligature width of 1-2 cm or less (moderate), and suspension type (weak to moderate support for full versus partial suspension).

Based on the findings in the literature, the features of this hanging (age 26, brief suspension duration [45 minutes], >4 cm ligature width, partial suspension [feet in contact with the ground]) it was determined that the neck organ injuries observed in the postmortem examination were unlikely to have arisen from the observed circumstances of the hanging. Further, out of 1342 cases in the literature, ~180 were in males <30 years of age, and among these there were only ten cases of neck organ fracture. Although the ten cases did not describe the presence of the other three risk factors, approximately 75% of suicidal hangings in which ligature width

is described involve a narrow (<2 cm) ligature, and 25-50% are complete suspensions. It was reasonable conclude that no more than 10, and likely five or less of all of the hangings described in the literature review could have produced the same type of injuries as those seen in this hanging, given the risk factors present. The prevalence of potentially similar cases in the database ranged from 0-0.7%.

Based on the forensic epidemiologic review, it was opined that 1) contrary to the assertion by the defense, the neck organ injuries observed in the decedent do not commonly occur in similar circumstances, and 2) such injuries are rare in suicidal hangings with the predictive variables present in the subject case, as a reasonable scientific certainty. A Bayesian analysis of the evidence will be presented.

Hanging, Probability, Homicide

G89 Accuracy of Death Certification and Medical Examiner Notification in Nova Scotia

Kelly A. Dakin Hache, MD, PhD, Anatomical Pathology, Dalhousie University, 5788 University Avenue, Halifax, Nova Scotia B3H 2Y9, Canada; Petra A. Rahaman*, Forensic Science-Biology, University of Toronto, 107 Linnsmore Crescent, Toronto, Ontario M4J 4K5, Canada; and Matthew J. Bowes, MD, Nova Scotia Medical Examiner Service, 5670 Spring Garden Road, Suite 701, Halifax, Nova Scotia B3J 1H7, Canada

After attending this presentation, attendees will gain an appreciation of the spectrum of problems associated with errors in death certification and medical examiner notification.

This presentation will impact the forensic community and/or humanity by providing the framework for assessing and designing interventions to improve the accuracy of death certification. Improvements in the accuracy of death certification have important implications for accuracy of Vital Statistics, basic science research, public health policy, and civil/criminal law implementation. Most importantly, the accuracy of death certification is important for families, in terms of peace of mind and insurance claims.

Background: Information from Vital Statistics is an important resource utilized by clinical researchers, public health authorities, and officials of the Department of Justice. Major errors in death certification have been identified among physicians in academic institutions, as well as among officials in coroner systems.^{1,2} At the very least, the accuracy of this information has implications for basic medical research, public health policy, and civil/criminal law. Most importantly, the accurate certification of death has important implications for the families of the decedent in terms of peace of mind and insurance claims. As such, it is important to assess and to design interventions to improve the accuracy of death certification on both a regional and national scale.

Hypothesis: The role of the Medical Examiner Service (MES) is to determine the cause and manner of death in circumstances defined by the Fatality Investigations Act (FIA). Under the terms if the FIA, all citizens have the obligation to report a death, although most commonly this is a member of a law enforcement agency or a physician. Despite established guidelines for reporting, physicians often miss cases. There are likely two components contributing to the numbers missed cases.

1. Non-compliance with the established reporting guidelines (not sure when to report)
2. Inaccurate certification of death (not sure how to accurately assign cause or manner of death)

Objectives: The objectives of this study are threefold: 1) to determine the proportion of cases missed during a two year period (2004-2005); 2) to determine the mechanisms by which these cases were ultimately identified; and 3) to determine why these cases were originally missed as medical examiner cases.

Methods: All available case files from the Nova Scotia Medical Examiner Service over a two-year period (January 1, 2004 to December 31, 2005) were reviewed and those classed as “missed cases” were included in the study. The nature of the missed cases was documented with respect to the original certification of cause and manner of death, the final certification of cause and manner of death, the mechanism by which the cases are identified as a “missed case,” as well as various epidemiological aspects of the cases. The results were evaluated using descriptive statistical techniques.

Results: The total number of medical examiner cases for the study period is 1516 (742 cases in 2004 and 774 cases in 2005). Of these, the “missed cases” made up 11% of the total number of cases investigated (total 167 missed cases: 80 cases in 2004 and 87 cases in 2005). The mechanisms by which “missed cases” are identified include cremation approval 56% (93 cases), Vital Statistics 28% (46 cases), hospital personnel 6% (10 cases), Trauma Registry 4% (7 cases), physicians 3% (5 cases), family of decedent 1% (2 cases), policing agency 1% (2 cases), and other 1% (2 cases). In 22% of cases (37 cases) the physician classified the death as unnatural, yet failed to notify the medical examiner service. In 59% of cases (99 cases), the physician misclassified the case as natural when the manner was accidental.

Conclusions: Both non-compliance with the established reporting guidelines (not sure when to report) and inaccurate certification of death (not sure how to accurately assign cause or manner of death) contribute to the numbers of “missed cases.” This study shows that 11% of medical examiner cases are originally “missed,” and are discovered by a variety of mechanisms. This number represents the “tip of the iceberg” in that a significant proportion of “missed” deaths are detected by cremation approval. It is worth noting that burial in Nova Scotia does not require approval by the Nova Scotia Medical Examiner System.

Death Certification, Notification of Medical Examiner Service, Missed Cases

G90 Comparative Analysis of Medical Examiner and Coroner Systems of Medicolegal Death Investigation: Is There a Bias Toward Manner of Death?

Michael J. Caplan, MD*, and Bamidele Adeagbo, MD*, Medical University of South Carolina, Department of Pathology and Laboratory Medicine, Suite 309, 165 Ashley Avenue, Charleston, SC 29425

After attending this presentation, attendees will become aware of some of the differences between a Coroner’s and a Medical Examiner’s jurisdiction regarding the relative percentages of natural and violent deaths that are investigated by the respective jurisdictions.

This presentation will impact the forensic community and/or humanity by encouraging critical examination of the differences between Coroner- and Medical Examiner-based medicolegal death investigation systems in order to learn more about the motivating factors behind the decisions to investigate various types of deaths; to retain the most positive and beneficial aspects of both systems; and, ultimately, to promote practices that are sound from an investigative standpoint yet also cost-effective.

Background and Objective: In the United States, two different types of medicolegal death investigative systems, namely, the Coroner and Medical Examiner, exist, the former, headed by an elected, often lay official, the latter, by an appointed physician, sometimes a pathologist. The origin of the Coroner system dates back to English common law when the “crown” was purely a political position; not surprisingly, such political overtones have persisted to the present day. The Medical Examiner system, on the other hand, is, at its best, led by a physician, preferably a pathologist, who has formal training in medicolegal death investigation and in the performance of forensic autopsies. The fundamental philosophical differences between the Coroner and Medical Examiner systems exert a substantial influence on the nature of the cases that are selected by the medicolegal official to come to autopsy; specifically, that the Coroner, in an effort to minimize spending and stay within the budget, is more likely to authorize cases for autopsy that will potentially result in a criminal proceeding (or a high-profile civil litigation), most frequently violent (non-natural) deaths, while the Medical Examiner will have a greater tendency to pursue sudden unexplained deaths, the majority of which result in certification of a natural manner of death. The objective of this study was to determine whether this hypothesis was indeed valid by comparing a contemporary Coroner and Medical Examiner system.

Methods: This study reviewed deaths spanning a 14-year period from 1992-2005 that were reported to a coroner’s office (the Charleston County, South Carolina Coroner) and over a 6-year period from 2000-2005 reported to a medical examiner’s office (the State of Delaware Office of the Chief Medical Examiner [OCME]). Data were coded and analyzed using the program SPSS for Windows, Version 14.0.

Results: The breakdown of cases according to manner of death for the two respective jurisdictions is as follows:

Jurisdiction	Number of Deaths	Natural	Accident	Homicide	Suicide	Undetermined
Charleston County, SC	2,638	827 (31.3%)	940 (35.6%)	422 (16.0%)	345 (13.1%)	104 (3.9%)
Delaware	4,608	2,302 (50.0%)	1,437 (31.2%)	230 (5.0%)	529 (11.5%)	110 (2.4%)
OCME						

Comparison of the two medicolegal systems showed a negative correlation ($r = -0.046$ [$P = 0.018$]) for 2,638 subjects. The difference between the means of the two groups was 0.171 (95% CI = 0.107 to 0.235; student’s $t = 5.3$; $df = 2,637$; $P < 0.001$).

Conclusion: The proportion of natural deaths appears to have been substantially greater in the State of Delaware Medical Examiner jurisdiction while the percentage of homicides was significantly higher in the Charleston County, South Carolina Coroner’s Office. While the obviously higher degree of inflicted fatal injury in Charleston County, South Carolina is beyond the scope of this study, the greater percentage of natural deaths in the Delaware OCME supports the hypothesis. More detailed analyses of these respective trends are necessary in order to create the most effective and efficient medicolegal death investigative systems possible.

Medicolegal Death Investigation, Manner of Death, Coroner/Medical Examiner

G91 Preliminary Findings of the Bureau of Justice Statistics 2005 Census of Medical Examiner and Coroner Offices

Matthew J. Hickman, PhD, and Kristen A. Hughes, MA, U.S. Department of Justice, Bureau of Justice Statistics, 810 7th Street NW, Washington, DC 20531; and Jeri D. Ropero-Miller, PhD, and Kevin J. Strom, PhD, RTI International, 3040 Cornwallis Road, Research Triangle Park, NC 27709*

After attending this presentation, attendees will gain an enhanced understanding of the nation's death investigation systems. The presentation will be based on findings from the Bureau of Justice Statistics (BJS)-funded Census of Medical Examiner and Coroner Offices (CMEC).

This presentation will impact the forensic community and/or humanity by providing the forensic community with reliable and previously unavailable information on the personnel, functions, resource needs, workload, and specialized death investigations reported by U.S. medical examiner and coroner offices.

Medical examiner and coroner offices serve the public by conducting medicolegal investigations, primarily of unnatural or suspected unnatural deaths, throughout the United States. The 2005 Census of Medical Examiner and Coroner Offices (CMEC) represents the first data collection effort by the Bureau of Justice Statistics (BJS) to focus on medicolegal investigations of death. The goal of the census is to provide accurate and timely information on the capabilities and resource needs of medical examiners and coroners. RTI International, a nonprofit research organization, administered the census on behalf of BJS.

Medical examiner and coroner offices were asked to voluntarily complete the census, which covered a variety of topics, including jurisdictions, budgets, funding sources, staffing, workloads, data and database usage, records and evidence processing and retention, and investigations of infant deaths and unidentified decedents. The collection effort began in October 2005, when the census was mailed to 1,920 medical examiner and coroner offices. As Hurricane Katrina had recently devastated the states of Louisiana, Mississippi, and Alabama, the census was not sent to these states during the first phase of the data collection effort. In February 2006, the census was mailed to 154 medical examiner and coroner offices in Alabama and Mississippi. The data collection effort will be finalized by August 2006.

A multimodal data collection process enabled the death investigation offices to complete the census by mail, facsimile, or Web (<https://cmec.rti.org>). All offices were mailed a unique access code for Web access. In a final effort to improve response, RTI and BJS developed a reduced-length survey instrument that collected basic information about laboratory operations. Currently, the overall response rate for the CMEC is 85%, and the response rate for offices covering populations of 250,000 or more is 92%. Of the 49 states included (Louisiana was omitted), 23 had a 100% response rate across their medical examiner and coroner offices. Overall response rates for medical examiner and coroner offices were similar.

This presentation will highlight similarities and differences in the nation's medicolegal death investigation systems. Variables include the types of systems found across states, expenditures, caseload measures by type of procedures involved, turnaround times for case completion, investigation protocols, and reporting levels for specialized death investigations. For example, the geographical distribution of types of offices, as well as aggregate population and jurisdictional coverage, will be detailed. In addition, the number of accepted cases for 2004 will be presented, with discussion of the various functions performed on a case, such as death scene investigation, autopsy, toxicology, and crime scene processing. This presentation will also summarize the policies for handling unidentified human decedents and infant deaths, as well as the related caseloads and resource needs.

The CMEC provides valuable information on the status and needs of medical examiner and coroner offices in the United States. Information collected in the 2005 CMEC may emphasize specific funding requirements or other areas that require further assessment of the nation's death investigation systems. These preliminary data represent the compiled data that will be available in a comprehensive BJS report on <http://www.ojp.usdoj.gov/bjs>. Understanding these issues will inform the development of plans to improve both the efficiency and functionality of medical examiner and coroner offices.

Medical Examiner, Coroner, Census

G92 Pituitary Macroadenoma Presenting as Hypothermia: A Case Report

Michelle A. Jorden, MD, Adrienne Segovia, MD, and Edmund R. Donoghue, MD, Cook County Medical Examiner's Office, 2121 West Harrison Street, Chicago, IL 60647*

The goal of this presentation is to present an uncommon cause of hypothermia due to a brain tumor and highlight the importance of central nervous system causes that affect body temperature regulation.

This presentation will impact the forensic community and/or humanity by demonstrating an unusual cause of hypothermia.

Hypothermia is diagnosed when an individual's body temperature is below 95°F (35°C). In forensic pathology practice, the most common cause of hypothermia is exposure to low temperatures without adequate warming measures. It is not uncommon for individuals to present to the emergency room having been exposed to extremely cold temperatures and then subsequently to die. In these cases in particular, forensic pathologists must rely on documentation of body temperature within the medical records to assess whether hypothermia may have caused or contributed to death. In cases in which hypothermia is a cause or contributing factor to death, the manner of death is rendered as an accident. The extreme ages of life, those encompassing the very old and young, are most vulnerable to hypothermia because of debilitating disease or lack of self-nurturing skills. The body responds to hypothermia by increased heat production through peripheral vasoconstriction and shivering. Shivering ceases between 85-90°F and the loss of hypothalamic function to regulate temperature ceases below 85°F. Once compensatory measures fail to increase heat production, individuals can experience ventricular fibrillation and death.

Less commonly, and rarely documented in the literature, brain lesions can cause hypothermia.

A 59-year-old black woman who initially came to clinical attention in May 2006 after falling out of her wheelchair and hitting her head on a concrete floor in her room at a nursing home. She had a history of a brain tumor and was on warfarin for deep venous thrombosis. The subject was taken to the emergency room to obtain a brain CT scan, as mandated by the nursing home protocol. En route to the hospital, the patient became hypotensive and was cool to touch. In the emergency room the patient was hypothermic with a temperature of 29°C (84°F) and continued in a hypotensive state. A CT scan of the head was negative for hemorrhage. Once her blood pressure was stabilized with vasopressors, the patient's hospital course was complicated by administration of antibiotics for a presumptive diagnosis of sepsis and subsequent development of anaphylaxis. She was intubated after upper airway swelling and developed adult respiratory distress syndrome, which ultimately led to her demise two days later.

At autopsy, there was diffuse consolidation of all the lung lobes and microscopic examination revealed diffuse hyaline membranes without organization. There was minimal laryngeal swelling. The skull showed evidence of a prior craniotomy site and an organizing subdural hematoma. The sella turcica was markedly enlarged and contained a 2.3 X 1.8-cm pituitary macroadenoma containing a small area of hemorrhage. The

macroadenoma grossly compressed and distorted the overlying hypothalamic area. Microscopic sections of the hypothalamic area revealed a symmetrical compressive infarct consisting of rarefaction of glial tissue, numerous axonal spheroids, and collections of parenchymal hemosiderin. The cause of death rendered in this case was hypothermia due to pituitary macroadenoma and the manner of death was rendered as natural.

This is an unusual case of a macroadenoma causing overlying compression of the hypothalamus. It is concluded that compression of the overlying hypothalamic area by the pituitary macroadenoma caused a disruption in the thermoregulatory function of the hypothalamus, thus causing hypothermia. The fall may have contributed to focal hemorrhage and enlargement of the pituitary macroadenoma with further compression of the hypothalamus and subsequent development of symptoms.

Hypothermia, Pituitary Macroadenoma, Death

G93 Diatoms and Their Forensic Significance

Ismail M. Sebetan, MD, PhD, and Irelise C. Clendenin, MFS, National University, 11255 North Torrey Pines Road, La Jolla, CA 92037*

The goal of this presentation is to demonstrate that diatoms could be critical evidence in criminal investigations when aquatic communities are involved. This research shows that diatoms are a good example of trace evidence and very valuable investigative tools, which can be used to link an individual to a crime scene. Additionally, this study findings support that these microorganisms can be recovered by using a simple methodology; and providing investigators with a reliable and quick technique that could help them determine the presence of diatoms in physical evidence recovered from a crime scene and/or individual.

This presentation will impact the forensic community and/or humanity by showing that diatoms could be critical evidence in criminal investigations when aquatic communities are involved. This study will provide investigators with a simple, reliable and quick technique that could help them determine the presence of diatoms in physical evidence recovered from a crime scene and/or individual. These results can be used to educate crime scene investigators and police officers on what kind of valuable trace evidence should not be overlooked at a crime scene or evidence items that show the presence of soil, mud, or water.

Diatom analysis could help determine if the person was dead or alive when the body is removed from the water. Because of the diatoms vary morphologically and taxonomically depending on their habitat, it is possible to determine the location or site of drowning. Moreover, if there is a possibility of linking a victim to the site of the drowning, there is also a possibility of linking a suspect to a crime scene. It is imperative to try to recover as much evidence as possible from a crime scene, especially; the type of evidence cannot be seen with naked eye such as trace evidence. Therefore, recovering diatoms from a crime scene or from articles of clothing of the victim or a suspect can provide an important evidence for use in criminal investigations. The use of diatoms for forensic purposes in the United States is very limited and under-utilized

Samples used in this study were collected from three different bodies of water; marine (beach shore), brackish (estuarine), and from a freshwater source (lake). Neutralized buffered formalin (NBF 10%) was added to each sample to fix and help in the preservation of the diatoms. The temperature and the pH of the water were recorded at the time the samples were collected, as well as the ambient temperature. Samples were stored at 4°C.

Under restrict sterile condition; the samples were centrifuged for three minutes at 2982 rpm and then re-suspended in a few drops of distilled water. A drop of each sample was placed on a glass slide and a high refractive index mounting medium was used to fix the cover slip to the slide. The samples were observed under the microscope for the

presence of diatoms, identification, and comparison. Images were recorded of the different genera observed under the microscope. The second experiment consisted of manually transferring some of the samples to different articles of clothing, in a spotted manner. The articles of clothing examined were a white cotton t-shirt, white socks, and jeans. Each piece of clothing was cut in small pieces measuring three by four inches. The samples once impregnated with the marine, brackish and freshwater samples were placed in plastic containers (16 oz) used for this experiment. These samples were treated and processed in the same manner as the first experiment.

Diatoms were recovered from all the samples collected, and a qualitative analysis was performed. Diatoms were abundant in the estuarine and freshwater samples. On the other hand, the seaweed sample yielded the least amount of diatoms, and only six different genera were observed. To determine if a common habitat or source could be indicated; comparison of the diatoms from different samples showed a total of 23 genera in all samples collected. For recovering the diatoms of different fabrics such as pieces of t-shirt, sock, and jean material, results showed 66% success. These findings prove that diatoms can be recovered, analyzed and can be categorized as trace evidence.

In conclusion, diatoms have proven to be a powerful tool that can be used as evidence in forensic cases. It was concluded that diatoms could be transferred to different items of clothing, car carpets, sneakers, etc., if an individual comes in contact with an area where diatoms are expected to be present. These results can be used to educate crime scene investigators and police officers on what kind of valuable evidence should not be overlooked at a crime scene or evidence items that show the presence of soil, mud, or water.

Trace Evidence, Diatoms, Crime Scene

G94 Evaluation of NT-proBNP as Marker of Heart Failure in Postmortem Examination

Katarzyna Michaud, MD, and Marc Augsburger, PhD, Institut Universitaire de Médecine Légale, Bugnon 21, Lausanne, 1005, Switzerland; Nicolas Donzé, Consilia, Grand Champsec86, Sion, 1950, Switzerland; and Marc Bollmann, MD, Béat Horisberger, MD, Bettina Schrag, MD, and Patrice Mangin, PhD, Institut Universitaire de Médecine Légale, Bugnon 21, Lausanne, 1005, Switzerland*

The goal of this study was to evaluate the new biochemical marker NT-proBNP in postmortem examination as a tool for diagnosis of heart failure in cases related to coronary ischemia.

This presentation will impact the forensic community and/or humanity by showing that measurement of NT-proBNP is reliable in postmortem examination and should be considered as a useful tool for autopsy diagnosis of acute or chronic heart failure, whatever its origin.

Introduction: Natriuretic peptides are synthesized and secreted by cardiomyocytes in response to increases in wall stress and their plasma levels are elevated in patients suffering from myocardial infarction with systolic dysfunction. Many publications consider one of these peptides, BNP, as an excellent marker of heart failure. Recently, in clinical medicine, the amino terminal part of pro-BNP (NT-proBNP) was introduced which is secreted in equivalent proportion to BNP. According to the published studies, this new cardiac marker has a longer half-life and a better stability in comparison to the BNP. Moreover, many authors considered high levels of NT-proBNP as an independent predictor of mortality.

The first goal of this study was to measure the levels of NT-proBNP in patients with coronary syndromes and compare them to a control group. As serum is not always available during postmortem examination, the second goal of this study was to evaluate a correlation between NT-proBNP levels measured in serum, blood, aqueous humor and pericardial fluid.

Material and Methods: This study included 34 cases. 25 patients presented an ischemic heart disease (21 men and four women), in 15 of them postmortem examination revealed an acute coronary syndrome. In a control group were included nine cases (5 men and four women) without cardiac pathology. According to the clinical history and autopsy findings, the cases were classified into four groups. For each case, an autopsy followed by a histological examination was performed. The examination of the heart included a macroscopic examination and the analysis of at least five slides of the myocardium, stained with haematoxylin and eosin, and with von Gieson trichrome. The putrefied cases were excluded from the study.

Postmortem blood samples were centrifuged in order to obtain "serum." The NT-proBNP measurements were performed in serum, blood, aqueous humor, and pericardial fluid using a chemiluminescent immunoassay kit (Elecsys 2010 analyzer, Roche Diagnostics).

Results: The highest serum levels were measured in patients with acute coronary syndrome associated with chronic ischemic disease revealed by a clinical history or detected at autopsy. No significant difference was observed between patients with acute coronary syndrome and without previous ischemic disease in comparison to a control group.

In this preliminary study, the levels measured in blood, aqueous humor and pericardial fluid were in accordance with levels obtained from serum.

Conclusions: Measurement of NT-proBNP is reliable in postmortem examination. In this study, the results obtained for patients suffering from coronary syndromes are compatible with clinical data. NT-proBNP measurement should be considered as a useful tool for autopsy diagnosis of acute or chronic heart failure, whatever its origin.

Natriuretic Peptides, Coronary Syndrome, Heart Failure

G95 An Unusual Case of Sudden Death

Luisa F. Florez, MD*, Baylor College of Medicine, One Baylor Plaza, Houston, TX 77030; Mary Anzalone, MD, Harris County Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054; and Carolina Gutierrez, MD, and Mario Cervantes, MD, Baylor College of Medicine, One Baylor Plaza, Houston, TX 77030; Kathy Haden-Pinneri, MD, Maximillian Buja, MD, and Luis A. Sanchez, MD, Harris County Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054

After attending this presentation, attendees will learn the importance of implementing the dissection of the atrio-ventricular node in all necropsies; but particularly in cases of sudden death.

This presentation will impact the forensic community and/or humanity by illustrating the utility of conduction system evaluation and its association with mechanism of death as discovered in conjunction with an unusual breast neoplasm.

A 49-year-old Asian female was found dead in her residence. Two weeks prior to her death, she presented to a local Emergency Room for pain and swelling of her right breast. Clinical examination revealed bilateral breast masses, suggestive of carcinoma. A mammogram was ordered, but never performed due to the patient's demise. Review of medical records reveal a mammogram performed six months prior, which was interpreted as negative. Evidence of a recent biopsy was identified at the time of autopsy; however, despite extensive searching the biopsy results were never located. The autopsy revealed a 7 cm mass in the right breast and a 2 cm mass in the left breast, both of which had an appearance clinically suggestive of carcinoma. The adrenal glands were completely replaced by tumor nodules. The heart weighed 195 gm and the posterolateral left ventricular wall and interventricular septum contained soft, white masses that ranged in size from 0.6 cm to 3.5 cm. There was no pericardial effusion or pericardial thickening. Of note, there were only two (right neck and supraclavicular) enlarged lymph nodes but no axillary lymph nodes; despite the large tumor burden in the breasts. A small

nodule was identified in the right lower lobe of the lung. The remainder of the internal organs were unremarkable. Microscopic examination of the breast masses revealed a primary non-epithelial breast neoplasm with involvement of the heart, lung and adrenal glands. Immunohistochemical analysis of the tumor was consistent with a large cell lymphoma of T-cell origin (CD 45 +, CD 3 +, CD 20 -, pancytokeratin -, CD 57 – and ALK1 –). Myocardial involvement included transmural infiltration, as expected from the grossly visualized masses, as well as focal permeation of the atrioventricular node, which was not associated with a grossly visible lesion. The enlarged lymph nodes were negative for lymphoma.

Primary breast lymphoma (PBL) is a rare form of extranodal non-Hodgkin's lymphoma accounting for less than 1% of all breast malignancies. Of these, the great majority will represent B-cell, rather than T-cell lymphomas. PBL is bilateral in up to 25% of the cases and the clinical presentation is similar to that of carcinomas of the breast, with the exception of slightly larger masses at the time of diagnosis. The growth is rapid, and several cases have been reported with recent negative mammograms, as in this case. Lymphoma has a high predilection to involve the heart, with an incidence of 25%, second only to lung carcinoma. Most cases with cardiac involvement are clinically silent and/or have non-specific symptoms until they present with sudden death.

The mechanism of sudden death related to carcinomas and lymphomas is often not determined, as these deaths generally are not considered 'unusual, unnatural or unexpected' deaths and therefore may not fall under the jurisdiction of the medical examiner or coroner. Known complications such as pulmonary emboli, treatment related problems, such as infection, or overall tumor burden are common enough processes that forensic pathologists typically don't perform autopsies. Even when performed in a hospital setting, it is unlikely that the hospital pathologist will examine the conduction system on such a case. As part of a thorough autopsy in a medical examiners office, the cardiac conduction system (in particular the atrioventricular node), is being examined more often and is occasionally revealing the underlying cause for the sudden death. Any foreign cell population, whether neoplastic or inflammatory in origin, in the atrioventricular node can precipitate an arrhythmia which may result in sudden death. In the presented case, not only were the cause and manner of death determined, but also the mechanism involved.

Breast Lymphoma, Atrioventricular Node, Sudden Death

G96 Use of Beta-APP Stain in a Case of Fatal Dog Attack

Paul L. Morrow, MD*, and Michael Rodriguez, MBBS, Department of Forensic Medicine, 42-50 Parramatta Road, Glebe, New South Wales 2037, Australia

After attending this presentation, attendees will understand the use of beta-APP histopathological stain to diagnose early central nervous system injuries.

Documentation of earliest stages of CNS injury is problematical. This presentation will impact the forensic community and/or humanity by making forensic pathologists aware of the use of beta-APP stain to document mechanism of death in cases where traditional autopsy techniques may be inadequate, and illustrate the use of this technique in a specific case with relatively short survival time.

β -APP is a protein that accumulates in damaged neurons and has been used to identify certain types of central nervous system injury. This study presents a fatal case of a dog attacking a two and one a half-year-old child who was found unconscious by her mother in the dog's mouth with the dog "shaking the child back and forth." The child's shirt was described as soaked with blood, and there was an undetermined, but "small," amount of blood at the scene. There was no active bleeding from wounds upon the arrival of first responders. The child survived unconscious, tachycardic and hypotensive, with minimal bleeding from the wounds, for about 90 minutes during transport to hospital in the ambulance.

Autopsy confirmed soft tissue injuries (bite marks) to the neck, including ligamentous injuries in the posterior nuchal region, a small defect in the left jugular vein and a small epidural hemorrhage at the level of the fifth cervical vertebra. There was no subdural or subarachnoid hemorrhage. Likewise, there were no obvious gross or microscopic injuries to the brain, spinal cord or other internal organs to document the mechanism of death. Positive β -APP staining of axons in the corpus callosum and cerebral white matter was found, often in a perivascular distribution, and there was rather diffuse positive staining of many neuronal bodies. Although axons stained positively in the corpus callosum, the predominantly perivascular pattern of positive β -APP staining suggested diffuse hypoxic injury to the central nervous system resulting from shock and hypotension.

The β -APP stain documented potentially lethal injury to the central nervous system in the absence of other specific anatomic findings, and gives some indication of the mechanism of death. Generally, it is considered that β -APP stain is positive as early as approximately two hours survival time. The documented survival time of one and a half hours is consistent with this, although it is somewhat earlier than often reported. This case illustrates the use of β -APP stain as an early marker of central nervous system injury before more traditional markers of injury may be obvious at autopsy.

Beta-APP, CNS Injury, Dog Attack

G97 The Postmortem Diagnosis of Diabetic Coma

Jørgen L. Thomsen, DMJ*, and Peter M. Leth, PhD, University of Southern Denmark, Winsløwparken 17, Odense, DK-5000, Denmark

After attending this presentation, attendees can expect to learn about a histology method that will make it easier to establish the postmortem diagnosis of diabetic coma and with a perspective to the significance of hyperlipidemia.

This presentation will impact the forensic community and/or humanity by significantly improving in the postmortem diagnosis of diabetic coma, but it is equally important to focus on the role of the lipids in the abnormal metabolism of diabetics and alcoholics.

The postmortem diagnosis of diabetic coma has always been difficult as one of the key markers of coma is a high glucose concentration, but this concentration is rapidly decreasing after death. Only few laboratories are able to quantitatively detect ketone bodies, and the diagnosis is usually based upon a combination of the history, the glycated hemoglobin concentration and a semi-quantitative detection of acetone.

It has long been known that in death due to diabetic coma there is a vacuolization of the proximal tubules of the kidneys. This vacuolization has until recently been believed to consist of glycogen, but it is now known that it represents an accumulation of triglycerides.

In a consecutive series of fourteen cases of diabetic coma, lipid staining was performed on cryostat sections of the kidneys. It was demonstrated in all of the fourteen cases that the vacuolization consisted of lipids. The sensitivity was thus 100 percent.

In alcoholic ketoacidosis, the lipid level in blood is high. So far, the authors have been able to perform lipid staining of one case of fatal alcoholic ketoacidosis and found the same phenomenon in the proximal tubules of the kidneys as in diabetic coma.

It is thus likely that the deposition of lipids in the proximal tubules is due to the high concentration per se and not increased permeability of the glomerulus as is seen in diabetics.

There has only been little focus on lipids in forensic medicine. One reason may be the need to do cryostat sections if lipids are to be demonstrated in the tissue. Otherwise they will be disguised as empty spaces due to dissolving in alcohol during tissue embedding.

Both in diabetic coma and in alcoholic ketoacidosis there are high levels of fatty acids and a disturbance of the metabolic balance that is influencing the citric acid cycle.

This study suggest that ketone body analysis should be done in cases of "fatty liver deaths" as there are indications that many of these deaths are due to the increased fatty acid concentrations following a binge and a subsequent development of ketoacidosis.

Diabetic Coma, Hyperlipidemia, Cause of Death

G98 Forensic Diaphanoscopy Imaging: A New Tool in Clinical Forensic Medicine

Beat Horisberger, MD*, University of Lausanne, Institute of Legal Medicine, 21 Rue du Bugnon, Lausanne, CH-1005, Switzerland; Sébastien Tanniger, School of Business and Engineering Vaud, HEIG-VD, 1 Route de Cheseaux, Yverdon-les-Bains, CH-1401, Switzerland; and Patrice Mangin, MD, PhD, University of Lausanne, Institute of Legal Medicine, 21 Rue du Bugnon, Lausanne, CH-1005, Switzerland

After attending this presentation, attendees will understand the principles of a new tool, the forensic diaphanoscopy imaging, and the benefits in comparison with more classical method (forensic diaphanoscopy), illustrated with practical examples of traumatic diagnosis in clinical forensic medicine.

This presentation will impact the forensic community and/or humanity by demonstrating how forensic diaphanoscopy imaging can facilitate the diagnosis of signs of violence on living adult, victims of aggression, or abused children.

The classical forensic diaphanoscopy method has been developed following the observation that there were no valuable methods to diagnose non visible hematomas on living subjects, such as adults who had been assaulted or abused children. This method has been used in Lausanne for over ten years in forensic clinical expertise. It is a complementary method to the clinical examination.

However, the probability of detecting a hematoma with this method (sensitivity) or the probability to diagnose correctly subcutaneous hematomas (specificity) depends on the training and the experience of the examiner. An insufficiently trained person should expect false positive or false negative results. The classical method of forensic diaphanoscopy is based on a subjective interpretation of the examiner. This is the reason why the forensic diaphanoscopy imaging technique, based on objective data, has been developed.

Compared to the classical method, forensic imaging diaphanoscopy has the following characteristics:

1. Use of an annular light source, aimed to integrate a centered video camera, and to increase the diagnostic reliability.
2. An integrated miniature video camera will help maintaining a database of analyzed traumas, and offer a source of pictures to be processed later by digital systems (computers).
3. The digital processing of the acquired picture will improve both sensitivity and specificity in detecting non-visible subcutaneous hematomas.
4. Automatic adaptation of the light source intensity, based on subcutaneous tissues thickness (not depending on body mass and corporal topography) and skin pigmentation.
5. Automatic exclusion of opaque zones due to intravascular blood.
6. Hematoma documentation using digital processing.

Forensic diaphanoscopy imaging represents a major advance compared to the classical method to diagnose traumas on living subjects. The technique is more user friendly and reliable, due to the use of technological assistance and computer information processing. Creating legal documentation is easier and images from the system can easily be

integrated in reports. This reliable investigation method can easily complete a clinical examination by making or confirming the diagnosis of suncutaneous hematomas that are not readily visible. This method is also useful in excluding this diagnosis. It is a non-invasive and easy to use tool. It is particularly useful when child abuse is suspected, when examining dark skinned persons where hematomas can be confused with skin color, or even among obese persons where deep hematomas do not appear or only appear after a significant period of time on the skin surface.

The aim of forensic diaphanoscopy imaging is to facilitate the diagnosis of signs of violence on living adult, victims of aggression or abused children.

Clinical Forensic Medicine, Diagnostic Imaging of Trauma, Invisible Hematoma

G99 “Drop Dead”: An Epidemic of Intravenous Fentanyl Deaths in Cook County, Illinois: 2005 to Present

J. Scott Denton, MD, Edmund R. Donoghue, MD, Mitra B. Kalelkar, MD, and Nancy Wu Chen, PhD, Cook County Medical Examiner's Office, 2121 West Harrison Street, Chicago, IL 60612-3705*

The goal of this presentation is to understand that fentanyl has suddenly appeared as an intravenous drug of abuse, and that medical examiners, public health officials, and emergency physicians should realize that clusters of sudden death may appear as an epidemic of fentanyl intoxications.

This presentation will impact the forensic community and/or humanity by demonstrating the response of the medical examiners office to a sudden onset and ongoing epidemic of sudden unexplained death, subsequently found to be from illicit intravenous fentanyl abuse. This has implications for public health in monitoring and quickly diagnosing clusters of sudden unexpected death in an urban population.

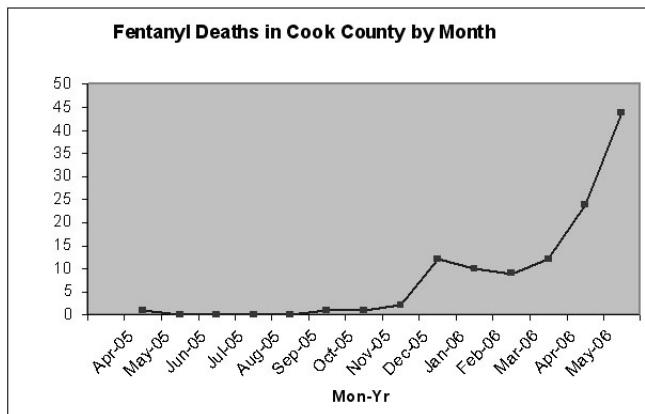

In November 2005 in Cook County, Illinois, an epidemic of intravenous fentanyl deaths began and quickly accelerated, and has not slowed as of June 2006. This epidemic of fentanyl intoxication in Cook County has not been previously described. Prior to 2005, fentanyl intoxication fatalities, or fentanyl-related deaths, in Cook County were almost exclusively from abuse or misuse of fentanyl transdermal delayed-release patches. Fentanyl is approximately 50 times more potent than heroin, and is a synthetic opiate used clinically during invasive medical procedures and for outpatient pain control through a transdermal patch delivery system. Some of the more unusual fentanyl intoxications in Cook County have been previously presented (Wu Chen, N, et al. Suicide by transdermal patch, AAFS abstract K19, Orlando, FL, 1999).

Cook County, Illinois, is a compact major metropolitan area of approximately 5.5 million people within an area of 950 square miles that surrounds and includes the city of Chicago. In December 2005 hospital emergency rooms began to report an increase of tight clusters of overdoses initially concentrated in the Near South Side of Chicago. In the emergency department setting, some of the survivors' urine toxicology testing results was positive for opiates from heroin, but some were not, even though all showed clinical signs and symptoms of a rapid acute opiate overdose. At the same time, fatalities occurring in these small clusters of apparent opiate intoxications were brought to the Cook County Medical Examiners Office for examination.

Death scene investigations and histories of these fatalities often showed a rapid collapse after the injection and the term “Drop Dead” was coined on the street to describe this new “tainted heroin.” The police used

the local media to warn the public about a deadly heroin product mixed with fentanyl. Syringes found next to the victims were sent by the Chicago Police to the Illinois State Police Crime Laboratory for rapid testing, revealing the presence of fentanyl. The fentanyl was purchased from street corner drug sellers as a white powder, in amount and consistency similar to heroin. Prior to this epidemic, fentanyl was not routinely tested for in the Cook County toxicology laboratory. A fentanyl testing protocol was begun for all suspected drug intoxication deaths after the epidemic was discovered, and then tested for retrospectively to September 2005.

Data of fentanyl intoxication deaths were retrospectively collected for the years 1995 through early 2006 from the Office's database. As numbers of fentanyl intoxications accelerated in 2006, data was collected and analyzed prospectively for entry into a real-time CCME Fentanyl Intoxication Database. For January 1995 to November 2005, the CCMEO averaged four cases per year (range 1 (1995, 2000) to ten (2002)). Criteria for certification for fentanyl intoxication deaths were similar to the office's criteria for opiate-related deaths. Intravenous fentanyl intoxication deaths from April 2005 through May 2006 are shown:

Fentanyl-related deaths initially appeared in November (2), accelerated in December (12), stabilized in January (10) and February (9), but then accelerated again through March (12), April (24) and May (44). Initial June data shows this upward trend is continuing. Of the fatalities from April 2005 through May 2006, 96 were male and 20 female. The average and median ages were 40 years, with a range of 16 to 61. The average concentration of fentanyl in postmortem peripheral blood was 23 ng/ml (median 17; range 0.9 to 134). These 116 fentanyl epidemic deaths through May 31, 2006, were further subcategorized as fentanyl intoxication without other drugs (43, 37%); fentanyl and opiate intoxication (20, 17%); fentanyl and cocaine intoxication (29, 25%); fentanyl, opiate and cocaine intoxication (6, 5%); fentanyl, opiate, cocaine and alcohol intoxication (3, 3%); fentanyl and alcohol intoxication (6, 5%); fentanyl, alcohol and opiate and intoxication (5, 4%); and fentanyl, cocaine and alcohol intoxication (4, 3%). This data shows that fentanyl is being sold in Chicago predominately as a single drug, not as a so-called “tainted heroin” product. But it also shows that fentanyl is being abused in combination with heroin or cocaine, although less frequently. Other drugs detected with fentanyl could either represent the purchase of a combined product, or the concurrent use of each individual drug. The origin of this illicit white powder fentanyl and the reason for its rapid and continued influx into the Chicago land area is currently under intense investigation by numerous government agencies.

Fentanyl Intoxication, Sudden Death, Cook County, Illinois

G100 Bidding for Poison: The New Availability of Poisons and How to Use Them

Rebecca A. Irvine, MD, University of New Mexico, Office of the Medical Investigator, MSC 11 6030, University of New Mexico, Albuquerque, NM 87131-0001*

After attending this presentation, attendees will have an awareness of the facilitative role of the Internet in obtaining and using deadly poisons and the impact this will have on forensic investigators, pathologists, toxicologists, and computer criminologists.

This presentation will impact the entire forensic community by highlighting the ease of access to deadly poisons and guidelines for lethal use on the Internet. In cases of an apparently negative autopsy and/or vague allegations of poisoning by family, the threshold of suspicion has been raised by almost universal access through the Internet. Strychnine, the poison inadvertently obtained for this study, should also be considered in unexpected death in athletes.

An online bid was placed on a collection of antique pharmaceutical bottles, some of which were known to have originally contained strychnine sulfate, and which were purchased for an extremely reasonable sum.

The bottles arrived by UPS Ground, left on the doorstep. While this seemed unusual at the time, the seller was clearly paying homage to the prohibition of sending toxins through the USPS. There were several bottles of strychnine sulfate, most of which unexpectedly contained the pure substance, a fact verified by the Toxicology office associated with the Office. The seller had no knowledge of the author's occupation or intent for the purchase. There was no communicated warning.

Strychnine has a long and colorful history, becoming available in the early 19th century as a "tonic" for people and a poison for pests (and, arguably, for people). It binds at stimulatory receptors in the central nervous system as well as the inhibitory receptors, resulting in a massive over-transmission of signals. Although caution has always been recommended with its use, the therapeutic applications were myriad and included impotence, alcoholism, constipation and prolapsed uterus. It may have had a limited clinical role in the treatment of surgical shock and congestive heart failure. It is to this day on the list of banned substances for athletes, having been implicated in the win of the 1904 marathon (along with raw egg and brandy, which carry their own risks). Eventually, of course, it was recognized that the risk far exceeded the therapeutic benefit and its use was abandoned. It is currently available to athletes as the herbal *nux vomica*.

It is hardly a perfect poison for homicide because of its bitter taste and short delay in causing respiratory muscle paralysis. Acute poisoning may be treated symptomatically. It is, however, one of the most potent poisons known and may be administered through multiple routes, including dermal. The horrific terminal phase of convulsions may be attractive to those with homicidal intent.

Strychnine is tightly regulated but widely available as a rodenticide. The latter would be particularly unpalatable in the volume required for homicidal intent. The safety recommendations for underground rodenticide use are comparable to biosafety standards for autopsy.

In his classic and arguably still relevant chapter on homicidal poisoning, Adelson cites both access and knowledge of use as prerequisites for the poisoner. Both are within reach of those accomplished in the use of the Internet.

A disturbing study was conducted by the California Poison Control System (Look what I found! Poison hunting on eBay, *Clin Toxicol* (Phila). 2005;43(5):375-9)). Over a 10-month period, 125 individual products too dangerous for commercial use were identified on online auctions; 24 were "supertoxic," including strychnine. Even a cursory search identifies guides to poisoning, including books in the popular press, some intended as a reference for crime novelists.

All medical examiners have undoubtedly had cases that were frustratingly negative for a cause of death. In addition, almost all have

likely had cases where relatives alleged poisoning, although no access or specific substance was implicated.

Medical examiners, previously protected by the obstacle of access to deadly poisons, need to lower their indices of suspicion for cases of poisoning. Courtesy of the Internet, access and knowledge of use are widely available. Not only must appropriate toxicological analysis be considered and performed but also law enforcement investigators with computer crime experience must be involved in a timely fashion.

Poison, Access, Internet

G101 Cluster of Fentanyl-Tainted Heroin Deaths in a Three-Week Period in Maryland

Mary G. Ripple, MS, MD, Barry S. Levine, PhD, and Rebecca Jufer-Phipps, PhD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD 21201; Erin Artigiani, Center for Drug Abuse Research, 4321 Hartwick Road, Suite 501, College Park, MD 20742; Suzanne Doyon, MD, Maryland Poison Center, 20 North Pine Street, Baltimore, MD 21201; and David R. Fowler, MD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD 21201*

After attending this presentation, attendees will understand the public health significance of cooperative efforts between the Office of the Chief Medical Examiner (OCME), the Maryland Drug Early Warning System (DEWS) at University of Maryland's Center for Substance Abuse Research (CESAR), the Maryland Poison Center (MPC), and the Maryland State Police (MSP) in the ability to detect a cluster of fentanyl-tainted heroin deaths in a short period of time.

This presentation will impact the forensic community and/or humanity by presenting the problems of detecting fentanyl by routine opiate screens and by emphasizing the importance of drug surveillance systems to detect emerging drug trends.

Fentanyl is a fast-acting, highly potent synthetic opioid agonist that is approximately 50-100 times more potent than morphine. Overdose effects occur rapidly and death occurs primarily from respiratory depression. Regional outbreaks of "super potent heroin" have been reported in the past. The outbreak in April and May 2006, of which this presentation is a part, included over 120 deaths in the Midwest, Northeast, and Mid-Atlantic regions. The primary markets included Chicago, IL, Detroit, MI, Philadelphia, PA, and Camden, NJ. In May 2006, authorities seized a fentanyl laboratory in Toluca, Mexico and this was the suspected source of the tainted heroin. A by-product of illicit fentanyl manufacture by the "Siegfried Method" is 4-Anilino-N-Phenethyl-Piperidine (4-ANPP).

Fentanyl is available by prescription as a transdermal patch, an oral lozenge and an injectable form. It is manufactured illicitly as powder or tablets. Fentanyl is abused in any of the prescribed or illicit forms. More creative forms of abuse include, wearing multiple patches, scraping the drug off the patches and snorting or injecting it, and chewing and/or swallowing the patches. Fentanyl is not detected using standard urine opiate immunoassays. As a result, negative tox screen results do not rule out a fentanyl overdose. Without performing a specific fentanyl immunoassay, the accepted detection methodology for the blood or urine is gas chromatography. However, detection can be problematic in that fentanyl is a late eluter and is usually present in very low concentrations. At the OCME, fentanyl was detected in the biological specimens following an alkaline extraction and analysis by gas chromatography-nitrogen phosphorus detection. Fentanyl was confirmed by full scan electron ionization gas chromatography-mass spectrometry (GC-MS). Fentanyl was quantitated by GC-MS, selected ion monitoring.

There were 15 fentanyl related deaths in the State of Maryland from 1/1/06 until the writing of this report and most were a result of the abuse of the patch. A cluster of five fentanyl-tainted heroin deaths occurred from

4/22/06 to 5/12/06. The MPC and CESAR initially reported to the OCME a series of 6-8 possible fentanyl-tainted heroin overdoses from the Eastern Shore of Maryland two days after the autopsy of the first suspected death. That individual survived for two days in the hospital where opiate confirmation was negative. Analysis of evidence from this scene by the local MSP crime lab revealed fentanyl and procaine. These results provided the first solid evidence that fentanyl was involved in this outbreak. At that time the OCME toxicology lab was alerted to look specifically for fentanyl. At a later date, the MSP crime lab also confirmed 4-ANPP in the same evidence. Thus far there are five confirmed fentanyl related deaths and three other suspected cases are currently under investigation. The age range of the deceased was 22 to 32 years old, four of five were Caucasian and four of five were male. Fentanyl concentrations ranged from 0.001 to 0.049 mg/L. One of five cases was positive for fentanyl only, three of five were positive for heroin, four of five had morphine in their system, four of five had cocaine in their system, and five of five scenes had intravenous drug paraphernalia. The areas of the state involved included Wicomico (1), Somerset (1), and Howard (1) counties, and Baltimore City (2).

Medical Examiner/Coroner's offices need to be aware of the limitations in detecting fentanyl and in cases where investigation points to a drug death and routine toxicology is negative, the toxicology lab needs to be informed of the possibility of fentanyl. A cooperative effort between the Medical Examiner/Coroner's offices and state drug surveillance systems is critical in order to detect emerging drug trends of public health significance.

Fentanyl, Heroin, Tainted

G102 Suicidal Caffeine Overdose

Wendy M. Gunther, MD, Tidewater District Office of the Chief Medical Examiner, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510; Connie M. Luckie, PhD, Department of Forensic Sciences, Commonwealth of Virginia, 830 Southampton Avenue, Suite 400, Norfolk, VA 23510; and Karen B. Looman, DO, Tidewater District Office of the Chief Medical Examiner, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510*

After attending this presentation, attendees will learn of an approach to the evaluation of a multi-drug overdose suicide by history and presentation. Recognition of the symptoms and signs of caffeine poisoning in a case of suicidal overdose.

This presentation will impact the forensic community and/or humanity by recognizing the existence of the abuse of caffeine in a suicidal overdose, how to assess the signs and symptoms of caffeine overdose, and recognizing the signs and symptoms of other drugs when assessing a multi-drug overdose.

A 44-year-old woman with a history of eight previous psychiatric hospitalizations and multiple previous suicide attempts was brought to the emergency room by her daughter at 9:20 p.m. on the day before her death. Her daughter related that she had made a suicide attempt by taking a number of prescription and nonprescription pills.

She was alert when she arrived, but her daughter gave the history for her. She said her mother had taken large but unspecified amounts of Cymbalta (duloxetine, an antidepressant), Vistaril (hydroxyzine, an antihistamine with central nervous system sedative properties), Relacor (a dietary supplement chiefly composed of water-soluble vitamins and alleged to regulate fat metabolism and homocysteine production), Seroquel (quetiapine, an antipsychotic sometimes used as an antidepressant), and an over-the-counter diet medicine, Stacker 2 (a diet medication composed of camellia sinensis white and yellow leaf polyphenols, yohimbine alkaloids derived from Pausinystalia Yohimbe bark, 6', 7'-dihydroxybergamottin, capsaicin, and anhydrous caffeine [150 mg per pill]). It was believed that she might also have taken trazodone (an antidepressant medication commonly sold under the brand name Desyrel).

She accepted PO charcoal while she was still alert, but rapidly became unresponsive and went into respiratory failure, requiring emergent intubation. In short order, her hypotension became so profound that she required a dopamine drip. Her pupils were symmetrically dilated to 4 to 5 mm. An initial episode of pulselessness at 0005 AM resolved with cardiopulmonary resuscitative efforts. Levophed (norepinephrine bitartrate, a sympathomimetic vasoconstrictor) and dopamine were maximized to maintain a mean arterial pressure of 65 mm Hg. At 0153, she became pulseless again, and remained in pulseless electrical activity during resuscitation until 0217. She maintained a pulse for thirteen minutes, but became pulseless again at 0230; with the administration of 40 mg of vasopressin, she regained a pulse at 0233. Following this third cardiac arrest, with her pupils dilated and minimally reactive, the family requested full resuscitative measures be discontinued. She survived in that condition until her final cardiac arrest at 0726. She was pronounced dead at 0736.

At autopsy, she was a well developed, moderately obese (68", 220 lb) woman with pale conjunctiva, without congestion of the face and neck. Numerous dental caries were visible on limited examination of the oral cavity. An abdominal scar correlated with internal signs of a remote cholecystectomy and gastric bypass. There were no external wounds and no wrist scars. Internal visceral examination was significant only for diffuse fine renal cortical granulation in the absence of significant heart hypertrophy (heart weight 359 gm), and a 3" abdominal fat layer, measured 2" below the umbilicus. Two quarter-inch foci of subgaleal hemorrhage were identified, and a thin film of subarachnoid hemorrhage coated the left cerebral hemisphere and both occipital lobes.

Histologic examination showed evidence of old ischemic disease in the form of delicate, ramifying collagenous replacement of subendocardial myocardium, to a degree surprising for the gross exam of the heart. There was slight emphysematous change of the lungs, sclerotic glomeruli of the renal cortex, and superficial subarachnoid hemorrhage confirmed in the brain, without evidence of any arteriovenous malformation. No etiology for the subarachnoid hemorrhage was determined.

Toxicology performed on hospital admission blood was reported negative for trazodone, quetiapine, methamphetamine or byproducts, cocaine or byproducts, opiates, or alkaline extractable drugs. Ethanol was reported positive at 0.05% by weight by volume. Diazepam was present at a concentration of 0.07 mg/L without nordiazepam. Caffeine was present at the extremely high level of greater than 180 mg/L.

Caffeine poisoning is a rare cause of fatal overdose. Caffeine use is extremely widespread, to the degree that many toxicologic laboratories do not test for it in routine specimens. Caffeine toxicity without fatal poisoning is frequently reported. The signs and symptoms of fatal caffeine poisoning in light of this case, and, in comparison to opiates, cocaine, and antipsychotic and antidepressant drugs, will be discussed.

Discussion: Review of this cases will illustrate the forensic methods used to elucidate multiple drug death with overlapping signs and symptoms.

Suicide, Caffeine, Multi-Drug Overdose

G103 Abuse of Prescription Narcotics: A Look Beyond Prescription Monitoring Programs

Gretchen A. Grisbaum, JD, Quick & Associates, Inc., 21449 Marion Lane, Suite 6, Mandeville, LA 70471; and Karen Ross, MD, Jefferson Parish Forensic Center, 2018 8th Street, Harvey, LA 70058*

After attending this presentation, attendees will have a broader understanding of the widespread problem of prescription narcotic abuse. Additionally, the attendee will understand the liability of physicians, pharmacists and pharmaceutical companies with regard to the dispensing of schedule II narcotics. Finally, the attendee will be introduced to an alternative means to prescription monitoring programs for dealing with narcotic abuse.

This presentation will impact the forensic community and/or humanity by informing the forensic community of the ongoing problem of schedule II narcotic abuse in this country while offering an alternative to currently utilized prescription monitoring programs used in some states. This issue affects physicians, attorneys, law enforcement, and the community as a whole.

Prescription narcotics enable individuals to undergo surgery and relieve pain for millions of Americans who suffer from legitimate chronic pain. While millions of people suffer legitimately from pain, many others obtain prescription narcotics for illicit purposes. This non-medical use of prescription medications is a widespread problem and a serious public health concern. In order to combat the illegal use of prescription narcotics, many states have established prescription monitoring programs (PMPs). These programs collect data on the dispensing of certain narcotics from physicians and pharmacies and disseminate it to regulatory and law enforcement agencies. While these state run PMPs are an asset to the investigation of illegal narcotic use, various professional and special interest groups voice concerns about the application of prescription monitoring programs.

This presentation will offer an alternative to the prescription monitoring program after a discussion of the factors involved in dispensing prescription narcotic medications. An overview of narcotics and their potential use and abuse will be addressed, as well as sources of illicit prescription narcotics for abuse. The physician duty of care owed to patients being treated for pain will be discussed. Included in this section will be an overview of the widespread problem of the under-treatment of pain in the United States, as well as the serious consequences of prescription drug abuse in this country.

Deaths due to the use/abuse of prescription narcotics account for an alarming number of deaths in many areas of the country as evidenced by the autopsy results from Jefferson Parish, LA where in 2005, 22% of autopsy cases were due to the acute effects of drugs - many involving Schedule II narcotics often in combination and usually accidental. Additional data on these cases will be presented. A third component of this presentation will assess the duty owed to patients by pharmaceutical companies who manufacture prescription medications. This section will address the liability of drug manufacturers for failure to warn, as well as liability for negligent marketing. The duty of care owed by pharmacists to patients will also be discussed including the scope of the pharmacist's duty, in addition to recent developments in the approach to pharmacist liability.

An overview of current prescription monitoring programs will be provided with particular attention to issues of privacy and confidentiality of medical information. This section will also encompass the successes and limitations of these programs and federal initiatives regarding prescription monitoring programs. Finally, improvements to the current system of state prescription monitoring programs will be suggested including a proposed alternative method of addressing prescription drug abuse in the United States.

Narcotic, Prescription Monitoring Programs, Abuse

G104 Murder By Poison: Experiences of a Medical Examiner's Office

Christopher Swalwell, MD, Office of the Medical Examiner,
5555 Overland Avenue, Suite 1411, San Diego, CA 92123*

The goal of this presentation is to review the number and nature of homicidal poisonings encountered by the San Diego County Medical Examiner's Office during the last 20 years. The audience should gain a better appreciation of the complexities of investigating homicides resulting from poisoning and the circumstances and nature of such deaths.

This presentation will impact the forensic community and/or humanity through a better understanding of the types and frequencies of homicidal poisonings encountered in a large Medical Examiner's Office.

These experiences may be helpful in future investigations of murder by poisoning.

Despite the common portrayal of murder by poisoning in movies and television, deaths from homicidal poisoning are rare. Since the scene and findings can be subtle, the investigation of such deaths may be challenging. The purpose of this paper is to present the nature and findings of homicidal poisonings seen in a large Medical Examiner's Office over a period of 20 years. The San Diego County Medical Examiner's Office covers a population of approximately three million people.

Poison can be defined as a substance that causes injury, illness or death primarily by chemical means. As such, a poisoning could involve any type of chemical, drug or medication and could be ingested, injected, inhaled or even absorbed through the skin. The Medical Examiner's database from 1986 to 2005 was searched to identify all homicides that involved some type of poisoning, overdose or intoxication. This was done in several ways, including homicide queries for key words and visual scanning of the causes of death. Cases in which the cause of the death was not a direct result of a poison, medication or drug administered by another person were excluded. Also excluded were law enforcement restraint deaths and other deaths in which the victim was intoxicated or under the influence of a drug or medication at the time they were killed by other means. In addition, cases of fire related deaths and deaths in hospice patients given high doses of medications for end of life care were excluded.

During this time period, there were a total of 3601 homicides. Only 12 cases were identified that were the result of some type of drug, medication or chemical overdose or intoxication. This represents 0.33% of the homicides and is consistent with previous reports of 0.14 - 0.5%.

Homicidal poisonings in general will be briefly discussed, and the history and circumstances of the 12 cases will be presented along with the toxicologic findings. A variety of substances were used, and in some cases more than one agent was administered. The nature of the perpetrators and outcome of the cases will also be reviewed.

Homicidal poisonings are rare, but by their very nature tend to grab the attention of the public and news media. From an investigative standpoint they may be difficult to detect, and one may wonder how many cases are missed. These cases reveal a variety of circumstances, substances and perpetrators indicating that there is no stereotype for murder by poison.

Murder, Poison, Homicidal Poisoning

G105 Vaccine Death: A Rare Case of Anaphylactic Shock After Hexavalent Immunization

Stefano D'Errico, MD, Francesco Maria Morreale, MD, and Raffaella Bisceglia, MD, Institute of Legal Medicine, University of Foggia, Ospedali Riuniti, via L.Pinto 1, Foggia, 71100, Italy; and Rossi Giuseppina, MD, Institute of Legal Medicine, University of Siena, Policlinico Le Scotte, Siena, 53100, Italy*

After attending this presentation, attendees will learn of a rare case of fatal anaphylactic shock after hexavalent (against diphtheria, tetanus, pertussis, poliomyelitis, Haemophilus influenzae type B and hepatitis B) immunization in a three month-old female white infant is presented. The aim of the paper is to alert scientific community on reactogenicity of recent hexavalent formulation of vaccine.

This presentation will impact the forensic community and/or humanity by demonstrating that any death that occurs within a few days of vaccination to be autopsied using immunohistochemical stainings, toxicological analysis on urine and blood specimens and detection of femoral blood concentration of mast-cell Beta-tryptase to rule out anaphylactic shock.

This case presentation concerns a first-born child, delivered at the 41st week of gestation by caesarean delivery, with a birth weight of 3.400 g and Apgar scores of 9-10. The mother related no significant family history, an unremarkable pregnancy and good health of the baby, who was bottle-fed. At three months of age the female infant received a hexavalent immunization during a morning clinic visit. The mother stated that a few hours after the immunization the baby had difficulty feeding. Early in the afternoon the clinical condition of the baby got worse with the onset of severe dyspnea, so she was immediately taken to the emergency department of the local hospital. A state of shock with critical acute respiratory failure was diagnosed. The baby appeared pale and unresponsive. The baby was hypotensive (systolic pressure 50 mmHg) and tachycardic (180 bpm) with an undetectable diastolic pressure. Laryngoscopy was unremarkable. Laboratory tests revealed the presence of hyper-eosinophilia and metabolic acidosis (pH 7.154) with blood desaturation (pO₂ 75.9 mmHg) and compensatory hypocapnia. Repeated administrations of adrenaline by aerosol were given along with intramuscular corticosteroids. Despite the aggressive intervention the infant died two hours after arriving at the hospital.

A complete postmortem examination was performed two days after the death. External examination was unremarkable, except for the immunization puncture site on the left thigh. The body was of a three month old, well-developed and well-nourished, white infant with a body weight of 4930 gr and body length of 55 cm. Internal examination was unremarkable except for lungs presenting white foam in the main bronchi. Histological examination revealed mild cerebral oedema, and a shock histomorphology of the main organs (lungs, liver and kidneys). Immunohistochemical analysis revealed the presence of numerous degranulating mast-cells in the pulmonary parenchyma. Toxicological analysis of blood and urine specimens for therapeutic and non-therapeutic drugs were unremarkable. Postmortem measurement of mast cell β-tryptase in femoral blood was determined using the AA5 antibody ELISA; high concentrations, more than 10 ug/l were recorded (11.3 ug/l).

Adverse events following immunization are defined as medical incidents that take place after an immunization. Serious adverse events after vaccination have generally been defined as those adverse events that result in permanent disability, hospitalization or prolongation of hospitalization, life threatening illness, congenital anomaly or death. They are generally associated with the inherent properties of the vaccine (vaccine reaction) or some error in the immunization process (program error). The event could also be totally unrelated but only temporally related to immunization (coincidental event). The use of combination vaccines is an ideal way to simplify the simultaneous administration of multiple vaccines, reducing the number of injections, and may also be the most effective way of ensuring high compliance rates to complex immunization schedules. Recently, parental concern about polivalent vaccines has become increasingly prevalent. Hexavalent vaccine has been developed for primary booster vaccination of infants against diphtheria, pertussis, tetanus, poliomyelitis, Haemophilus influenzae type B and hepatitis B. Post marketing study confirmed the safety and immunogenicity of hexavalent vaccine as an alternative to other licensed vaccines. Members of the European Agency for the Evaluation of Medical Products in 2003 investigated whether there might be a link between hexavalent vaccines and some cases of sudden infant deaths occurred after immunization. It was concluded that there was no significant benefit/risk profile of these products, and, therefore, no changes in the present conditions of use were recommended. SIDS, viral infection, metabolic disorders, allergic reactions or airway obstruction were plausible but were not definitely proven to have been the cause of death. Vaccine associated anaphylaxis is a rare occurrence with only few cases reported despite the million of doses administered, giving a relative risk of 0.65 cases per million doses. It is not always clear which component of vaccine is involved in the anaphylactic reaction (antigens, preservatives, adjuvants, manufacturing residuals). Postmortem measurement of mast cell β-tryptase in serum is the only possible means of diagnosing or confirming death due to anaphylactic

shock because autopsy findings after acute anaphylactic death are generally non-specific; a cutoff value of 10 ug/l has been established to be optimal, with a sensitivity of 86% and specificity of 88%.

Hexavalent Vaccination, Mast-Cell Beta Tryptase, Anaphylaxis

G106 Pattern of Injury in Child Fatalities Resulting from Child Abuse

Ann H. Ross, PhD, North Carolina State University, Department of Sociology and Anthropology, CB 8107, Raleigh, NC 27695-8107; Suzanne M. Abel, PhD, Charleston County Coroner's Office, 4050 Bridgeview Drive, North Charleston, SC 29405; Deborah Radisch, MD, MPH, Office of the Chief Medical Examiner, CB 7580, Chapel Hill, NC 27599-7580; Beth Murnane, MD, Sunrise Pediatric Associates, 3909 Sunset Ridge Road, Suite 103, Raleigh, NC 27607; and Sheena Harris, BA, and Kelsie Ballance, North Carolina State University, Department of Sociology and Anthropology, CB 8107, Raleigh, NC 27695-8107

After attending this presentation, attendees will understand some of the contributing factors and demographic characteristics in child fatalities due to abuse.

This presentation will impact the forensic community and/or humanity by assisting the forensic community/humanity in identifying key elements in maltreatment child fatalities.

When evaluating injuries in young children, physicians should consider nonaccidental trauma as an etiology of trauma. According to the U.S. Department of Health and Human Services, in 2002, an estimated 1,500 children died of maltreatment. Of these, 36 percent were as a result of neglect, 28 percent were victims of physical abuse, and 29 percent were due to multiple types of maltreatment. In 2003, children younger than four years old accounted for 79 percent of all maltreatment fatalities, with 44 percent of these deaths occurring in infants (DHHS 2005). The purpose of this study is to further examine the pattern of bony injuries in child maltreatment fatalities, with an emphasis on the prevalence of antemortem fractures and the presence of associated perimortem fractures. The sample was 130 male and female children, ages 0 to six years of age. The majority of the data were collected from the case files of the NC Child Fatality Prevention Team at the Office of the Chief Medical Examiner in Chapel Hill North Carolina (n = 120). An additional ten cases were included from the Charleston County Coroner's Office, Charleston, SC. Six age categories were used in this study: 1 (0 - 3 months), 2 (4 - 6 months), 3 (7 - 9 months), 4 (10 - 16 months), 5 (17 months - 2 years), 6 (2 - 6 years). Each individual's lesions were documented and categorized into one of four general body loci (1 = craniofacial, 2 = thoraco/abdominal, 3 = other, 4 = multiple). The prevalence of trauma and distribution of injury patterns were tested for independence and significance for biological and demographic categories (e.g. age, sex, race, month of death) using simple frequencies and Chi-square tests. In this study, the peak age categories of death were 0-3 months (23 %) and two – six years (21.5 %), with 50 percent of deaths occurring in infants nine months old or younger. The two different age categories could reflect newborn stress and coincide developmentally with toddlers seeking independence, respectively. Black males were the most numerous victims. Deaths occurred most often in the month of December. The body locus most frequently affected was the craniofacial area, 55 percent, usually the result of blunt force trauma (abusive head trauma). Notably, ante- or perimortem fractures were not usually associated with known abuse deaths. In this study, eighty percent of the cases did not show any antemortem fractures. Thus in cases of suspected abuse, radiographic skeletal surveys may not be an effective method for identifying or predicting the possibility of abuse, which suggest that current detection techniques need to be reevaluated.

Child Abuse, Fatalities, Injury Pattern

G107 Histopathology of Antemortem Infant Bone Fractures: Estimation of Time Since Insult

Murray K. Marks, PhD, University of Tennessee, Department of Anthropology, 250 South Stadium Hall, Knoxville, TN 37996-0720; and Darinka X. Mileusnic, MD, PhD, Regional Forensic Center, University of Tennessee Medical Center, 1924 Alcoa Highway, Knoxville, TN 37920*

After attending this presentation, attendees will understand the gross, radiologic and histological signatures of antemortem (chronic) and perimortem (acute) infant bone fractures associated with child abuse and apply a general timetable to better estimate “time since insult” for wounds.

This presentation will impact the forensic community and/or humanity by providing a means of accurately dating antemortem fracture times, the pathologist and investigating team serving the pathologist can better pinpoint the association of a victim to suspect. This association (or lack thereof) will provide a date line to when wounds may have been received prior to death and help establish a history and pattern of abuse.

Autopsy protocols that allow only macroscopic and radiological evidence fail to provide adequate information about wound diagnosis and time since insult. The obvious importance of recognizing and evaluating evidence of this violence in cases of suspected child abuse is necessary to gain an appreciation a clear understanding of vulnerable bone, fracture site biomechanics and wound healing processes crucial to causation and response. Klotzbach and coworkers (2003) first qualified the radiological and histological signatures relevant to “time since insult” indicators and this research follows that protocol and the procedures of Marks and coworkers (2005) by expanding those diagnostic criteria of for microscopically qualifying and quantifying osseous apposition rates at various postmortem intervals. The rich cellular osteogenic environment characteristic of growing bone demonstrates a unique response when compared with static adult bone, regardless of location.

Twenty antemortem “healing” and five perimortem occult (hidden) and acute fractures from ribs and various appendicular bones from four infant victims were radiographically and histologically assessed for degree of bony response. The specimens were seized at autopsy and represent various stages of healing. All were prepared as undecalcified dry thin sections using normal petrographic methods. Both dissecting and light microscopy and SEM were utilized to document, diagnose/qualify and quantify defects.

Longitudinal and cross sections taken through wound sites reveal telltale structural remodeling correlating to chronology. These include the location and degree of woven “blastic” bone proliferation during conversion and obliteration of the comminuted byproducts of the hematoma soon after trauma, subsequent manifestation of the transformation of the initial solid callus into bone and finally, full mineralization and “clastic” remodeling of the callus. Besides recognition of these qualitative events, the ability to recognize, document and radiograph the wound at autopsy are described with a method for harvesting, processing for histology and the manner of embedding and sectioning for light and scanning electron microscopy. Finally, while validation of these results was performed using light and SEM, utilization is made by dissecting microscopy.

Like previous research, this study demonstrated a detailed continuum of bone healing in rib and diaphyseal fracture calluses and among diaphyseal surface woven bone proliferation. These data may imply one of three isolated or correlated scenarios: differential inter-bone response to similar forces causing breakage/trauma, differential wounding forces or chronological specificity in wound appearance.

Histology, Child Abuse, Bone Fracture

G108 The Likelihood of Inflicted Injury Is Better Evaluated by the Use of Inconsistent Histories With the Constellation of the Triad of Findings: Subdural Hemorrhage, Brain Swelling, and Retinal Hemorrhages

M.G.F. Gilliland, MD, Brody SOM at ECU, Department Pathology and Laboratory Medicine, Brody 7 S 10, Greenville, NC 27858*

After attending this presentation, attendees will learn the value of the use of inconsistent histories obtained by investigation as well as autopsy findings in determining the likelihood of inflicted injury in children.

This presentation will impact the forensic community and/or humanity by confirming that evaluating histories and autopsy findings is a reliable method of ruling in and ruling out many possibly inflicted injuries in children.

Hypothesis: The reliability of the methods used to identify inflicted injury deaths in children has been called into question in the global community. Reviewing a series of child deaths can test the use of the constellation of inconsistent histories with autopsy findings to diagnose such deaths.

Synopsis: Correctly distinguishing inflicted from inadvertent injury and from natural disease is critical to the criminal justice system. Certain patterns of injuries found clinically or at autopsy have been proposed to identify injuries inflicted on children. An observational study of the neuropathology of inflicted head injury in infants and children by Geddes et al in 2001 reported the frequent finding of: subdural hemorrhage, increased intracranial pressure, and retinal hemorrhages. Others have advocated use of this triad of findings to make the diagnosis of inflicted injury. A nursing education website asserts, “The triad of subdural hematoma, cerebral edema, and retinal hemorrhage represents a diagnosis of SBS (Shaken Baby Syndrome)”.

Histories have been important in identifying inflicted injury. Inquiry into the phenomenon of absent or fluid histories in the presence of subdural hemorrhages and extremity fractures led to the original recognition of battered children.

A study of 169 child deaths compared the patterns of ocular and systemic findings in children dying as the result of inflicted injury with those found in injuries from motor vehicle collisions, falls, and various asphyxial deaths and in natural disease. Inflicted injury was distinguished from accidental injury, undetermined causes, and natural disease by investigation of medical and social history, and circumstances surrounding collapse as well as autopsy findings.

The validity of using a limited subset of histories and a limited subset of autopsy findings (the triad) to identify inflicted injury was assessed using data from the study. The immediate causes of death included: 76 (45%) intentional injuries, 36 (21%) inadvertent injuries, 47 (28%) natural causes, and 10 (6%) undetermined causes.

The triad of findings of subdural hemorrhage, brain edema, and retinal hemorrhages was seen in 47 of the total 76 (62%) inflicted injury deaths and in eight accidental deaths of the total 36 (22%). The triad was not seen in any of the 46 natural deaths or any of the 10 classified as undetermined deaths.

The sensitivity of finding inconsistent histories with the presence of the triad was 80%. The negative predictive value of finding a consistent history when the triad was absent was 88%. The relative risk of the triad being found with an inconsistent history was 4.56 with confidence limits of 2.53-8.20 and a P-value << 0.01.

Finding the triad with more than one injury history showed good sensitivity (85%). The negative predictive value of the finding was 87%. The relative risk of the presence of the triad with more than one injury history was 3.49 with confidence limits of 1.77-6.90 and a P-value << 0.01.

In these subsets, consistent histories included confessions as well as impartial information about events preceding injury. Specificity in these cases was 69% and the positive predictive value was 56%.

Similarly, certain unusual "multiple histories" became clear when further investigated. Since "more than one history" was used in defining the subset, these unusual cases yielded a calculated specificity of only 48% and positive predictive value of 44%.

Summary: Subsets of histories and autopsy findings can be reliably used to identify deaths which are more likely to be the result of inflicted injury - deaths with an inconsistent history and the autopsy findings include the triad of subdural hemorrhage, brain edema, and retinal hemorrhages. With a consistent history and no triad, inflicted injury is unlikely. With an inconsistent history, or multiple histories, and the presence of the triad, inflicted injury is likely. Thorough investigation and complete autopsy findings must be used to establish whether or not a particular child's death was caused by inflicted injuries.

Triad (SDH, Brain Edema, RH), Inflicted Injury, Retinal Hemorrhages

G109 Compressional Asphyxia Due to Prone Restraint Hold in a Child

Robert F. Corliss, MD, Andrew M. Baker, MD, and Kathryn K. Berg, MD, Hennepin County Medical Examiner's Office, 530 Chicago Avenue, Minneapolis, MN 55415*

After attending this presentation, attendees will learn the dangers of prone restraint with compression, particularly in children, and how to approach the autopsy and investigation of such cases.

This presentation will impact the forensic community and/or humanity by helping forensic scientists question the role of prone restraint for behavior modification in children and consider alternative restraint procedures and monitoring for combative children.

This presentation reports a case of compressional asphyxia due to a prone restraint maneuver that occurred in a day treatment facility for children with behavioral problems. The decedent was a 7-year-old female with a history of aggressive behaviors since the age of two. She was enrolled in the treatment facility for approximately one month, during which time several disciplinary actions, including prone restraint, were employed for behavior modification. During extended prone restraints, staff noticed she would appear to "fall asleep" after calming down, but was easily awoken. On the day of the fatal restraint, she was displaying improper table manners and reportedly "gargling" her drink during lunch. After repeatedly ignoring staff requests to cease the behavior, she was taken for a five minute "cool-down" in a separate room. She became aggressive, and was placed in a prone restraint control hold on the floor. A small towel was placed under her head and two staff members employed the restraint with one laying across the calves and holding the left wrist, with the other staff semi-prone across the back controlling the right arm and torso and monitoring the head.

The two staff initiating the restraint were each relieved by another staff member at different times. The entire restraint was longer than an hour. The second staff controlling the torso was a 240-pound male who relieved his co-worker 30 minutes into the restraint. He noticed the child to be combative and resisting when he took over. The child claimed she needed to use the bathroom, and that she felt like she was going to throw up. It was apparently not uncommon for restrained children to make such claims, and this child had recently vomited during a previous prone restraint. The restraint continued uninterrupted, and the child calmed down, apparently falling asleep. It was noticed that she had urinated in her pants. After a reported period of about 30 minutes of no resistance, the staff began processing the release. The child was not responding, and when turned over she appeared blue around the mouth and lips. Resuscitative efforts were employed, and the child was air lifted to a

children's hospital from the local emergency room. She showed no neurological recovery and was removed from life support approximately 50 hours following the restraining incident.

At autopsy a 67 pound, normally developed female child was examined. A recent abrasion to the left face and healing abrasions to both knees were seen. Serosal petechiae of the thymus and hilar visceral pleura were present. An area of localized intra-abdominal serosal hemorrhage involved the mid transverse colon, distal stomach and pancreas with intrapancreatic extension. These findings were interpreted as possible manifestations of compressional force, but may have resulted from aggressive or misguided resuscitation. Early bilateral bronchopneumonia was also identified.

Deaths during prone restraint are generally associated with police custody, with elements of excited delirium or illicit drug toxicity as potentially contributing factors. The importance of this case lies in the fact that the restrainee was a child, with significant weight and size disparity from the restrainers. This restraint protocol placed significant weight over the torso of the child, and did not allow adequate visualization of the face to monitor breathing and consciousness.

Prone Restraint, Compression, Asphyxia

G110 Combined Types of Violence in Child Abuse: Report of Three Cases

Wendy M. Gunther, MD, Leah L. Bush, MD, Elizabeth L. Kinnison, MD, Department of Legal Medicine, Virginia Commonwealth University, Medical College of Virginia, Tidewater Office of the Chief Medical Examiner, Commonwealth of Virginia, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510-1046; and Karen B. Looman, DO, Tidewater Office of the Chief Medical Examiner, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510*

After attending this presentation, attendees will learn how different types of injury and neglect may contribute to child death in abuse, evaluate the differential contributions of neglect and battering in child homicides, recognize two or more distinct contributing causes to death in child homicide, and evaluate impact of such recognition on courtroom testimony.

This presentation will impact the forensic community and/or humanity by demonstrating overlapping and concurrent types of injury contributing to death in cases of child abuse, assessing relative contributions of injury and neglect in child homicide, and considering judicial outcomes and defense strategies in child homicides due to combined types of injury.

Forensic autopsy on battered children often identifies characteristic findings such as evidence of head impact with and without shaking, beating with and without patterned injury, fractures of ribs and long bones in various stages of healing, liver lacerations and other visceral injuries, and burns. Forensic autopsy on neglected children frequently reveals starvation, untreated medical illnesses, growth retardation, and dental caries. Neglect may also be diagnosed at autopsy when a caretaker has allowed a child to suffer injury through inattentiveness, such as when an unwatched child drowns.

The concurrence of neglect and battering is less common. This case series presents two children who came to forensic autopsy because of a combination of fatal neglect and fatal injury on the part of caretakers, and one child whose fatal injuries were due to two unusual overlapping kinds of violence, smothering and shaking/impact. Defense strategies and judicial outcomes for these cases are reviewed.

Case 1. Drowning and battering. A 3-year-old girl was left alone in a bathtub filled with water for what the mother described as ten minutes. The mother stated that the girl was underneath the water when she returned, lifeless. Emergency medical services found the child lying on a couch in the livingroom, with a large amount of water on the couch. The

girl had numerous bruises, lacerations, and abrasions over the back, chest, and extremities. Autopsy showed pulmonary edema with abundant froth in the tracheobronchial tree, supportive of drowning. There were also healing fractures of the left clavicle and of a left rib, and numerous scars of the head, trunk, and extremities; some of the wrist scars were due to ligatures. Malnourishment was diagnosed by the weight (less than 5th percentile for a normal girl of the same age) and height (less than 25th percentile), with a weight-to-height ratio less than the fifth percentile. Death was certified as due to drowning, with the manner homicide.

The mother was charged with felony second-degree murder in the setting of felony child abuse and neglect. Defense strategy included the argument that there was no connection between the abuse and the drowning. The mother was convicted. At the time of conviction, she was pregnant. The sentence of 16 years reflected the judicial decision to maintain her incarceration until all her five surviving children (including the fetus) should grow up.

Case 2. Smothering and shaken impact. His father found a 23-month-old boy dead in his bed, with obvious injury to the face and abdomen. The child had been in the care of his girlfriend before he was put to bed. Autopsy showed that the child had severe blunt force trauma to the head, torso, and extremities. This included bilateral subdural hematomas with retinal hemorrhages and optic nerve sheath hemorrhages, consistent with shaking, and multiple subgaleal hemorrhages and a brain contusion due to impact. There were multiple contusions and abrasions of the abdomen, including patterned injury, with contusions of the bowel and contusions and laceration of the mesentery, and right perirenal hemorrhage. There were multiple abrasions and contusions of the extremities without fractures. However, there was also evidence of smothering, including abrasions and contusions of the face, chin, and lips, and petechiae of the conjunctiva, face, scalp, and oral mucosa. Death was certified as due to acute blunt force head injury and asphyxiation from smothering, with the manner homicide.

The girlfriend was charged with felony child homicide. Defense strategies included the allegation that the caretaker was not the batterer, but that the child's 21-year-old developmentally challenged brother had fatally injured him during rough play on the floor; and that if the defendant had smothered him accidentally against her clothing, she had done so while holding a fatally battered child. The defendant was found guilty. The brother was not charged. Sentencing is pending at the time of this abstract.

Case 3. Starvation (neglect) and battering/shaking. An 8-week-old infant girl was found dead in her crib. A history was given that she had not been eating well for three weeks, but there had been no contact with medical professionals since birth. At autopsy, the child was dehydrated and severely malnourished (autopsy weight 5 lbs; birth weight 7 lbs 10 oz). The eyes were sunken, and the contour of the ribs was visible through the skin. The thymus had atrophied. The gastric pouch was empty, the duodenum and small bowel were nearly empty of chyme, and there was very little stool in the colon. There were bruises of the right forearm and left elbow, and on internal examination, there were multiple rib fractures in varying stages of healing. Examination of the head revealed multiple subgaleal hemorrhages, a linear right parietal skull fracture, and multifocal subdural hematomas of varying ages overlying recent and old brain contusions. Histology showed a dense neutrophilic inflammatory response in the subdural hematomas and the meninges of the brain and spinal cord, and multiple autopsy cultures grew out a single organism, *Salmonella arizona*. Death was certified as due to meningitis, due to infected subdural hematoma, due to inflicted traumatic brain injury, with starvation contributing; with the manner homicide. The mother pled guilty. Sentencing is pending at the time of this abstract.

Review of these cases will illustrate the forensic methods used to elucidate multiple overlapping types of injury and neglect that may contribute to complex cases of child homicide.

Child Abuse, Child Neglect, Combined Types of Violence and Injury

G111 Brainstem Axonal Injury and Retinal Hemorrhages as a Substrate for Sudden Death in Second Impact Syndrome: A Case Report

Rudy J. Castellani, MD, University of Maryland, Baltimore, 22 South Greene Street, NBW-81, Baltimore, MD 21201; and Joyce L. deJong, DO, Division of Forensic Pathology, Sparrow Health System, 1215 East Michigan Avenue, Lansing, MI 48912*

After attending this presentation, attendees will gain an assessment of central nervous system at autopsy for axonal injury, and globes at autopsy for retinal hemorrhage.

This presentation will impact the forensic community and/or humanity by increasing the awareness of the pathology and pathophysiology of so-called second impact syndrome. Moreover, it will raise the much needed concept that retinal hemorrhages, while a useful "marker" of abuse, are not diagnostic of abuse, and that a degree of circumspection is required in assessing accidental vs. nonaccidental trauma in children.

Second impact syndrome is an ill-defined syndrome in which presumably trivial head injury, following a concussion or other significant head injury is associated with sudden death. The pathophysiology of this process is unclear, although diffuse cerebral swelling has been implicated.

An 18-month-old boy who suffered a closed head injury from fall from a balcony, following which he underwent a short period of rehabilitation and was discharged with a helmet. The helmet was prescribed because the child's motor skills had slightly deteriorated. Four weeks following the fall from the balcony, the child suffered a fall from a coffee table witnessed by both a parent and another adult, after which he immediately became unresponsive and expired several days later with cerebral swelling and nonperfusion. He was not wearing the helmet at the time of the fall from the coffee table. At autopsy, marked edema with diffuse bilateral ischemic necrosis was present throughout the cerebrum, cerebellum, and brainstem. In addition, the right lateral brainstem as well as the corticospinal tract at the pontomedullary junction showed axonal shear injury, including numerous swollen axons and microglial activation that were temporally consistent with the initial closed head injury. Bilateral retinal hemorrhages and bilateral optic nerve sheath hemorrhages were also present. This case demonstrated that this subject may have been predisposed to sudden decompensation following trivial head injury because of pre-existing brainstem axonal injury and a vulnerable brainstem cardiorespiratory center. Close examination of the brainstem for evidence of axonal injury is warranted in subjects who expire following trivial head injury, especially in the case of previous head injury. This case further highlights the lack of specificity of retinal hemorrhages in terms of accidental vs. non-accidental trauma, and that careful assessment of individual cases is necessary before concluding injuries were inflicted by another.

Second Impact Syndrome, Axonal Injury, Retinal Hemorrhage

G112 Sexual Abuse: Hymenal Findings in Girls With a History of Vaginal Penetration

Annie Vesterby, MD, DMSc*, and Lene A. Hansen, MD, Institute of Forensic Medicine, University of Aarhus, Peter Sabroes Gade 15, Aarhus C, 8000, Denmark; and Svend Sabroe, MD, Institute of Public Health, Dept. of Epidemiology, University of Aarhus, Vennelyst Boulevard 6, Aarhus C, 8000, Denmark

After attending this presentation, attendees will understand that hymenal lesions at colposcopic examination are seldom seen in late disclosure of sexual abuse in children with vaginal penetration.

This presentation will impact the forensic community and/or humanity by assisting professionals in understanding that hymenal lesions are seldom seen in sexually abused girls who report vaginal penetration.

The Institute of Forensic Medicine, University of Aarhus, at the request of the police, performs colposcopic examination of children suspected of being sexually abused.

From January 1, 1996, to September 2002, 482 children living in Jutland, Denmark, were investigated (1.48/10,000 children from birth to 16 years).

This study focuses on hymenal findings in cases of a history of vaginal penetration given either by the child or by the perpetrator or both.

Results: Two hundred twenty-six girls reported vaginal penetration at least once, and of these 116 were penile penetration.

The median age of the girls was 12 years (range 2-14 years).

Forty-nine girls (22%) were examined within 24 hours after the last sexual assault, 27 (12%) less than a week and 116 (51%) more than a week later; and in 34 cases (15%) the time since the alleged penetration was unknown.

The hymen was normal in 155 girls (55%), showed erythema in 18 (8%) and lesions in 20 (9%); the rest had other irrelevant findings or were unknown.

Hymenal clefts were found in 50 girls (25%), but only 17 girls (38%) had a complete hymenal cleft and of these 15 were above 12 years of age (median age 14 years). In a nine-year-old girl an anteriorly located cleft was observed.

The incidence of hymenal clefts (both incomplete and complete) in the 426 girls investigated increased with increasing age. Thus, 78% of the clefts were found among the oldest girls (above 11 years).

Eight of the girls with a hymenal cleft had used tampons on a regular basis. One hundred and nineteen cases were prosecuted and of those 102 suspects (86%) were convicted. Eight perpetrators admitted vaginal penetration, and the victims in these cases all had a complete posterior hymenal cleft.

No significant correlation was found between hymenal clefts and appearing at court or being convicted, nor between complete clefts or conviction at court.

There was, however, a relationship, although non-significant, between the age of the girls and the probability of the perpetrators to appear at court; the age of the girls in cases resulting in a conviction was significantly higher than in those resulting in acquittal ($p=0.02$).

Conclusion: In cases of late disclosure of sexual abuse, the history from the child and the perpetrator, not physical findings, remains the single most important feature in evidence of sexual abuse.

Child Sexual Abuse, Vaginal Penetration, Hymenal Lesions

G113 A Chest Full of Blood: Hemothorax as a 26 Year Delayed Consequence of Repair of Transposition of the Great Vessels

Karen B. Looman, DO*, and Wendy M. Gunther, MD, Tidewater Office of the Chief Medical Examiner, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510

After attending this presentation, attendees will learn about an uncommon consequence they may see long after surgical correction of transposition of the great vessels.

This presentation will impact the forensic community and/or humanity by providing useful information about a potentially lethal delayed complication of a common surgical procedure to correct a congenital heart problem; describing newer procedures that do not have this kind of problem; and illustrating signs and symptoms to look for in a similar autopsy case.

A 27-year-old woman had been born with transposition of the great vessels (TGV), a congenital heart disorder that was always fatal before corrective surgery was developed. In TGV, blood oxygenated by the lungs never reaches the rest of the body, and blood returning from the body never reaches the lungs. This occurs because, in TGV, the pulmonary artery is attached to the left side of the heart and the aorta is attached to the right side of the heart.

Twenty seven years ago, a standard treatment for this disorder was the Mustard procedure, in which the pulmonary veins are detached from the left atrium and surgically reattached to the right atrium, and the superior and inferior vena cava are detached from the right atrium and reattached across an "atrial baffle" to the left atrium. This procedure allows oxygenated blood to flow to the body, and deoxygenated blood from the body to return to the lungs. It also allows the coronary arteries to remain in their native position in the aorta. It has the disadvantage that the right ventricle is responsible for pumping blood to the body, which causes it to hypertrophy, and the left ventricle pumps blood to the lungs, under too much pressure.

The patient's Mustard procedure was performed at 11 months of life. She recovered well and lived for twenty-six more years. Approximately three months prior to her death, she was diagnosed with pneumonia, and was treated with antibiotics. The day before her death, she complained of chest pain. The night of her death, while talking on the phone, she had a fit of coughing. The expectorant contained blood. She went to the emergency room, and during the initial work-up, collapsed and died.

At autopsy, external examination revealed a slender, gracile and nearly cachectic female who had pallor of the face and body. There was a midline chest scar as evidence of her previous cardiac surgery, but no recent injuries or surgical procedures. Blood for toxicology was hard to obtain by inguinal or subclavian puncture.

Internal examination revealed a right hemothorax with 1700 cc of blood and clots, visceral pallor, and depletion of the vascular tree. The heart showed evidence of the Mustard procedure, with all anastomoses intact. However, there were bilateral pulmonary artery aneurysms. The right ventricle showed evidence of extreme hypertrophy, with the wall measuring up to 1.5 cm thick. The right pulmonary artery showed a 10 cm aneurysm at the hilum that extended into the lung. The left pulmonary artery revealed a 3cm aneurysm. A fresh rupture was found in the right pulmonary aneurysm near the hilum, creating the hemothorax and causing the young woman's death.

Extensive recent and older thrombosis of pulmonary artery branches leading from the aneurysm into the right lower lobe was noted, suggesting this might have prompted the diagnosis of pneumonia. Thrombosis of these vessels might have been responsible for raising the pressure in the aneurysm, ultimately leading to rupture.

The Mustard procedure has been known to extend victims' lives for ten years or more. However, pulmonary artery aneurysms, although rare, have been reported in the literature as a long term sequela. Commoner

problems with the Mustard procedure include cardiac arrhythmias and baffle leaks. Transposition of the great vessels is now treated by a different procedure, the arterial switch.

This case report will compare the long term complications and advantages of the arterial switch to the Mustard procedure in light of this catastrophic delayed result. This will aid forensic personnel in the future when they have a case for forensic autopsy with a history of surgical repair of transposition of the great vessels. They will know what to expect on heart dissection from these surgeries, and to anticipate the possible long term problems that can accompany these types of techniques.

Transposition of Great Vessels, Aneurysm, Sudden Death

G114 Suicidal Hanging of a Postpartum Woman Who Discontinued Anti-Depressant Medication During Pregnancy

Gregory L. Hess, MD, Jeffery M. Jentzen, MD, and Russell T. Alexander, MD, Milwaukee County Medical Examiner Office, 933 West Highland Avenue, Milwaukee, Wisconsin 53233*

The goal of this presentation is to review a case of postpartum suicide in a woman with a history of major depression who discontinued her psychotropic medications during the first trimester of her pregnancy. The current controversies surrounding the treatment of depression during pregnancy and in the postpartum period will be reviewed.

This presentation will impact the forensic community and/or humanity by discussing the risks and benefits of treating depression in the puerperal period.

The decedent was a 30-year-old female who hanged herself with a dog leash 45 days after the uncomplicated vaginal delivery of her third child. Three days prior to death she began expressing depressive symptoms reported as sleep disturbance, restlessness and obsessive preoccupation with her youngest child. The day before her death she sought medical attention at a local walk-in clinic for depression and was prescribed sertraline (Zoloft). The next evening she fashioned a noose from a dog leash and using a cut log as a step stool, fully suspended herself by the neck from a tree in the back yard of her home. Scene investigation revealed copious emesis in the kitchen trash, and an empty bottle of sertraline.

She had a history of two previous inpatient hospitalizations for major depression, the first of which was an involuntary hospitalization manifested by self induced starvation and dehydration. During the first hospitalization, five years prior to her terminal event, she tried to hang herself by her bra strap three times. A second depressive episode, approximately one year before her suicide, was punctuated by her threatening to kill herself with a kitchen knife. Neither of these depressive episodes appeared related to her prior pregnancies. Her psychiatric medications prior to her third pregnancy consisted of sertraline and quetiapine on which her symptoms appeared well controlled. She discontinued her medications during the first trimester of the last pregnancy in consultation with her obstetrician secondary to the unknown teratogenicity of these medications (both are pregnancy category C). She had not restarted her medications immediately after delivery because, according to her husband, she had not felt depressed and she was breastfeeding.

At autopsy a dried ligature abrasion partially encircling the neck crossed the neck anterior midline over the superior edge of the thyroid cartilage. No petechiae were identified on the conjunctivae of the eyes, facial skin, lips or oral mucosa. A layer-wise anterior neck dissection did not reveal hemorrhage or injury within the strap muscles of the neck, the hyoid bone, or the thyroid cartilage. No pill fragments were found in the stomach. Postmortem toxicology testing revealed an elevated level of sertraline (0.24mg/L), but no additional drugs or alcohol in iliac blood.

Approximately 10% of women develop depression during pregnancy or in the postpartum period, and a previous history of major depression is a risk factor. The previous held belief that pregnancy offers "protection" from major depression has been challenged by a recent study showing a significantly higher rate of relapse amongst women who discontinued anti-depressant medication compared with those who continued treatment (Cohen et al., 2006). Selective serotonin reuptake inhibitors (such as fluoxetine, sertraline, and paroxetine) have been recommended for the treatment of depression during pregnancy due to their efficacy, as well as historical data suggesting they are not associated with birth defects (Kahn et al., 2001). Although sertraline is the most commonly prescribed anti-depressant in breastfeeding women, controversy still exists over the adverse effects it exerts on breastfed infants of mothers taking this medication (Gentile, 2005; Whitby and Smith, 2005). Concerns of fetal teratogenicity and infant toxicity due to intrauterine or breast milk exposure to anti-depressants must be balanced against the documented adverse effects that pregnancy related depression imparts on fetal and infant outcomes (Bonari et al., 204; Mian, 2005). A rare though dramatic outcome of pregnancy related psychiatric illness is maternal suicide or infanticide. Postpartum psychosis affects approximately 1% of women and may increase the risk of maternal or infant death.

This case presentation highlights the risk of discontinuing anti-depressant therapy during pregnancy for a woman with a history of major depression and previous suicide attempts. Medical examiners and investigators need to seek out a history of discontinuation of psychiatric medication in women who kill themselves or their children during pregnancy or postpartum. Only by being aware of the current controversies surrounding the treatment of depression during pregnancy and in the postnatal period will medical examiners be able to offer informed opinions when suicide or infanticide occurs in these settings.

Pregnancy, Depression, Suicide

G115 A Simple Model for Teaching Postmortem Monocular Indirect Ophthalmoscopy

Terrill L. Tops, MD, and Patrick E. Lantz, MD, Wake Forest University Health Sciences, Department of Pathology, Medical Center Boulevard, Winston Salem, NC 27157*

After attending this presentation, attendees will understand the enhanced potential for skill acquisition in postmortem monocular indirect ophthalmoscopy using a simple and inexpensive model simulating the ocular fundus.

This presentation will impact the forensic community and/or humanity by demonstrating a teaching model that can be used to enhance skill acquisition in postmortem monocular indirect ophthalmoscopy and be assessed to accurately identify and describe fundal abnormalities of pathological significance such as retinal hemorrhages.

Postmortem examination of the fundus oculi has relied on direct ophthalmoscopy or ocular evisceration, but recently the techniques of postmortem ophthalmic endoscopy and monocular indirect ophthalmoscopy have been delineated. Direct ophthalmoscopy has been used to attempt estimates of postmortem interval and identify retinal abnormalities but its usefulness is hindered by postmortem corneal clouding (swelling), inherent limited field of view, an inability to view the peripheral retina and lack of stereopsis. In most medical examiner/coroner jurisdictions ocular enucleation is not a standard autopsy procedure unless child abuse is suspected, thus invariably inuring observational bias when citing the prevalence of certain fundal findings (e.g., retinal hemorrhages). Postmortem endoscopic funduscopy permits viewing and documentation of retinal abnormalities; however, the equipment is costly and training necessary to gain expertise in operating the endoscopic equipment and subsequent image acquisition. The material necessary for postmortem monocular indirect ophthalmoscopy (PMIO) is inexpensive and when

compared to direct ophthalmoscopy the technique is less affected by corneal clouding, cataracts, or vitreous hemorrhage. Other advantages include a relatively large field of view, high resolution and an ability to visualize the peripheral retina. Disadvantages include low magnification and a projected aerial image that is inverted and laterally reversed.

A valuable skill for forensic pathologists, the technique of postmortem monocular indirect ophthalmoscopy can be challenging for pathology residents and forensic pathology fellows to master. Indirect ophthalmoscopy is not routinely taught in most medical schools so with the exception of ophthalmologists-in-training most residents and fellows have a limited exposure to the technique. Because the projected aerial image is inverted and laterally reversed precise descriptions or recording of fundal abnormalities can be challenging. Since the image cannot be viewed simultaneously by the instructor and student, learning PMIO can be intimidating because the more experienced forensic pathologist must teach the technique and describe the orientation of any fundal abnormalities observed.

To facilitate skill acquisition in PMIO, a simple and inexpensive teaching model can be constructed from hinged, cylindrical plastic containers having an internal diameter of 35 mm and a depth of 30 mm. A 9-mm hole drilled in the center of the hinged lid from a 1-oz cylindrical plastic canister creates an artificial pupil. Fundal images depicting hemorrhagic retinopathy printed on 8 x10-inch matte photographic paper are cropped into 3.5 mm circles with available imaging software. Trimmed images from the photographic paper are fitted into the canister's base. The lid of the canister marked as to the appropriate eye and correct orientation completes the model. Using a procedural headlight and an aspherical indirect condensing lens, the resident or fellow can practice viewing the simulated fundal image. Multiple funduscopic abnormalities with retinal hemorrhages can be created for teaching with variations in the number, location (preretinal, intra-retinal, subretinal), distribution and orientation relative to the optic disc. Using this simple teaching model, the pathology resident or fellow can be assessed as to his/her ability to accurately identify and describe the number, location, distribution and orientation of retinal hemorrhages and various other fundal abnormalities of pathological significance.

Postmortem Monocular Indirect Ophthalmoscopy, Ocular Fundus, Retinal Hemorrhage

G116 A Case of Fatal Water Intoxication in a Toddler

Nadia L. Krupp, MD, Indiana University School of Medicine, 702 Barnhill Drive, Indianapolis, IN 46202; Michele J. Catellier, MD*, Forensic Pathology Associates of Indiana, LLC, 521 West McCarty Street, Indianapolis, IN 46225; and Antoinette L. Laskey, MD, MPH, Indiana University School of Medicine, 702 Barnhill Drive, Indianapolis, IN 46202

After attending this presentation, attendees will have reviewed the physical and chemical signs and symptoms of water intoxication, thereby broadening the differential diagnosis in cases of sudden death particularly in pediatric practice.

This presentation will impact the forensic community and/or humanity by demonstrating the clinical signs and symptom of water intoxication as well as the differential diagnosis of this condition so that it might be a consideration in cases of sudden unexpected death particularly when environmental conditions include exposure to water.

This presentation concerns a case of fatal water intoxication in a toddler after a day of swimming and a review of the literature on pediatric water intoxication.

A 2.5-year-old, 12 kg, previously healthy female presented to a community emergency department with profoundly altered mental status. Her caregiver reported the child had been at a home pool for several hours

and on leaving had been "fussy" and may have fallen "onto her bottom" on the way to the car. She had one episode of copious clear emesis. Immediately after this she became progressively lethargic and unresponsive.

On presentation to the emergency department, her vital signs (HR 67, RR 35, O₂ saturation 64% on room air, BP 145/84) were consistent with Cushing's triad. She was emergently intubated and her vital signs normalized. Neurological exam revealed response only to painful stimuli. Her pupils were sluggishly reactive. Initial laboratories (prior to administration of any fluids) revealed a serum Na⁺ 128, Cl⁻ 95, K 3.3, CO₂ 15, BUN 15, Cr 0.2, and Glc 259. A bolus of 400cc of normal saline was ordered and transfer to a tertiary care pediatric hospital was arranged. Inadvertently, a bolus of D5W was reportedly administered instead of normal saline.

Initial labs at the tertiary care facility revealed a serum Na⁺ of 120. Her pupils were fixed and dilated and she had no respiratory effort. Physical exam was normal with the exception of her neurological exam and specifically did not reveal any evidence of rashes or signs of trauma. Her neurological exam revealed she had no doll's eye reflex, corneal response, cough or gag. She did withdraw minimally to painful stimuli. An emergent head CT demonstrated diffuse cerebral edema with herniation and no radiological evidence of intracranial hemorrhage, although the differential diagnosis included trauma. She was admitted to the Pediatric Intensive Care Unit and fluid resuscitation was initiated. Within hours she developed central diabetes insipidus, with high urine output (8 cc/kg/hr), urine specific gravity or 1.000, and a rapidly increasing serum sodium (maximum Na⁺ 155), despite changing intravenous fluids to 0.45 normal saline. Vasopressin therapy was initiated. Ophthalmologic examination ten hours after initial presentation showed splinter retinal hemorrhages in the posterior poles bilaterally. Over the next three days, her neurological exam deteriorated until she no longer withdrew to painful stimuli. At that time, her family elected to withdraw life support. A postmortem skeletal survey was negative for fractures.

The case fell under the coroner's jurisdiction and a forensic autopsy was ordered. At autopsy, no external signs of trauma were identified. Her thoracic and abdominal cavities were normal with the notable exception of cardiomegaly (76 g) and splenomegaly (90 g), neither of which were noted premortem. Cranial contents were consistent with diffuse cerebral edema and uncal herniation without intracranial hemorrhage. Cerebral spinal fluid collected using sterile technique was noted to be xanthochromic and somewhat gelatinous but not frankly purulent. Culture of the CSF grew *Klebsiella pneumoniae* in the broth only. No organisms were identified on gram stain of the CSF.

Local law enforcement officials conducted an investigation including interviews of all parties who had contact with the child. Her adult caregivers on the day of her presentation reported that she had been in a floating toy in a backyard above ground pool for several hours during the day. Both adults present at the time did not recall the child becoming submerged at any time. One caregiver indicated that the adults and older children present at the pool had been jumping in from the edge creating "tidal waves" repeatedly. Repeated interviews with the caregivers revealed consistent histories of the events of the afternoon.

The cause of death was cerebral edema due to hyponatremia due to acute accidental water intoxication. The manner of death was determined to be accidental.

A review of the English language literature on accidental water intoxication reveals five cases in the pediatric population with symptoms similar to this case. With timely, appropriate fluid resuscitation a full recovery is possible, even when the presentation includes a comatose state. It is most likely that this child swallowed a large volume of pool water, which acutely dropped her serum sodium that resulted in her symptoms, with subsequent irreversible cerebral edema and herniation.

Water, Intoxication, Pediatric

Pathology/Biology

G1 Otologic Injury as a Consequence of Blast Trauma; Evaluated by Postmortem Otoscopic and Computed Tomography Examination

Carol J. Solomon, MS, MD, Louis N. Finelli, DO, and John M. Getz, BS, Office of the Armed Forces Medical Examiner, 1413 Research Boulevard, Building 102, Rockville, MD 20850*

After attending this presentation, attendees will recognize the pattern of middle ear injury from blast trauma and its correlation with postmortem otoscopic findings and computed tomography results.

This presentation will impact the forensic community and/or humanity by providing a systematic evaluation of middle ear structures injured as a result of primary blast trauma. Techniques evaluated are intended to augment the routine gross and microscopic examination of victims of blast injury. The results of these studies will aid in the evaluation of patients status post injury and possibly assist in preventive measures in the appropriate setting.

The ear is one of the most frequently injured organs affected in an explosion. Otologic injury is a far more prevalent problem than has been previously reported. A more thorough evaluation of victims combined with an increase in both the number of civilian and military blast injuries cause us to recognize the extent of the problem. The short and long term sequelae of this type of trauma may include findings such as hearing impairment, tinnitus, and vertigo and cholesteatoma formation. A clearer understanding of the pattern and etiology of injury should benefit survivors in the planning of treatment strategies to optimize outcome. The techniques utilized in this study have enabled us to evaluate the mechanism and extent of injury to otologic structures.

Evaluation of middle ear injuries, postmortem, has been a laborious process. The current study provides two techniques that will provide additional information in the assessment of blast trauma. These techniques are useful in the evaluation of tympanic membrane perforation, hemorrhage into the middle ear and ossicular damage.

A series of cases is presented demonstrating the application of postmortem otoscopic examination and computed tomography to evaluate middle ear structures. These findings are correlated with the results of the corresponding circumstances of death.

Blast Injury, Otologic, Computerized Tomography Scan

G2 Natural Central Nervous System (CNS) Causes of Death: A Ten Year Retrospective Review (1994-2003)

Gregory L. Hess, MD, University of Arizona Health Sciences Center, 1501 North Campbell Avenue, PO Box 245108, Tucson, AZ 85724-5108; and David C. Winston, MD, PhD, Pima County Forensic Science Center, 2825 East District Street, Tucson, AZ 85714*

The goal of this presentation is to explore the incidence and specific demographic information (age/sex) for natural CNS deaths in Pima County, AZ from 1994-2003.

This presentation will impact the forensic community and/or humanity by reviewing the incidence and demographics for natural CNS deaths in Pima County, AZ from 1994-2003. Forensic pathologists and other forensic scientists may find this information useful to compare with the incidence of natural CNS deaths in their own practice.

Sudden unexpected natural deaths of CNS etiology are not an uncommon finding in many medical examiners offices. The authors performed a retrospective review of 262 cases of natural deaths attributed to a CNS etiology over a 10-year time period to compare the cause, incidence, and demographic profiles of such cases. Natural deaths were sorted from 11,152 total autopsies performed at the Pima County Forensic Science Center between 1994 and 2003. These natural deaths were then screened for a primary CNS cause of death (COD) excluding systemic diseases with CNS manifestations if the CNS pathology could not be determined to be the primary mechanism of death. COD and demographic information on each case was then tabulated with particular attention to the top three causes of death by year. Primary CNS deaths accounted for an average of 7.2% of natural deaths in this ten-year review. The majority of these (28% of CNS totals) were attributed to unexpected death in patients with a clinically documented seizure disorder with a slight male predominance (1.6:1 male: female ratio) and an average age of 38 years. The second most common cause of death (27% of CNS totals) was hypertensive stroke. The average age of this population was older as compared to the patients with seizure disorders and with a slight male predominance (average age 59 with a 1.4:1 male: female ratio). Ruptured aneurysms in various CNS anatomic locations were the third most common cause of death (16% of CNS totals) occurring in middle age with a male predominance (average age 48 with a 1.5:1 male: female ratio). Infectious meningitis, most commonly of bacterial or viral etiology, was also a frequent cause of CNS death (14% of CNS totals with average age 35 years with a 1.3:1 male: female ratio). Infectious etiologies were the most age variable COD ranging from 4 months to 69 years of age. Other, less frequent, COD, in order of descending frequency, included primary brain neoplasm, idiopathic intracerebral hemorrhage, congenital anomalies, progressive neurodegenerative dementias, and idiopathic encephalopathies. These findings are felt to be representative of a typical forensic autopsy population with an over representation of sudden death (seizure disorder, stroke, and aneurysm) and under representation of chronic CNS pathology (neurodegenerative dementias, neoplasm) than what would be expected in the general population.

Central Nervous System, Natural Death, Review

G3 Frequency of Cases of Fatal Gunshot Wound Victims With Retained “Old” Projectiles From Previous Penetrating Gunshot Wounds

Daniel W. Dye, MD, University of Arkansas for Medical Sciences, 4301 W Markham, Slot 517, Little Rock, AR 72205; and Charles P. Kokes, MD, Arkansas State Crime Laboratory, #3 Natural Resources Drive, PO Box 8500, Little Rock, AR 72215*

After attending this presentation, attendees will learn the importance of considering “old” projectiles in assessing a gunshot wound homicide.

This presentation will impact the forensic community and/or humanity by increasing awareness of the “old” projectile as a possible pitfall in the multiple/complex gunshot wound case.

When considering multiple gunshot wound cases, the simple equation of number of entrance wounds equals the number of exit wounds plus the number of bullets lodged in the victim is always an excellent starting point in the forensic examination. However, when there are intermediate targets, atypical entrance wounds or fragmented projectiles the situation can be more complex. The equation can be further complicated by individuals

who have sustained a penetrating gunshot wound in the past, survived the injury, and for medical or personal reasons elected not to have the projectile removed. These "old" projectiles can be easily distinguished from acute projectile injuries based on their gross appearance with lack of acute hemorrhage and usual encasement within an area of fibrosis, but when plain film radiographs are used in the original accounting process, this old retained projectile can complicate the equation.

A review of all of the victims of fatal gunshot wounds at the Arkansas State Medical Examiner's office from January 1, 2000-December 31, 2004 was performed to determine the frequency of cases in which an "old" bullet was discovered in addition to the acute, fatal, gunshot wound or wounds. A total of 703 gunshot wound homicides were reviewed; twenty-five of which had evidence of remote gunshot injury and retained projectiles or fragments identified on radiologic exam and internal examination. Individuals with evidence of remote gunshot injury were further classified based on anatomic location of the remote projectile, bullet caliber (large or small), or bird-shot pellets. This classification allows a discussion of possible reasons for leaving the "old" bullet in the patient; either for difficulty/futility of retrieval or the patient's desire to retain the bullet for show as a "souvenir" bullet.

In this retrospective study, four percent (4%) of the cases of gunshot wound homicides at the Arkansas State Crime Laboratory had retained projectiles from previous gunshot wounds. The frequency of these cases points out the importance of considering the possibility of old bullets when approaching complex gunshot wound cases. One should always remember that every projectile on the x-ray may not be from acute injury.

Gunshot Wound, Homicide, Old retained Projectiles

G4 Small Cell Carcinoma of the Lung Contributing to Pulmonary Barotrauma With Air Embolism in a Recreational Diver: A Case Report

Carl W. Wigren, MD, and J. Matthew Lacy, MD, King County Medical Examiner's Office, 325 Ninth Avenue, HMC Box 359792, Seattle, WA 98104*

The goal of this presentation is to review the pathophysiology of pulmonary barotrauma in the setting of SCUBA diving fatalities and to discuss the potential contribution of local bronchial obstruction to the development of pulmonary barotrauma.

This presentation will impact the forensic community and/or humanity by demonstrating how divers would benefit from consulting a qualified medical professional about the risks of diving with an intrinsic lung disease prior to engaging in this sport.

SCUBA diving is a popular sport in the United States and approximately 90 deaths are reported each year, mostly from coastal states. Drowning is the leading cause of death in diving related fatalities but a host of injuries unique to diving may contribute. This presentation will impact the forensic community and/or humanity by increasing awareness of the potential danger of recreational SCUBA diving in those with obstructive pulmonary processes.

A 45-year-old man was SCUBA diving with a partner in seawater at a spot familiar to both of them. He was an experienced rescue-certified diver with over 450 dives. The dive lasted approximately 29 minutes with a maximum depth of 84 feet of seawater. During the decompression stop the divers became separated in murky water. The partner surfaced then resubmerged and recovered the decedent from the bottom approximately 25 feet below the surface. The decedent was removed from the water and resuscitation was attempted in the field prior to the pronouncement of death. No central lines or other procedures invasive to the central vascular bed or chest were attempted.

The SCUBA gear was examined by a Diving Safety Officer. All components were in good condition and in working order with adequate unadulterated air in the tank. The diving computer was interrogated and a depth/time histogram was produced. At approximately 23 minutes into the dive the histogram has a spike-like irregularity after which the depth remains steadily at approximately 25 feet until the data terminates.

Prior to autopsy an anterior-posterior radiograph of the chest in the left lateral decubitus position was obtained. Air fluid levels in the right and left sides of the heart, gas in the central vascular structures of the chest and neck, and pneumomediastinum were observed. Opening the myocardium under water produced a gush of bubbles. No gas emboli were grossly apparent in the coronary or cerebral arteries. There was no substantial heart disease.

A 3.0 centimeter white subcarinal mass, histologically confirmed as small cell carcinoma, extended into the hilum of the left lung. It caused subtotal obstruction of the left upper lobe bronchus and encased the pulmonary artery. The pulmonary parenchyma distal to the obstruction was hemorrhagic and atelectatic. Metastases were present in the mediastinal lymph nodes and liver.

Medical records revealed that the decedent had been diagnosed with metastatic lung cancer approximately six months before his death. He underwent chemotherapy with shrinkage of his metastatic lesions. Chronic cough caused him to undergo bronchoscopy approximately one month prior to his death, which revealed partial obstruction of the left upper lobe bronchus by the neoplasm. He received two fractions of palliative radiation to that area, the last on the morning of the fatal dive.

We hypothesize that 1) the presence of a carcinoma obstructing a bronchus resulted in fatal barotrauma in an experienced diver, and 2) filling of the central vascular bed by gas resulted in unconsciousness while submerged, in the absence of cerebral and coronary artery gas emboli.

Divers would benefit from consulting a qualified medical professional about the risks of diving with an intrinsic lung disease prior to engaging in this sport.

Scuba Diving, Air Embolism, Postmortem Radiograph

G5 Serum Levels of Pulmonary Surfactant Associated Proteins A and D (SP-A & SP-D) in Some Causes of Death

M. Essam E. El-Sheikh, MD, PhD, and Taisseur M. Mostafa, MD, PhD, Farwania, PO Box 1747, Kuwait, 1747, Kuwait*

After attending this presentation, attendees will recognize the potential benefits of testing for pulmonary surfactant proteins in certain types of sudden deaths, especially those occurring with an asphyxial or intoxication mechanism.

This presentation will impact the forensic community and/or humanity by demonstrating research that may be considered as a step in determining the potential diagnostic role of surfactant proteins in post-mortem settings.

It has been suggested that surfactant proteins A and D (SP-A, SP-D) may be useful markers of lung injury in the clinical setting. In this present study, cadaveric serum samples were analyzed by specific enzyme linked immunoassays for the levels of SP-A and SP-D in certain causes of death, such as mechanical asphyxia, drowning, fire, sudden unexplained deaths, carbon monoxide intoxication, narcotics abuse, and organophosphate poisoning. Results in these types of cases were compared to the serum levels in a group of healthy volunteers, which served as the control group. No significant differences were observed in the median serum SP-A and SP-D concentrations among the groups of volunteers, sudden unexplained death, mechanical asphyxia, and carbon monoxide intoxication groups. Significantly increased SP-A levels compared to controls were found in deaths caused by fire, drowning, narcotic abuse, and organophosphate poi-

soning. Similarly, increased SP-D levels were observed in fire, drowning, organophosphate poisoning, and narcotic related deaths, when compared to controls and cases of natural sudden death. A positive correlation was found between the levels of SP-A and SP-D. These results suggest that analysis of serum surfactant proteins may be useful in estimating the intensity of alveolar functional damage at autopsy.

Cause of Death, Autopsy, Surfactant Proteins

G6 Gliomatosis Cerebri as a Cause of Sudden Death in a Young Woman

Timothy L. Williams, MD, and William F. Hickey, MD, Dartmouth-Hitchcock Medical Center; Department of Pathology, One Medical Center Drive, Lebanon, NH 03756; and Thomas Andrew, MD, Office of the Chief Medical Examiner, 246 Pleasant Street, Concord, NH 03301*

After attending this presentation, attendees will be made aware of gliomatosis cerebri as a rare yet potential cause of sudden natural death.

This presentation will impact the forensic community and/or humanity by providing a well-illustrated example of an uncommon disease entity that can be a cause of sudden death that has not heretofore been well described in the forensic science case literature.

This central nervous system (CNS) neoplasm is briefly reviewed, which follows a typical premortem course, demonstrated in this case. The report is richly illustrated with premortem neuroradiographic images, postmortem images of whole and cut brain, and photomicrographs. In particular, the gross and microscopic postmortem findings provide an excellent example of the kind of subtle changes one may encounter in the postmortem neuropathologic evaluation of cases of gliomatosis cerebri. The pathogenesis of sudden death in the context of gliomatosis cerebri is discussed vis-à-vis changes in the permeability of the blood-brain barrier.

Sudden death due to undiagnosed primary intracranial neoplasm is uncommonly encountered by the forensic pathologist. In a recent review [1] of nearly 55,000 autopsies performed over a twenty year period at the Chief Medical Examiner of Maryland, undiagnosed primary CNS tumors comprised 0.02-0.05% of sudden deaths. Glial tumors, particularly astrocytomas and glioblastoma multiforme, were the most frequent tumor types in these cases, and mechanisms of death included seizure, acute hemorrhage, and herniation. In all of the reviewed cases, discrete CNS tumor masses were identified at the time of autopsy.

Gliomatosis cerebri is a rare brain neoplasm characterized macroscopically by enlargement, often subtle, of affected brain regions with preservation of native CNS architecture and absence of a discrete tumor mass. Microscopically, the tumor consists of proliferating malignant glial cells which diffusely infiltrate large areas of the CNS, involving more than two lobes [2], and often involving both supratentorial and infratentorial brain regions. The majority of patients diagnosed with gliomatosis cerebri are relatively young (median age 44 [3]), and experience insidiously progressive symptoms, which can include headaches, alteration of mental status and cognition, dysphasia, visual deficits, hemiparesis, and seizures. Often these cases present significant diagnostic challenges to clinicians, and final diagnoses are not made until postmortem examination. Invariably the mechanism of death in cases of gliomatosis cerebri is compressive sequelae from expanding intracranial mass.

This presentation describes a case of sudden death in a young woman due to previously undiagnosed gliomatosis cerebri. The patient, 40 years old, had a several month history of intermittent headaches that were gradually increasing in frequency and severity. Over this period the patient underwent multiple clinical evaluations, which were unremarkable, apart from nonspecific white matter enhancement and mass effects by magnetic resonance brain imaging. The patient's headaches were effectively controlled with mild analgesia and she remained fully active up until her death. This witnessed event occurred suddenly, shortly after the characteristic onset of episodic headache. General autopsy was unremarkable.

Neuropathologic examination showed changes consistent with acute transtentorial herniation as a mechanism of death. Subtle mass effects and white matter expansion were noted on gross and cut brain examinations. Histologic evaluation revealed malignant glial infiltration diagnostic of gliomatosis cerebri. Immunohistochemical staining of lesion tissue suggests the pathogenesis of sudden death in cases of gliomatosis cerebri may be related to catastrophic failure of the blood-brain barrier vis-à-vis its permeability regulatory function.

Gliomatosis Cerebri, Tumor, Death

G7 Death in a Confined Space

Nunzio Di Nunno, MD, PhD, Universita' di Lecce, Via G. Dorso n. 9, Bari, 70125, Italy; Francesco Vimercati, MD, Universita' di Bari, Sezione di Medicina Legale, Piazza G. Cesare n. 11, Bari, 70125, Italy; Fulvio Costantinides, MD, Universita' di Trieste, P.zza Ospedale, Trieste, 34100, Italy; and Sandra Cornetta, MD, and Di Nunno Cosimo, MD, Universita' di Bari, Sezione di Medicina Legale, Piazza G. Cesare n. 11, Bari, 70125, Italy*

After attending this presentation, attendees will understand the pathogenesis of confined-space asphyxia through the study of three forensic cases. Confined-space asphyxia is a quite rare event, caused by a lack of environmental oxygen that becomes inadequate to sustain life. This occurs when individuals find themselves trapped in airtight or relatively airtight enclosure, causing depletion of the oxygen supply and they asphyxiate.

This presentation will impact the forensic community and/or humanity by demonstrating the forensic approach in investigating cases of death due to confined-space asphyxia, thereby avoiding confusing this entity for a natural death.

Asphyxia due to a confined space is a quite rare event, caused by a lack of oxygen that becomes insufficient to allow normal respiration. This happens when a person is trapped in airtight space without exchange of air, as breathing exhausts the available oxygen, beginning the asphyxiation process.

The Department of Health, Education, and Welfare defines a confined space as "a space, which, by design, has limited openings for entry and exit combined with unfavorable natural ventilation." Examples of confined space are caves, refrigerators, tunnels, pipelines, sewers, silos, tanks, pits, mines, trenches, holds, vaults, excavations, manholes, and chimneys. In the past, this kind of accident usually involved people working in building, shipyard, and other manufacturing and service industries. As society changes, the causes and modalities of confined space deaths are different. In fact, the illegal immigration phenomenon and the search of new ways to reach Europe have become one of the main causes of these accidents in these last years. People try to enter a country travelling hidden among the cargo of trucks. If the trip is long and the space is very narrow, the deficiency of oxygen could become serious and fatal for the illegal passengers.

This paper presents two cases, occurring in two different Italian regions, describing the deaths of three men by confined space asphyxia during the travel to reach Italy illegally.

The first report concerns the death of two Kurdish men. They were found in the refrigerator van of a truck, completely loaded with watermelons, coming from Greece by a motor-ship and arrived to the port of Brindisi. The autopsies of the two deceased's did not show any remarkable pathology, and histological and toxicological tests were negative. The most

significant anatomic-pathological findings of the autopsy were cyanosis of the face and fingernails, copious and deep reddish-purple postmortem hypostasis, visceral congestion, brain and lung oedema, conjunctival petechiae (in one of the two corpses) and fragmentation of myocardial fibres. All these findings were compatible with the diagnosis of death by asphyxia and the discovery of the two bodies in the truck trailer. The circumstances of the deaths confirmed that they were due to confined space asphyxia.

The second report regards a stowaway found in a truck trailer near Trieste. When he arrived to the local hospital he was in coma, with cutaneous temperature at 43°C and completely dehydrated. He died after few hours because of progressive deterioration of general health conditions and massive bleeding from his stomach and bronchi.

On basis of all the clinical symptomatology, the results of laboratory tests and review of the medical records, and the external examination, it was established that the death was due to a "heatstroke". This diagnosis was confirmed by the circumstances of the discovery of the body, and the high environmental temperature (about 40°C). Also in this case, the confined space where victim had been in hiding for prolonged time, without any ventilation, had a key role in causing the death. The lack of oxygen in this confined space, and the overheating within the van of the truck became a lethal combination for this man.

These two reports bring to attention the serious problems of clandestine immigration occurring within a confined space. Confined space asphyxia has caused trouble in the past with occupational deaths, and now seems to come back under a different aspect.

The contribution of the medical examiner to these investigations should be to identify the correct cause of death due to confined space asphyxia. As the few and non-specific anatomic-pathological findings of this kind of diagnosis is difficult to determine without history, it is very important to carry out a careful analysis of the circumstances of the death. A correct diagnosis in these types of cases requires scene information coming from an "on-the-spot investigation."

Confined Space Asphyxia, Death Investigation

G8 Primary Hyperoxaluria: A Case Report and Review of the Literature

Julia M. Braza, MD and Karoly Balogh, MD, Beth Israel Deaconess Medical Center, Pathology Department, 330 Brookline Avenue, Boston, MA 02215

The goal of this presentation is to discuss a case of the rare metabolic syndrome primary hyperoxaluria (PH), with a literature review. The attendees will learn about the inherited form of the disease, its systemic manifestations, genetic alterations and the potential mechanisms of death. PH is relevant and important to the medico-legal and public health fields to identify such cases, especially because it can lead to sudden death in affected patients, who are mostly children and young adults.

The presentation will impact the forensic community and/or humanity by identifying and discussing the etiologies of the disease, its renal and extra-renal manifestations, current therapeutic approaches, i.e. combined liver-kidney transplantation, and the common causes of death in these individuals. The entity is a surgical and anatomic/forensic curiosity, with remarkable gross and histological findings.

Primary hyperoxaluria is a rare autosomal recessive metabolic disorder, caused by the deficiency of the liver-specific peroxisomal enzyme, alanine: glyoxalate aminotransferase (AGT). AGT normally converts glyoxalate to glycine, but when absent, results in an increase of the glyoxalate pool, which is converted to oxalate.

This presentation will discuss the clinico-pathologic features, post-mortem gross and microscopic findings of a fatal case of primary hyperoxaluria.

Case Report: The patient MS, a 24-year-old female with end-stage renal disease, presented to *Beth Israel Deaconess Medical Center* institution with gross hematuria of one month duration. She was eight months old when diagnosed with a rare metabolic disorder, Primary Hyperoxaluria (PH). The patient had two failed renal transplants (one in 1981 at eight months of age, and another in 1991). She began hemodialysis in 2000 and continued the treatment until presenting in January 2005, with gross hematuria. A CT scan also revealed a mass in the left renal allograft. Therefore, a nephrectomy was performed, and pathology ruled out post-transplant lymphoproliferative disorder, and revealed chronic allograft nephropathy, with extensive deposition of calcium oxalate crystals. The patient was discharged, with no complications, and returned to the institution one month later for a combined left kidney/liver transplant. Shortly after the procedure, the patient suffered thrombosis of the hepatic artery-aorta conduit, which was repaired the following day. During repair, it was noted that the liver allograft was necrotic *in vivo*, and a liver biopsy showed massive necrosis consistent with ischemic-type injury (left lobe). The patient quickly became hemodynamically unstable, developed supra-ventricular tachycardia, and after attempts at resuscitation had failed, was pronounced dead.

At autopsy, the body was that of a jaundiced female of small build with kyphosis, and a large abdominal surgical wound, covered by mesh. There were many adhesions throughout the peritoneum. The transplanted liver was partially necrotic (40%), and a hemorrhagic infarct was found in the left lower lobe of the lung. The left, newly-allografted kidney was anteriorly placed, and had a dusky hue. The right, previously (1991) transplanted kidney, was significantly atrophic, and could not be identified. The heart (280 gms) revealed no acute or remote infarcts. The abdominal aorta had an intact stent in place.

Histologic findings of the liver revealed necrosis in the majority of the left lobe, and marked bile stasis in the remaining tissue. The heart had abundant polarizable oxalate crystals in the myocardium, with associated fibrosis. The kidney showed pigmented tubular casts, and focal calcium oxalate deposition. The final autopsy diagnosis was death due to thrombosis of the hepatic artery and aortic conduit that led to massive liver necrosis/failure, and hemodynamic instability. Pre-mortem cardiac conduction defects were most likely due to the diffuse deposition of calcium oxalate crystals within the myocardium.

Primary hyperoxaluria (PH) is a rare metabolic disorder due to a functional deficiency of the enzyme alanine:glyoxalate aminotransferase (AGT). There are at least 20 documented mutations in the gene encoding AGT (AGXT), but two mutations are associated with about 30% of the disease alleles in PH. More specifically, these mutations are associated with mitochondrial mistargeting and defective peroxisomal uptake of the AGT protein. Symptoms develop in 15% of children less than one year of age, and by five, 50% of patients are symptomatic. Infants may suffer from chronic renal failure and parenchymal oxalosis, and older children may have symptoms of urolithiasis, or complete ureteral obstruction. The kidney is the primary organ of involvement, since one of its functions is to excrete oxalate. Renal failure ultimately occurs, and subsequently, the oxalate crystals deposit in other organs, such as the heart, bone marrow, and soft tissues (systemic oxalosis). Chronic renal failure (uremia) leads to secondary hyperparathyroidism, which in a growing individual can cause marked skeletal abnormalities. Possible causes of death are end stage renal failure, cardiac conduction deficits, or a multitude of complications from surgical intervention. Combined liver-kidney transplant is the recommended treatment for these patients, along with hemodialysis, maintaining a high urine output, and thiazide diuresis.

In conclusion, in the presented case, the clinical picture and autopsy findings demonstrate a case of primary hyperoxaluria. The disease entity has numerous clinical manifestations, including renal failure and cardiac conduction defects, and has a high-risk management, (combined liver-kidney transplant); all of which can lead to early, sudden death in these mostly young patients.

Primary Hyperoxaluria, Calcium-oxalate Deposition, Combined Liver-Kidney Transplantation

G9 Planned Complex Suicide: Report of Two Cases

Cristian Palmiere, MD, Institut Universitaire de Médecine Légale, 9 Avenue de Champel, Genève, 1211, Switzerland; Francesco Ventura, MD, and Daniela Picchioni, MD, Dipartimento di Medicina Legale, Via de Toni 12, Genova, 16132, Italy; and Maria del Mar Lesta, MD, and Romano La Harpe, MD*, Institut Universitaire de Médecine Légale, 9 Avenue de Champel, Genève, 1211, Switzerland

Planned complex suicides usually present a challenge to the forensic pathologist and the police in determining the manner and mechanism of death. After attending this presentation, attendees will learn the importance of a careful evaluation of all elements to reconstruct the lethal chain of events.

This presentation will impact the forensic community and/or humanity by improving knowledge of planned complex suicide in the forensic practice.

Case report: Two cases of planned complex suicide are reported. In the first case (ingestion of sodium hypochlorite bleach with associated razor blade wounds), a 27-year-old unemployed female was found dying in the early hours of the day in the bedroom of her apartment, lying in a pool of blood. Her forearms had been incised at wrist level. A blood stained razor blade was found near the body. Traces of blood were evident on the floor in the hall between bathroom and bedroom. She also presented clinical signs of caustic substance ingestion: the lips were burnt, the interior of the mouth was eroded, and the tongue was swollen. A bleach bottle (hypochlorite bleach, 5.25% sodium hypochlorite, pH 11.4) was found in the bathtub. Upon external examination, numerous recent incised wounds were found on the left forearm, most probably inflicted by the razor blade found near the body. These wounds were parallel and superficial, with deeper wounds appearing on both wrists, which had lead to significant blood loss. Autopsy revealed oral, pharyngeal, esophageal, and gastric mucosal erosions. Stomach contents contained blood and had the smell of bleach. All the internal organs were pale. Toxicologic analysis revealed sodium hypochlorite in gastric contents. Death was ascribed to razor blade wounds followed by ingestion of sodium hypochlorite bleach. In the second case, an 86-year-old man was found dead in the bedroom of his apartment. A blood stained razor blade was found on the bed, next to the left arm. A nylon cord, similar to that used for a clothesline, was found bound tightly around the neck several times. The left arm and chest showed multiple superficial incised wounds. There was marked facial congestion and numerous petechial hemorrhages in the skin of the face. Petechial hemorrhages were also prominent in the conjunctivae and oral mucosa. Numerous, recent cuts were found on the chest. These cuts were superficial and parallel to each other, indicating tentative or hesitation cuts. Numerous (68) recent cuts were found on the left forearm, inflicted by the razor found near the body. Most of them were superficial cuts of sizes ranging from 2.5 to 3 cm. Upon autopsy, recent hecatomb was noted to the muscles of the neck, especially the stern mastoid muscles. The tongue showed a recent hemorrhage. Fresh blood was found in the larynx and trachea. The lung showed mild congestion. Toxicological analysis did not detect any drugs or alcohol. Death was ascribed to asphyxia due to strangulation by ligature with associated razor blade wounds.

Complex Suicide, Razor Wounds

G10 Effect of Toilet Detergent on Morphological Change of Spermatozoa

Jian Tie, MD, PhD*, Yuka Serizawa, BS, and Shigemi Oshida, MD, PhD, Department of Legal Medicine, Nihon University School of Medicine, 30-1 Oyaguchi Kamimachi, Itabashi-Ku, Tokyo 173-8610, Japan

After attending this presentation, attendees will be able to identify and appreciate the morphological changes that occur to spermatozoa when exposed to toilet detergent.

This presentation will impact the forensic community and/or humanity by showing how toilet detergent can affect changes in spermatozoa, helping the criminalist determine the length of spermatozoa exposure to the detergent, and providing further assistance in identifying perpetrators of sexual assault.

Human semen is an important specimen in forensic casework. A girl was killed at her own home and found approximately ten days after death. Five persons were suspected as the killer. A condom containing human semen and filled with toilet detergent was found in the toilet chamber pot. Results of DNA identification matched the specimen to one of the suspects. However, the problem was to determine the time when the semen was discarded. For this reason, the following experiment was designed and performed. Human semen samples were collected from fifteen healthy volunteers, and the samples were confirmed to be normal by routine semen examination. The semen samples were mixed in two concentrations of the toilet detergent (0.2 mg/ml and 0.02 mg/ml), or in water as control. All preparations were kept at room temperature and were examined periodically under a microscope. The Oppitz method was used for spermatozoa staining. In the first five days, no definite change in shape of spermatozoa was observed in all the samples. The major change of spermatozoa was separation of the tail and the head, which was clearly observed after ten days under 400 × magnifications. In samples mixed with 0.2 mg/ml solution of toilet detergent, dissociation of the tail and head was observed in approximately 40% of the spermatozoa by ten days, 80% by twenty days, and 98% by thirty days. When mixed with 0.02 mg/ml of toilet detergent, the corresponding proportions were approximately 40%, 70% and 95%, respectively. In the water control, only 25% showed separation by 10 days, and the percentage by 20 and 30 days was similar to 0.02 mg/ml detergent. Increase in bacteria was observed after 20 days. However, when magnification was increased from 400 to 800, approximately 70% of the spermatozoa in toilet detergent solution were found to possess a tail up to 30 days, whereas very few spermatozoa in the water control maintained a tail. The authors find is that after immersed in toilet detergent for a long time, many spermatozoa maintain the head and tail, but the tail becomes thinner and shorter.

Spermatozoa, Toilet Detergent, Morphological Change

G11 An Unusual Death of a Child at the Obstetrician's Office

Albert Y. Chu, MD*, and Luis A. Sanchez, MD, Harris County Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054

After attending this presentation, attendees will be presented with a case of a 13-month-old child who died after his pregnant mother accidentally fell on him while she was at her obstetrician's office. The goal of this presentation is to illustrate the severity of injuries that may result from such a seemingly innocuous event.

This presentation will impact the forensic community and/or humanity by increasing awareness of the potential for fatal injuries in a case where the severity of injuries was in excess of what might have been expected given the history and, had the event not been witnessed, might have been mistaken for child abuse.

A witnessed case of a 13-month-old child whose mother fell on top of him at her obstetrician's office is presented, resulting in severe head injuries that, under different circumstances, might be mistaken for abuse.

A 31-year-old, 5-foot 8inch, 180-pound woman in her 8th month of pregnancy was at her obstetrician's office with her two children, a 3-year-old girl, and a 13-month-old boy. While the woman was being weighed on a scale, the 13-month-old boy walked behind her. Not noticing her child behind her, the woman stepped backward off the scale and onto her child, losing her balance and falling on top of the boy. According to a statement to police, her "tailbone hit her son's head." The height of the scale was 4 inches from the carpeted floor. The event was witnessed by the doctor's nurse; whose statement corroborated that of the mother's and further indicated that the left side of the boy's face was down against the carpet when his mother landed on him.

The boy, who immediately became unresponsive, was taken to the hospital where his Glasgow coma scale on arrival was 4-5 and he was exhibiting decerebrate posturing. Computed tomography scans of the head showed a depressed frontal skull fracture, bilateral subarachnoid hemorrhage (left greater than right), left subdural hematoma (without midline shift), and elevated intracranial pressure. No funduscopic examination was performed. Despite medical intervention, he died the next day and was brought to the Harris County Medical Examiner's Office for autopsy.

At autopsy, external examination revealed diffuse, right-sided scalp hemorrhage and right periorbital ecchymosis. Internally, a gaping 7-1/4" linear skull fracture involved the parietal skull bilaterally, anteriorly extending to and involving the coronal suture. Dura and brain matter herniated through the fracture. Approximately 20 milliliters of subdural hemorrhage were present bilaterally (right greater than left). Bilateral parasagittal subarachnoid hemorrhage and bilateral tonsillar herniation were also present. Coronal sections revealed contusions of the right frontal and parasagittal contusions. No other injuries were noted.

In the United States, an estimated 1,400 deaths due to child neglect and abuse occurred in 2002; of these, 30% were due purely to physical abuse. The majority of pediatric homicides occur within the first two years of life, and the cause of death most commonly involves blunt force injuries to the head or abdomen. Typically, fatal injuries in children do not occur as a result of minor mishaps during ordinary activities of daily living. The discrepancy between the history provided by the caregiver and the severity of the injuries themselves is often the initial indication of abuse. Such stories may describe the decedent rolling off of a bed, falling from the arms of the caregiver, or the caregiver falling while carrying the child. Had the events described in the case above not taken place at the doctor's office and been witnessed, the "discrepancy" between the story and the severity of the injuries sustained by the decedent would likely have raised serious suspicions of child abuse.

Fall, Head Injuries, Child Abuse

G12 Methadone Treatment and Drug Overdose in Geneva, Switzerland, From 1994 to 2003

Guillaume Perret, MD*, Institut Universitaire de Medecine Legale de Geneve, 9 av. de Champel, CMU, Geneva, 1211, Switzerland; Ann Ho, PhD, and Mary Jeanne Kreek, MD, Laboratory of the Biology of Addictive Diseases, Rockefeller University, 1320 York Avenue, New York, NY 10021; and Romano La Harpe, MD, Institut Universitaire de Medecine Legale de Geneve, CMU, 9 av. de Champel, Geneva, 1211, Switzerland

After attending this presentation, attendees will learn how lethal methadone intoxications while on methadone treatment are very rare and probably due to a lack of strict medical oversight.

This presentation will impact the forensic community and/or humanity by demonstrating why it is important to collect good information regarding drug and clinical history when considering lethal methadone intoxications. In this study, most of the decedents were not enrolled in methadone programs. Wide access to methadone treatment with good medical oversight does not lead to an increase of lethal methadone intoxications and may be responsible for a large decrease of overall drug intoxication deaths.

This presentation will show that methadone treatment is safe when well controlled medically and that methadone overdoses are in most cases due to diverted methadone. It will extend an earlier study reported in 2000, covering the years 1994 to 1998, showing that in Geneva, the wide access to methadone treatment did not lead to an increase of lethal methadone intoxication and may be responsible for a large decrease of overall drug intoxication deaths.

It is hypothesized that the decrease in the number of lethal drug intoxications that started in 1995 had continued through 2004 because of the wide access to methadone treatment, which provides treatment to most of the heroin addicts in Geneva. In 2000, the estimated number of addicted drug users in Geneva, including users of heroin, cocaine, cannabis, and benzodiazepines was 2500. The number of methadone treated patients in 2005 is 1356 and the new heroin users asking for methadone treatment is dropping steadily. From 1 January 1994 to 31 December 2003, the authors studied systematically all toxicological data from all cases in which methadone and/or morphine was found. Cases were selected on the basis that the only cause of death was a potentially lethal drug concentration in the postmortem blood sample. For each case in which methadone was found, information regarding drug and clinical history was collected from police sources and from the Health Authority for each registered methadone-treated patient.

It was discovered that the drop of lethal drug intoxications starting in 1995 continued until 2003. Methadone lethal intoxications remain stable and low - around five cases per year. Most of them are due to illegally diverted methadone used by a person not in treatment. Cocaine overdoses have increased since 2002. Most of the lethal overdoses have other drugs present in the blood, the commonest being benzodiazepines and alcohol.

In conclusion, methadone treatment has been very successfully implemented in Geneva since the 1970s and has been widely available since the 1990's, with a dramatic decrease of heroin overdoses. This can be explained by the fact that almost all heroin addicts have easy access to treatment. The wide access to methadone treatment has not lead to an increase of lethal methadone intoxications. The lethal methadone intoxications while on methadone treatment are very rare and probably due to a lack of strict medical oversight. It is important to note that most of the decedents were not enrolled in methadone programs.

Methadone, Addiction, Overdose

G13 Pathological Changes Associated With Aortic Valve Stenosis

Lise A.M. Matzke, MSc*, and Courtney Young, BSc*, James C Hogg iCAPTURE Centre, Room 166, 1081 Burrard Street, Vancouver, BC V6Z 1Y6, Canada

After attending this presentation, attendees will understand the pathology of aortic valve stenosis (AVS). Aortic valve stenosis is a cause of sudden cardiac death in older individuals and young athletes.

As such, this poster will impact the forensic community by highlighting major pathological features of degenerative and bicuspid aortic stenosis as well as the underlying pathogenesis of these diseases.

An analysis of the morphological features and pathogenesis of this common heart valve disease will aid pathologists and researchers in understanding its role in sudden death. As the incidence of aortic stenosis increases, the rate of sudden death due to this disease does as well. This presentation will impact the forensic community and/or humanity by assisting in the understanding of the environmental and genetic determinants of its pathogenesis, which will aid those conducting pathological examinations to better understand the underlying features of the morphological changes seen at autopsy.

Aortic valve stenosis is the most common valvular heart disease among adults in the western world, and continues to increase in prevalence as the average lifespan of the population increases. As such, AVS has become a focus of intense investigation at the James Hogg iCAPTURE Centre in Vancouver, British Columbia, Canada.

Aortic valve stenosis may be due to congenital malformation of the valve, rheumatic fusion of commissures, secondary calcification of a congenital bicuspid valve, or primary degenerative calcification of an otherwise normal three cuspid valve. While the exact pathogenesis of AVS is unknown, several genetic and environmental determinants are most likely responsible.

AVS is characterized by narrowing of the aortic valve due to scarring and calcification, changes which create an obstruction to blood flow out of the main pumping chamber of the heart into one's circulation. Symptoms can include chest pain, fainting, or heart failure. If left untreated, the outcome of patients with AVS is poor. Once treated, however, mainly by valve replacement, the patient survival rates and well being greatly improve.

This poster will demonstrate some of the pathological changes associated with aortic valve stenosis with a discussion of its possible pathogenesis.

Aortic Stenosis, Cardiovascular Pathology, Sudden Death

G14 Fatal CO₂ Suicidal Poisoning

Gilles Tournel, MD*, Fabrice Dedouit, MD, Anne Becart-Robert, DDS, PhD, Pierre Dutrieux, MD, Valéry Hedouin, MD, PhD, and Didier Gosset, MD, PhD, Institut de Médecine Légale, Faculté de Médecine, 1, place de Verdun, Lille, 59000, France

The goal of this presentation is to recognize that the cause and manner of death requires deliberate consideration, even when the circumstances may lead to an initial obvious, but misleading, direction. It is important to consider the case, the crime scene, and the autopsy findings, especially if the death is non-natural.

This presentation will impact the forensic community and/or humanity by demonstrating an interesting case for the forensic pathologist and forensic toxicologist. It is important that these two disciplines work together and to share the findings to go to the truth.

Introduction: The authors describe a case of suicide in a workplace. A 45-year-old man who worked in a vegetable and fruits packaging business was found dead in his workplace. Because of the scene circumstances, analysis of an arterial blood sample taken with an airtight syringe at the scene revealed absence of carbon monoxide but high levels of carbon dioxide (CO₂). Autopsy found no significant injury and police investigators found a handwritten note of intent, describing a recent personal crisis. Therefore the authors concluded that the cause of death in this case was a suicide by carbon dioxide intoxication. This means of suicide is rare, with cases previously described in the literature as accidental carbon dioxide intoxications. This is the first case of suicide by CO₂ intoxication within a closed-space tank in which the atmosphere is modified for the package of fruits and vegetables.

Case report: A 45-year-old male who worked as a packager of vegetables was found dead on the floor in his workplace. The location of the death was a confined room used for packaging vegetables, fruits, and apples. External examination showed no sign of struggle and the victim had no history of psychiatric disorders. The rescue team thought that cause of death could be carbon monoxide intoxication. In the residence of the deceased, police investigators found a handwritten note of self-destructive intent, describing a recent personal crisis.

Autopsy findings: An autopsy was performed by a board-certified forensic pathologist. The external examination of the body was significant for an absence of cherry red lividity, which is normally a good indicator of CO₂ intoxication. Autopsy found no significant injury and no traumatic lesion.

Toxicology: Toxicological analysis was carried out, including blood ethanol levels and screening for common drugs and illegal substances. Surprisingly, carboxyhemoglobin was positive only at 2% saturation. The cause of death was unclear. The forensic pathologists had the idea to perform the quantification of PCO₂ and PO₂ in the arterial blood. An analysis of the airtight arterial peripheral blood sample found an oxygen saturation of 34.1%. The partial arterial CO₂ level was 204 mmHg and the O₂ 38.6 mmHg. The normal range of partial arterial CO₂ extends from 40 to 60 mmHg; the normal range of partial arterial O₂ extends from 95 to 60 mmHg.

The cause of the death was attributed to asphyxiation caused by CO₂ intoxication and especially the depletion of oxygen in the room. The manner of death was determined to be suicide. In spite of a suspected rapid postmortem increase in PCO₂ and because of the context of death, assessment of the PCO₂ level was performed in this case. The results of the PCO₂ were elevated to such a degree, that it was possible to conclude that the cause of death was CO₂ intoxication.

Discussion: the mechanisms of toxicity of CO₂ are discussed. Carbon dioxide is produced when organic material decomposes or ferments. Asphyxiation from CO₂ exposure has occurred in workers entering grain elevators (cereal stocking), the holds of cargo ships, and brewery vats. It occurs accidentally when these spaces are not aerated or ventilated, or when the ventilation system dysfunctions. Sub acute toxicity may be caused by the body's failure to eliminate endogenous CO₂, as it occurs in hypoalveolar ventilation resulting from chronic obstructive pulmonary disease, opioid poisoning, or other causes of respiratory failure. Clinical signs of CO₂ intoxication are presented and compared with the concentration in mmHg found in this case. Other sources of CO₂ exposure are detailed. The most frequently encountered causes of CO₂ intoxications are accidental and occur in the occupational setting. Examples of these types of cases are also presented. Deaths by intentional carbon dioxide intoxication are rare. Generally, such cases are suicide by intentional inhalation of automobile exhaust gases with low carbon monoxide emissions within an enclosed garage.

CO₂, Occupational Suicide, Asphyxiation

G15 Case Report – Sudden Death Due to Cystic Tumor of the Atrioventricular Node

Carlos F. Chavez Arias, MD*, Kathryn Haden-Pinneri, MD, Maximilian Buja, MD, and Luis A. Sanchez, MD, Harris County Medical Examiner's Office, Joseph J. Jachimczyk Forensic Center, 1885 Old Spanish Trail, Houston, TX 77054

The goal of this presentation is to show the importance of including cystic tumors of the atrioventricular node as one of the main differential diagnoses in cases of sudden death, especially in the context of congenital heart block with the adjunct of performing a thorough examination of the cardiac conduction system.

This presentation will impact the forensic community and/or humanity by demonstrating how this type of tumor will be missed if routine sections of the AV node are not submitted in cases of sudden death, especially those involving young, healthy individuals, and it should always be considered in cases of sudden death in the context of congenital heart block.

Cystic tumor of the atrioventricular (AV) node is a benign, congenital, cystic mass located at the base of the atria septum in the region of the AV node. Although cystic tumor of the AV node is the most common intracranial tumor causing sudden death it is considered a rare neoplasm with less than 100 cases reported in the literature to date.

A case of a woman in her 30's who was diagnosed as an infant with complete heart block is reported. A permanent pacemaker with epicardial leads was subsequently placed. She functioned normally with the exception of exercise related shortness of breath. She underwent several pacemaker changes throughout her life. She had a very active lifestyle. She was in her usual state of good health when she experienced a sudden witnessed collapse at her workplace. Her initial cardiac rhythm at the scene was pulseless electric activity with appropriate pacemaker discharge. She was pronounced dead at the hospital after unsuccessful resuscitative measures.

At autopsy, examination of the cardiovascular system disclosed a 550-gram heart. The coronary arteries had a normal distribution and were free of atherosclerosis. The pacemaker leads were appropriately positioned. No gross lesions were visible on examination of the cardiac conduction system.

Microscopic examination of the myocardium showed hypertrophic myocytes, focal interstitial fibrosis, and focal contraction band necrosis. Sections from the region of the AV node showed a proliferation of cells forming nests, cysts, and glands of variable size and shape measuring a minimum of one centimeter. The cell population ranged from those resembling transitional cells and those with squamous differentiation to cuboidal cells and clear, sebaceous-appearing cells.

Cystic Tumor of the Atrioventricular (AV) node has been called one of the "smallest tumors causing sudden death." When symptomatic the majority of patients present with complete heart block. The diagnosis of heart block in patients with AV nodal tumors may be made at birth or as late as the ninth decade of life. It has a female predominance. The majority of known cases are diagnosed at autopsy although a few reported cases have been diagnosed during life and treated. Pacemaker is the first line of therapy; however they are not always effective, as seen in this case. Although rare and histologically benign, cystic tumors of the AV node are the most common intracardiac neoplasms causing sudden death. They are located in the AV nodal region because this is an area of embryologic fusion and therefore prone to accidental incorporation of embryologic structures. The mechanism of death is related to its intracardiac location, which can precipitate conductive and hemodynamic abnormalities. Cystic tumors of the AV node are rarely seen grossly, but when visible it is seen as an elevated nodule above the septal leaflet of the tricuspid valve. Most of the time they are first identified microscopically. This lesion is characterized by multiple microcysts, gland like structures, and nests of epithelioid (occasionally squamoid) cells within a fibrous stroma. Previously thought of as a mesothelioma of the AV node, this lesion has since been shown convincingly to represent an endodermal heterotopia.

The tumor will be missed if routine sections of the AV node are not submitted in cases of sudden death, especially those involving young, healthy individuals. It should always be considered in cases of sudden death in the context of congenital heart block and congenital fibrosis of the AV node.

Cystic Tumor of the AV Node, Sudden Death, Heart Block

G16 Sudden Death in a Healthy 37-Year-Old Man While Driving: Spontaneous Dissection of the Posterior Segment of the Right Coronary Artery

Wendy M. Gunther, MD*, Department of Legal Medicine, Virginia Commonwealth University, Medical College of Virginia, 1101 E Marshall Street, Richmond, VA 23298-0568; and Jonrika M. Malone, MD, Office of the Chief Medical Examiner, Tidewater District, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510-1046

After attending this presentation, attendees will recognize spontaneous coronary artery dissection as a cause of sudden death, and as a discrimination between auto accident injury and natural cause of death. Review of the epidemiologic, gross, and histologic features and characteristics of this rare disorder will be presented to forensic pathologists

This presentation will impact the forensic community and/or humanity by increasing the awareness of the existence, characteristics, gross presentation, and histology of a rare natural disorder which frequently presents with sudden death, and which may complicate deaths in motor vehicle accidents.

A 37-year-old man with no history of heart disease, including no family history, was driving down a state highway when his car ran off the left side of the road, struck a sign, veered across the median across the oncoming traffic lane, and struck a utility pole. There was no attempt to brake, according to witnesses, and no skid marks. No other cars were involved in the accident. The victim was wearing his seat belt and shoulder belt, and the airbag deployed. A witness said the victim showed signs of life after the car came to rest. Emergency medical personnel who reached the scene noted there was no visible injury, but the victim was unresponsive and asystolic, and they believed him dead. Attempted cardiopulmonary resuscitation at the scene and in a local emergency room was unavailing.

At autopsy, the victim measured 68" tall and weighed 198, with a muscular body habitus with no evidence of obesity. External signs of injury were limited to several small bruises on the left side of the shoulder at the base of the neck, consistent with a shoulder harness. There were no xanthomata of the eyelids or elbows. The heart weighed 375 grams, less than five percent of estimated lean body weight; there were no signs of hypertrophy. The renal cortices were smooth. The coronary arteries had normal takeoffs, without atherosclerosis other than proximal fatty streaks. There were no coronary anomalies or previous infarcts. There were no significant internal injuries.

On sectioning of the ventricles, a "red dot" was noted in the epicardial fat over the posterior septum. Examination with a hand-held magnifying glass confirmed hemorrhage both inside and around the posterior septal segment of the right coronary artery. A delicate layer of coronary wall could be seen creating an S-shape between foci of hemorrhage.

On histology, the coronary artery had dissected through the outer plane, and a mixed inflammatory infiltrate including eosinophils surrounded the adventitia, and infiltrated the wall. No other area of the heart or coronaries showed eosinophils. There were no foci of lymphocytic myocarditis. No myocardial scarring, myocyte hypertrophy, or small vessel disease was present.

Dissection of the coronary arteries as a spontaneous event has been well reported in the literature, with an undetermined but possibly

autoimmune etiology. More than two thirds of patients present at autopsy; the remaining third often recover with stenting or thrombolysis. Coronary artery dissection accounts for approximately 0.5% of sudden deaths in patients 30-40 years old. The typical victim is female, of childbearing age, frequently in her thirties, occasionally postpartum. The victims do not have a history of hypertension (or hypertension is present as an unrelated factor). Over 90% of cases that come to autopsy involve the left anterior descending coronary artery. Under the microscope, the dissection plane is in the outer media, unlike the dissection of atherosclerotic arteries. There is a striking infiltrate of eosinophils, lymphocytes, neutrophils, and macrophages in the adventitia. Some believe that the inflammatory infiltrate is secondary to the dissection, and not a vasculitis. There is no time of day, drug, or activity, which is correlated with initiation of the dissection.

Spontaneous or eosinophil-associated dissection of the coronary arteries in males is rare. Men comprise about 15% of the victims of this unusual disorder. The posterior segment of the right coronary artery is the most frequently reported site in men. Researchers were unable to find information that would answer the family's questions as to risks for other family members. The etiology and genetics of spontaneous coronary dissection are unknown. The case is discussed in conjunction with a review of the literature and the sparse information that is available on this rare disorder.

Spontaneous Coronary Artery Dissection, Males, Motor Vehicle Accident

G17 Fibrosis of the Cardiac Conduction System as a Possible Cause of Death in Chronic Cocaine Addicts

Katarzyna Michaud, MD*, Thomas Krompecher, MD, Frank Sporkert, PhD, Franco Taroni, PhD, Béat Horisberger, MD, Marc Augsburger, PhD, and Patrice Mangin, MD, PhD, Institut Universitaire de Médecine Légale, Bugnon 21, Lausanne, 1005, Switzerland

The goal of this presentation is to present a study of the fibrosis of the cardiac conduction system in chronic cocaine addicts.

This presentation will impact the forensic community and/or humanity by demonstrating and emphasizing that the early onset of fibrosis in the cardiac conduction system may explain sudden death in chronic cocaine users and especially whose measured drug levels are relatively low

It is well known that the results of toxicological analyses can be difficult to interpret in drug addicts because of their increased drug tolerance. Thus, the forensic pathologist is occasionally faced with death cases in chronic drug addicts that demonstrate relatively low drug concentrations in their blood. In some cases, autopsy does reveal the anatomic/pathological cause of death, but in other cases no lesion can be found at the macroscopic or microscopic levels.

The goal of the present work is to study fibrosis of the cardiac conduction system in chronic cocaine addicts. Myocardial fibrosis may provide the morphological substrate in certain arrhythmias and may even explain a sudden death. At the same time, a review of the literature shows that the cardiac conduction system is rarely examined in drug addicts, including individuals whose drug consumption is chronic, as revealed by hair analysis.

Materials: The group of cocaine addicts was comprised of 33 cases all known by the police to involve chronic substance abusers. In each case, cocaine was detected in the hair. Hair analysis also revealed that for all cases, cocaine was associated with other illicit drugs, such as opiates, methadone, and amphetamines. In the majority of cases (27), the cause of death was attributed to an overdose. The control group was comprised of 31 cases where death was attributed to trauma, hanging, or a natural cause. No illicit substance was detected in the blood, urine, or hair of the control cases. The age ranged from 21 to 45 years in the drug addict group

(average of 31.6 years) and from 21 to 50 years in the control group (average of 31.7 years).

Methods: Samples were collected at the level of the atrioventricular junction. Slides were stained with haematoxylin-eosin and Masson's trichrome. The extent of fibrosis was determined using a 4-point semi-quantitative scale. Fibrosis assessment was carried out in the following regions of the atrioventricular junction: the atrioventricular node, the penetrating part of the node, the branching bundle and the left and the right bundle branches. In addition, the superior septum was also analysed.

Results: The mean values obtained from the different structures of the conduction system and the superior septum were higher for the group of drug addicts than for the control group.

Statistical analysis: The pair wise comparison population test showed significant differences ($p<0.01$) in the atrioventricular node, in the left bundle branch and in the myocardium of the superior septum.

Conclusion: Fibrosis of the different structures of the conduction system and of the superior septum is a degenerative lesion whose severity increases with age. Early occurrence of fibrosis in drug addicts appears to be linked primarily to chronic cocaine consumption. This is not surprising, as cocaine cardiotoxicity has been known for a number of years. At the same time, the hair analyses conducted in this study show that repetitive cocaine consumption is almost always associated with chronic abuse of other illicit drugs. Thus, one cannot exclude the role played by these other substances in the appearance of fibrosis in the studied cases.

Myocardial fibrosis may cause problems in the cardiac rhythm and even lead to sudden death. Thus, in the context of this study, the early onset of fibrosis in the cardiac conduction system and the superior septum may explain sudden death in chronic drug users whose measured drug levels in the bloodstream are relatively low.

Conduction System, Hair Analysis, Drug Abuse

G18 Fatal Venous Air Embolism in a Postmenopausal Female During Consensual Sexual Intercourse: A Case Report and Review of the Literature

Erik D. Christensen, MD*, Office of the Greenville County Medical Examiner, 890 West Faris Road, Suite 110, Greenville, SC 29605

After attending this presentation, attendees should have an understanding of the varied setting in which venous air embolism can occur and can cause sudden death.

This presentation will impact the forensic community and/or humanity by presenting a case with an unusual cause of sudden death and to review the relevant literature for future reference.

Case Report: A sixty-year-old female had recently begun an infrequent sexual relationship with a younger man. Following sexual intercourse on the day of her death, her partner noted blood on his penis. She denied pain, but stated that she did not feel well and was having some shortness of breath. She then collapsed and expired despite resuscitative measures, which were delayed, as her partner dressed her prior to summoning help.

Autopsy revealed an atrophic vaginal mucosa with a laceration of the right lateral sidewall. Intravenous air was present in the pelvic veins and there was also interstitial emphysema. Aspiration of blood from the coronary sinus revealed frothy blood and air bubbles were present in her epicardial veins.

Methods: Autopsy protocol and investigative findings for this patient are reviewed. The medical literature was searched using the keywords *air embolism*, *venous air embolism*, *sudden death*, and *vaginal laceration* for citations relating to venous air embolism. References from citations found were further reviewed for relevant literature.

Results: Venous air embolism is a well-described phenomenon, associated with neurosurgical procedures in both the seated and prone position, as well as in pelvic procedures ranging from transurethral prostate resection to hysteroscopy. It has also been reported to occur in the pregnant women following vaginal insufflation and intercourse, in non-pregnant women following intercourse and autoerotic manipulation. Cranial blunt injuries may result in air embolism. Cases related to central venous catheter use, percutaneous lithotripsy, endoscopy and intraoperative hydrogen peroxide irrigation have also been reported.

Conclusions: Venous air embolism is an unusual cause of sudden and unexpected death and this report documents the first case of this phenomenon occurring in the setting of a vaginal laceration resulting from consensual sexual intercourse in a post-menopausal woman.

Air Embolism, Vaginal Laceration, Sudden Death

G19 Incidence of Laryngeal and Hyoid Fractures in Hangings and Strangulations Using Enhanced Examination Procedures

Dana Austin, PhD, and Marc A. Krouse, MD, Tarrant County Medical Examiner, 200 Feliks Gwozdz Place, Fort Worth, TX 76104-4919

After attending this presentation, attendees will understand that enhanced examination of the larynx and hyoid will reveal subtle injuries of bony and cartilaginous structures that might otherwise not be found

The rate of injury of the larynx and hyoid is significantly higher when examination of these structures is enhanced by high-resolution radiography and maceration and removal of soft tissues followed by macroscopic examination. This presentation will impact the forensic community and/or humanity by demonstrating how these simple and inexpensive procedures can reveal subtle injuries of bone and cartilage that otherwise might not be seen and complete the forensic examination of the neck in cases of known or suspected strangulation, hanging or other neck injury.

Between 1996 and 2005 the examination of the larynx and hyoid in cases of suspected or known neck injury was enhanced by the following methodologies:

1. Visual inspection and palpation of the larynx and hyoid at autopsy, in situ and after en bloc resection and limited dissection of soft tissues
2. High-resolution radiography of the fresh en bloc specimen utilizing mammography film
3. Maceration of soft tissue in water with removal of residual tissue and macroscopic visual inspection of laryngeal and hyoid bone and cartilage

The sample consists of 105 individuals who died of hanging or strangulation or suspected strangulation between 1996 and 2005. The sample population contains 52 males and 53 females with an age range of 8 to 81 years (mean of 36.32 years). For analytical purposes the ages were divided into decades: the first decade and the ninth decade each represented by one individual; the second through eighth decades ranged from four individuals (eighth decade) to 31 individuals (third decade). The ancestry of the sample was 62% European, 18% African, 18% Hispanic, and 2% Asian.

Examined were 62 hangings, 20 manual strangulations, 10 ligature strangulations and 13 strangulations not otherwise specified (mechanism unknown or evidence of arm lock or combination of manual and ligature). Sixty-one hangings were ruled suicide or consistent with suicide, one 15-year-old was ruled accidental and was consistent with autoerotic asphyxiation - this was the only hanging where padding was included with the ligature. The strangulations cases were all ruled homicide.

Of the hanging cases (N=62), 19.4% had hyoid fracture and 48.4% had thyroid fracture. Of cases of ligature strangulation (N=10), 20% had hyoid fracture and 40% had thyroid fracture. Of cases of manual strangulation (N=20), 45% had hyoid fracture and 50% had thyroid fracture. In cases of strangulation, not otherwise specified (N=13), 7.7% had hyoid fracture and 46.2% had thyroid fracture.

The most commonly fractured sites in the hyoid were the midshaft of the greater cornu either unilaterally (18.5% for left side, 25.9% right side) or bilaterally, 18.5%. This agrees with findings on a much smaller sample by Pollanen et al (1995). The most commonly fractured sites in the thyroid cartilage were bilateral fractures of the left and right superior cornua (32%), left superior cornu unilaterally (24%) or right superior cornu unilaterally (30%). The most common location for the superior cornu fracture was at its juncture with the lamina (18% left; 16% right). Ubelaker's review of the literature (1992) cites a cohesive fracture rate of 8% hyoid fractures and 15% thyroid fractures in hangings, 11% fractures hyoid and 32% fractures thyroid in ligature strangulations, and 34% hyoid and thyroid fractures in manual strangulations.

The data of the group support earlier contention that the supple nature of these structures in children and young adults does not lend them to easy fracture (O'Halloran & Lundy, 1987; Pollanen & Chiasson, 1996). The earliest age of hyoid fracture in this series occurs in the third decade with 19% fractured, all in the mid-portions of the greater cornua. The fourth through seventh decades show fracture rates varying between 14 to 26%. In the eighth and ninth decades the fracture rates are 100%; however this number is based on a total of five individuals. The earliest age of thyroid cartilage fracture is the second decade with one 18-year-old individual with a fracture of the left superior cornu at the base. Fracture rates of the thyroid cartilage range from 32% to 70% in the third through seventh decades and are at 80% in combined eighth and ninth decades.

In cases where ligature type is known for hangings and ligature strangulations, the frequency of fracture type with ligature type was detailed. Cord type ligatures, which included ropes, electrical cords, telephone cords, shoelaces, and other small diameter strings, resulted in 22% hyoid and 44% thyroid fractures. Strap type ligatures, which included cargo straps and belts, resulted in 12% hyoid fractures and 53% thyroid fractures. Fabric type ligatures, which included clothing such as t-shirts, sheets, curtains and neckties, resulted in 18% hyoid fractures and 45% thyroid fractures. In three cases where the ligature was not recovered at the scene, all had hyoid fractures and 2 out of 3 had thyroid fractures.

G20 Agonal Sequences in a Filmed Suicidal Hanging: Analysis of Respiratory and Movement Responses to Asphyxia by Hanging

Anny Sauvageau, MD, MSc*, Laboratoire de Sciences Judiciaires et de Médecine Légale, 1701 Parthenais Street, 12th Floor, Montreal, Quebec H2K 3S7, Canada; Stéphanie Racette, BSc, Laboratoire de Sciences Judiciaires et de Médecine Légale, 1701 Parthenais Street, 12th Floor, Montreal, Quebec H2K 3S7, Canada

After attending this presentation, attendees will gain a better understanding of the physiological responses of asphyxia by hanging.

This presentation will impact the forensic community and/or humanity by demonstrating a unique case that will allow a better understanding of the respiratory and movement responses of asphyxia by hanging.

The goal of this presentation is to first review the literature of physiological responses to asphyxia by hanging in humans and animals, and to compare such data to a unique case of suicide by hanging that was recorded by a video-camera.

There is just one report in the literature of an analysis of agonal movement sequences in hanging, published in 1989 in German. In this case, a man recorded his autoerotic hanging with a video camera and died accidentally. Except for this foreign language case, there is very few data on human hanging. A few experimental studies have been conducted on dogs, but the application of those results to human hanging is limited. Of course, there are witnessed reports of judicial execution hangings, but those are very different in nature from typical hanging, since death is caused mostly by fracture-dislocation of the upper cervical vertebrae with transaction of the spinal cord, rather than asphyxia by neck structure compression.

A case of a 37-year-old man who filmed his hanging suicide is presented. The man tied a padded rope to his neck and fixed the other end on the rail system of an electric garage door. He used the remote control to close the door, therefore hanging himself. His feet were fixed in ski boots, tied with chains to a metal platform. A camera was previously set to film his suicide. This film allows a unique analysis of agonal movement sequences.

Before the final hanging, the man first hesitated for 23 seconds, testing the door by moving it up and down with the remote control. Then, he finally closed the door and hanged himself.

Considering the time of hanging to be time 0, the agonal sequences consisted of the following: loss of consciousness (thirteen seconds), convulsions (fifteen seconds), decortication rigidity (twenty-one seconds), decerebration rigidity (forty-six seconds), second decortication rigidity (one minute eleven seconds), loss of muscle tone with a few isolated muscle movements (one minute thirty-eight seconds) and last isolated muscle movement (four minutes ten seconds).

Twenty-one seconds after hanging, the body presented decortication rigidity, with extension of trunk and lower limbs combined with upper-limb flexion. This pattern of rigidity is caused by cerebral cortex impairment. Twenty-five seconds later, the body suddenly moved from this pattern of rigidity to decerebrate rigidity, with full extension of both upper and lower limbs. Mesencephalon impairment causes this rigidity pattern and is generally accompanied by irreversible coma and unstable vital signs.

The amplitude of movement during the initial convulsions, as well as during the rigidity pattern changes, explains the minor traumatic lesions often seen in hanging in closed areas, such as a wardrobe.

The hanging in the present case does not seem to completely occlude the airway and respiratory movements are well seen in the film. Twenty-seconds after the hanging, very deep respiratory attempts with rhythmic respiratory chest and abdominal muscle contraction started. The respiration was loud and wheezing. At one minute eleven seconds, abundant saliva freely flowed from the mouth. Respiratory movements progressively decreased and completely stopped at two minutes.

This case confirmed the well-known occurrence of rapid loss of consciousness within seconds. Moreover, it gives a unique opportunity to study the agonal movement sequences in hanging.

Asphyxia, Hanging, Forensic Pathology

G21 Visual Misidentifications of Human Remains: Lessons Learned

Joyce L. deJong, DO, Sparrow Hospital, 1215 East Michigan Avenue, Lansing, MI 48909-7980*

After attending this presentation, attendees will learn of two visual misidentifications made by parents after the death of their sons.

This presentation will impact the forensic community and/or humanity by examining the procedures followed after one of the parents alerted officials of the possible misidentification and suggests (1) methods to avoid visual misidentifications, and (2) measures to routinely follow to respond to claims of bodies being "mixed-up" in the morgue.

Misidentifications are often reported by the general media and rarely presented formally in the forensic science literature. This presentation will impact the forensic community and/or humanity by assisting the forensic community by pointing out the situations that most commonly result in misidentifications, the steps needed to prevent the misidentifications, and other measures to take to address where the misidentification occurred.

An automobile driven by a drunk driver, struck two 14-year-old white males, Child A and Child B, as they walked home from a skateboarding park. The mother of one of the boys (Mother A) "claimed" Child A as her son at the scene and rode to the hospital in the ambulance with the child. A second ambulance transported Child B. Child B died in the emergency department; "Mother B" and her husband arrived at the emergency department after Child B died and claimed him as their son. Child A died hours later in the pediatric intensive care unit with his parents and many others in attendance at his bed. An autopsy performed the following day on both of the boys showed the cause of both deaths to be multiple injuries due to pedestrian struck by a motor vehicle. Both children had severe head injuries. Photographs and fingerprints were obtained during the autopsy. Close family members viewed the body of Child A at the funeral home and then had him buried at a local cemetery. The family who claimed Child B had him cremated after an open-casket visitation and funeral. During the open-casket visitation, many students from the school the boys attended strongly voiced their opinion that the boy in the casket was Child A and not Child B. The parents denied the claims of the visiting children and the funeral directors believed the parents.

About one year later, Mother A reported that she believed she had claimed the wrong child; her opinion developed after reading the autopsy reports and recognizing the report with her son's name described the other child and vice versa. Mother A had antemortem fingerprints available for comparison with the two sets of postmortem fingerprints obtained at the autopsy; the prints matched the postmortem prints of Child B. Child A was exhumed and antemortem dental records were obtained for both children. The forensic odontologist compared the two sets of antemortem dental records to the exhumed remains of Child A; the odontologist was blinded as to the identity of the antemortem records. The antemortem records provided by Mother B matched the postmortem dental features of Child A. By both fingerprint and dental record comparison it was determined that Child A was the child of Mother B and Child B was the child of Mother A. In one photograph of Child B, the name of the child is clearly visible on the hospital identification band with the associated autopsy case number indicating the bodies were not mixed up in the morgue after being banded in the hospital. The parents visually misidentified the children.

Lessons learned from this case are multiple and include: (1) Visual identifications are not always accurate – even parents can claim the wrong individual as their child. (2) Incidents involving victims of the same sex, race, and approximately the same age, should be identified using a biological method such as fingerprints, dental record comparison, medical X-ray comparison, or DNA. (3) Photographs of all identifying tags with the autopsy case number clearly visible should be routinely obtained.

Human Identification, Forensic Science, Exhumation

G22 Identifying Corpses of Foreigners in the State of Advanced Decomposition: Sri Lanka After the Tsunami 2004

Heike Klotzbach, MD, PhD*, Institute of Legal Medicine, Stiftsplatz 12, Bonn, 53111, Germany; Klaus Benedix, DMD, Dental Services German Air Forces, Dachauer Strasse 128, München, Bavaria 80637, Germany; Guido Beutler, Embassy of the Federal Republic of Germany, 6/50 Shantipath, Chanakyapuri, New Delhi, 110 021, India; and Thomas Lubnau, and Kerstin Schneider, Federal Criminal Police Office, Georg-Marshall-Strasse 20, Wiesbaden, 65173, Germany; Stephan Klein, Federal Criminal Police Office, Georg-Marshall-Strasse 20, Wiesbaden, 65173, Germany

After attending this presentation, attendees will gain an understanding of disaster victim identification under difficult conditions.

This presentation will impact the forensic community and/or humanity by assisting the forensic community in understanding the necessity of cooperation of different nations and individual specialists concerning mass disaster victim identification under difficult conditions (e.g. foreign country, different mentality, and multinational victims advanced decomposition)

After the tsunami numerous tourists were reported missing in Sri Lanka. Main objectives of the German disaster victim identification (DVI)-team were sustaining a general survey of the circumstances and to achieve actual dates concerning foreign victims, German citizens in particular, and to proceed with their identification. Exceptional conditions consisted in a relatively small percentage of multinational foreigners among a vast amount of local disaster victims and in the enormous area where the deceased were disseminated. Extensive search operations revealed that dead bodies of presumptive foreigners were located in hospitals, funeral parlours, swamps, or provisional graves. Lead-managed by local authorities, exhumations could be performed. Major challenges consisted of advanced decomposition, and some of the bodies were almost skeletonized by feeding defects. Moreover several bodies had been embalmed with formaldehyde. Pre-screening for an assumable foreign nationality was performed on the grounds of clothing, items carried along by the victims and dental work. The final identifications by multinational DVI-teams were mainly based on dental findings and results of DNA-examination performed in Austria. Targeted police investigations also revealed that numerous people were alive either in Germany or still in Sri Lanka.

At February 25th, 2005, the mission was completed successfully and no more German citizen was reported missing in Sri Lanka. It has to be emphasized that the complaisant support of the local authorities and the notable obligation of each individual specialist appointed by different nations, comparably contributed to the successful and effective completion of this complex and exceptional task.

Identification, Mass Disaster, Tsunami

G23 Mass Disaster Victim Identification: The Tsunami Disaster

Sawat Kanluen, MD*, Chulalongkorn University, Department of Forensic Sciences, 254 Phayathai Road, Patumwan, Bangkok 10330, Thailand; and Tony Kanluen, MD, Henry Ford Hospital, Department of Emergency Medicine, 2799 W Grand Boulevard, Detroit, MI 48202

After attending this presentation, the attendee will understand how to organize, implement, and utilize the Interpol Disaster Victim Identification Protocol in mass disaster. Attendees will learn the various identification techniques used in the tsunami disaster in Thailand.

This presentation will impact the forensic community and/or humanity by demonstrating the importance of an organized approach to victim identification in mass disasters.

The Interpol Disaster Victim Identification Protocol has frequently been utilized in mass disasters like earthquakes, fires, and hurricanes however, never in a tsunami. The victim identification process in Thailand was challenging due to multiple factors including, rapid decomposition of bodies due to heat, significant number of foreigners, unprecedented number of victims, and lack of prior fingerprint and dental records. The death toll in Thailand included over 5,395 persons (1,953 foreigners) dead and 2,932 (909 foreigners) missing.

Three sites were established in Southern Thailand for the processing of victims, two in Khao Lak, Thailand, and one in Krabi, Thailand. Victims were then identified as either Thai or foreigner. All foreigners were processed by the International Disaster Victim Identification (DVI) Team while all Thais were processed by the Thai Victim Identification Team. Utilizing the Interpol Disaster Victim Identification Protocol, bodies were numbered and photographed. Forensic pathologists examined victims noting birthmarks, tattoos, scars, jewelry, clothing, height, weight, and other distinguishing characteristics. Due to the tropical environment and lack of initial refrigeration, many bodies rapidly decomposed before a forensic pathologist could examine the victim. Dentition was photographed and documented by forensic dentists for comparison to prior dental records. If possible, fingerprints were obtained from victims and recorded in the Automated Fingerprint Identification System (AFIS). In a few countries, fingerprints are part of the national ID card however, in most cases, anti-mortem fingerprints were difficult to obtain. Molar teeth and femur DNA samples were obtained for DNA profiling. According to the Interpol protocol, victims can be identified utilizing four methods: 1) Dental Records 2) Fingerprints 3) DNA 4) Property. All post-mortem information was forwarded to the Thai Tsunami Victim Identification Information Management Center (TTVI-IMC) and entered into a database.

Concurrently, embassy officials were obtaining anti-mortem records such as DNA, fingerprint, dental, clothing, and victim characteristics from victim's families around the world. The international scope of the disaster initially limited victim identification due to the logistics involved in obtaining dental and fingerprint records.

All anti-mortem information is entered into a database and cross-matched with postmortem information utilizing PLASDATA, a software database program. Of the 721 victims at the Krabi site, 560 (77.6%) were identified. 357 (63.8%) were of Thai nationality and 203 (36.3%) were foreign citizens. Utilizing property, location, and distinguishing physical characteristics identified 511 victims (91.3%). Dental records identified 49 victims (8.8%), primarily foreign citizens. DNA and fingerprints did not identify any of the victims.

At the Krabi site, identification of Thai nationals proved more successful than foreign citizens for multiple reasons. Family members physically identified Thai victims through clothing, property, and tattoos prior to body decomposition. Dental records, fingerprints, and DNA were rarely used for Thai victims. Foreign citizens were identified through property, clothing, and dental records. To date, DNA has not proven effective for Thai victim identification.

The Interpol Disaster Victim Identification System can be utilized in tsunami disasters where resources, technology, and personnel may be limited and multiple nationalities are involved.

Mass Disaster, Victim Identification, Tsunami

G24 Victim Trauma as an Identification Tool in Mass Disasters

Maurice G. Rogev, MD, MBChB*, 11/1 Zamenhof Street, Tel-Aviv-Jaffo, 64373, Israel

After attending this presentation, attendees will learn that it is important to consider the victim's injuries in relation to his location at the time of a Mass Disaster. This relationship is the basis of further identification procedures.

This presentation will impact the forensic community and/or humanity by demonstrating the need to reinforce its commitment to finance full identification procedures. There is a need to employ Forensic Science officers capable of implementing a full identification program.

Ipsa facta, "Mass Disasters" involve large numbers of victims. In the Medical Legal field, dealing with such disasters includes the identification of victims of trauma in a very wide variety of circumstances. In addition to enabling families of the victims to learn the fate of their loved ones, results of identification procedures are made available for use by law enforcement agencies.

The final identification of the victim is usually confirmed by his/her DNA profile, and /or by examination of the dentition of the victim after experiencing the trauma. This identification process is greatly simplified if the victim's pre-trauma identification characteristics can be located in existing database of DNA or dental records for comparison purposes.

Difficulties are encountered when no such pre-trauma records of a particular victim can be located and the identification procedure needs to start ab initio. The aim is to attempt to determine the probable identity of a particular individual by a compilation of data such as details of where the individual was found, the trauma suffered and anthropological features, [gender, age, height and race], for comparison with DNA profiles and/or dental records of known missing persons. The DNA profile of a particular individual can be determined from the DNA profiles of parents or children. The dental history of an individual obtained from dental records kept by dentists can also be used in identification. Other indications may be obtained from tattoo marks or moles and in some cases implants such as pacemakers (with serial numbers), artificial joints, and the like.

Victims may be found in collapsed buildings following natural disasters such as tidal waves, severe flooding, hurricanes or earthquakes as well as due to human action. Human action can include direct injury as well as building collapse due to defective building design or construction or terror explosions.

Accidents involving road transport, aircraft and maritime vessels can cause large numbers of victims. The injury to each victim is largely determined by his location in relation to the area of the damage caused by the disaster. Traumatic injuries inflicted on a group of individuals, who were in close proximity to one another at the time of the disaster, will cause similar pathological changes in each member of the group. Different types of injury may often be associated with different locations at the scene of the incident e.g. injuries to passengers in the rear of an aircraft are likely to be different than those in front seats which are closer to burning fuel. Consequently, careful examination of the nature of the traumatic injury may in some cases enable the investigator to establish where an individual victim had been located at the time the incident occurred and therefore narrow the possible identities to persons who were known to be in that particular locality, e.g. from passenger seating lists or lists of occupants of rooms in a hotel.

If the identities of individual members of the group are known from records compiled before the disaster, the DNA profile comparison search is limited to a much smaller number of individuals and the identities of indi-

vidual members of the group can be established more readily. (e.g. aircraft passenger lists or wedding invitation lists). The identification procedure is obviously much more complex when diverse crowds in public places are involved.

Injuries can be due to crushing, fire, gas or smoke inhalation, blast effects in explosions, penetration of primary or secondary missiles, laceration of soft tissue and the effects of bio-chemical agents. Examples will be shown to illustrate the various injuries and their relevance.

Victim, Location, Identification

G25 Differential Diagnosis: Antemortem vs. Postmortem Bone Trauma

Nermin Sarajlic, MD, PhD*, International Commission on Missing Persons, Alipasina 45A, Sarajevo, 71000, Bosnia and Herzegovina; John Clark, MRCPPath, University of Glasgow, Joseph Black Building, Glasgow, Scotland G12 8QH, UK; and Eva-Elvira Klonowski, PhD, International Commission on Missing Persons, Alipasina 45A, Sarajevo, 71000, Bosnia and Herzegovina

The goal of this presentation is to evaluate the difficulties in differentiation between antemortem and postmortem bone trauma in human skeletal remains

This presentation will impact the forensic community and/or humanity by demonstrating how antemortem - postmortem bone trauma is always challenging for the forensic pathologists who have to deal with predominantly skeletonised remains. This presentation will have an impact on forensic sciences by demonstrating a way of judging bone trauma on skeletonised remains.

Four years of the war in Bosnia and Herzegovina from 1992 to 1995 has left more than 30,000 missing persons, most of whom are presumed dead. Until now, between 14,000 and 16,000 sets of human remains have been exhumed from numerous single or mass graves in burials, wells, septic tanks and caverns, or as bodies simply left unburied in fields, meadows and forests. The majority of the remains were completely skeletonized, but occasionally they were saponified or mummified.

Variable burial conditions and variable decomposition of the remains caused deterioration and injuries to the bones. Also, the transfer of the remains from primary to secondary, or even tertiary, mass graves, and the different techniques used during the exhumation process, caused postmortem injuries to the bones.

Postmortem examination of the remains to determinate antemortem injuries revealed a considerable amount of additional postmortem damage.

Assessment of antemortem injuries is not only important in the legal process in order to determine cause and manner of death, but it is also helpful in the identification process, when considering antemortem information obtained from family members or witnesses about injuries sustained.

Cases from the authors' work on exhumed skeletal remains, discuss the injuries seen, and consider potential causes will be presented (in particular, consideration will be given to):

- cases with clear signs of antemortem trauma to the bones
- cases with clear signs of postmortem trauma to the bones
- cases with postmortem injury possibly due to the influence of the saponification process during the decomposition
- cases in which it is not possible to determinate whether the trauma is antemortem or postmortem

Forensic Pathology, Skeletal Remains, Bone Trauma

G26 Personal Identification by Morphometric Analyses of Retinal Vascular Pattern

Francesco Intronà, MD, PhD*, and Antonio De Donno, MD, Section of Legal Medicine (Di.M.I.M.P.), University of Bari, P.zza Giulio Cesare n.11, Bari, 70124, Italy; Carlo Sborgia, MD, and Francesco Boscia, MD, Section of Ophthalmology, University of Bari, P.zza Giulio Cesare n.11, Bari, 70124, Italy; Giuseppe Mastronardi, PhD, Electronic and Electrotechnic DPT, Via Orabona n.4, Bari, Bari, Italy; and Francesca Bellomo, MD, and Domenico Urso, MD, Section of Legal Medicine (Di.M.I.M.P.), University of Bari, P.zza Giulio Cesare n.11, Bari, 70124, Italy

The goal of this presentation is to report the results of a biometric personal identification study conducted by comparing retinography samples obtained from different subjects

This presentation will impact the forensic community and/or humanity by demonstrating an interesting approach for personal identification for security environments

MATERIALS AND METHOD: A new method for personal identification by morphometric analysis of the retinal vascular pattern is presented.

In collaboration with the Ophthalmology Clinic of Bari University Hospital, two sets of color images of the right retinal fundus were acquired at two different times in 68 subjects, after instillation of mydriatic and using computerized fluorangiography. The system consists of a scanning laser camera connected to a computer, color monitor and operative software. This system enables acquisition of Megaplus 1.6 resolution images with 1534x1024 pixels that are immediately digitalized and stored on hard disk.

After making a quality selection of the images, they were submitted to morphometric analysis at the Electrotechnical and Electronics Department of Bari Polytechnic, using dedicated software.

Following the operative protocol, 5 reference points of the retinal vascular tree were identified: the origin of the superior temporal artery, the first bifurcation of the superior temporal artery, the origin of the superior temporal vein, the first bifurcation of the inferior temporal artery and the origin of the inferior temporal vein. These points were individuated and marked by the software on each image of the retinal tree. The program then automatically supplies the values for the absolute distances, the relative distances excluding reciprocals, the perimeter values and the areas of the triangles obtained by joining the points, as well as the independent variable consisting of the differences, albeit minimal, between similar irregular figures. Five numerical sets were thus obtained for each image. Statistical comparison was made of the sets by linear regression, determining the correlation coefficient. Cross-analysis was made of each of the five numerical sets obtained from the 136 images (68 patients x 2), yielding 23120 comparisons (5 X 68 X 68) for heterologous correlations and 340 comparisons for homologous correlations (5 x 68).

RESULTS: Analyses showed that the *independent variable* and the *areas of the triangles* did not serve for identification purposes due to overlapping, the maximum values for the correlation coefficient in the heterologous comparisons being in the same range as those for the homologous comparisons in over 60% of the samples.

Instead, cross comparison of the correlation coefficients for the sets of *absolute distances*, *relative distances* and the *perimeters of the triangles* showed that they could potentially be useful, possibly in association with other analyses, for identification purposes.

There was no overlapping between the coefficients for the *absolute distances*, which yielded separate, distant dispersion curves for homologous and heterologous comparisons. Similarly, there was no overlapping for the triangle perimeters, which provided separate, albeit close clusters, for the correlation coefficients. There was only 1% overlap for the correlation coefficients for the *relative distances* (46 false positives/4620 comparisons).

The numerical results were:

- The correlation coefficient for autocorrelations for the *absolute distances* was between 0.999 and 0.992

- The correlation coefficient for heterocorrelations for the *absolute distances* was between 0.991 and 0.566
- The correlation coefficient for autocorrelations for the *triangle perimeters* was between 0.999 and 0.99299
- The correlation coefficient for heterocorrelations for the *triangle perimeters* was between 0.99293 and 0.56651
- The correlation coefficient for autocorrelations for the *relative distances* was between 0.99995 and 0.97876
- The correlation coefficient for heterocorrelations for the *relative distances* was between 0.99248 and 0.92452

Our results indicate that:

- The section point for the output of comparison of the *absolute distances* is 0.992; higher correlation coefficients indicate certain identification and lower values certain exclusion.
- The section point for the output of comparison of the *triangle perimeters* is 0.99299; higher correlation coefficients indicate certain identification and lower values certain exclusion.
- The section point for the output of comparison of the *relative distances* is 0.97876; higher correlation coefficients indicate positive identification, with a 1% risk of false positives.

Finally, it should be noted that the cases yielding false positives for comparison of the *relative distances* presented very negative values for the correlation coefficients of the *absolute distances* and the *triangle perimeters*. Thus, interpolating the results, it can be concluded that if comparison of the two retinal maps yields a higher correlation coefficient than the minimum threshold for autocorrelation of the absolute distances, relative distances and triangle perimeters, there is certain identification.

The method is currently being patented.

Biometric, Personal Identification, Retinal Vascular Pattern

G27 Laryngeal Nerve Iatrogenic Lesions

Luigi Viola, MD*, Marina Albano, MD, Francesco Vimercati, MD, and Nunzio Di Nunno, MD, PhD, Università di Lecce, Via G. Dorso n. 9, Bari, 70125, Italy

After attending this presentation, attendees will deepen their understanding of the surgical practices most likely responsible for damage concerning the lower laryngeal nerve. For this reason, the authors examined the surgical operating procedures that more frequently involve this nerve. Therefore, thanks to the study of the specific international bibliography, procedures have been highlighted which must be carried out, in order to avoid this complication.

This presentation will impact the forensic community and/or humanity by studying the circumstances surrounding medical malpractice concerning laryngeal nerve lesions.

The aim of this work is to highlight the surgical practices mostly responsible for damages concerning the lower laryngeal nerve. Iatrogenic lesions of the recurrent laryngeal nerve have always been one of the most serious and frequent complications in the field of the thyroid surgery. During a thyroid operation, according to the medical literature, the complication rate ranges from 0.3 to 4%, but can range up to 17% with an operation concerning a thyroid neoplasia relapse. The lower laryngeal nerve iatrogenic lesions are supported by documentary literature in the field of the thoracic surgery, especially in the surgical literature on heart surgery.

Studying the most specific reliable and recent bibliographical sources, one can learn of the different factors which cause the onset of lower laryngeal nerve lesions, so they can be identified in a timely manner, in order to prove any possible medical mistake that has occurred.

An essential role is played in this case by the fundamental features of the main pathology of recurrent laryngeal nerve damage. In particular, it depends on whether the pathology concerns primarily the nerve itself (traumatic, toxic/infectious, auto-immune, etc) or is the nerve just secondarily involved by another pathological process (thyroid and laryngeal pathologies, aortic and carotid aneurysm, pulmonary neoplasia, dilatation

of the left atrium in the mitrals, mediastinum lymph node disease, cervical adenopathy, etc). Other factors that need to be considered in a case of alleged medical responsibility are the different surgical operating procedures carried out, especially the nerve isolation techniques, which is the main step during an operation concerning frames adjoining the nerve itself.

With regard to this study, the authors found a greater number of recurrent nerve lesions occurring during a surgical operation due to thyroid pathologies and malignant neoplasia behind the breastbone that are particularly widespread. In fact, statistical data shows a higher risk of iatrogenic damage during more drastic operations, such as with a total or subtotal thyroidectomy or after a second operation in the same location. By observing and analyzing six cases of recurrent nerve paralysis, and after a review of the pertinent literature, this study attempts to underscore the medico-legal difficulty in assessing the nerve damage, or identifying the professional responsibility in causing the damage. The examination of these cases showed a sharp preponderance of mistakes made by the surgeon. Among the above-mentioned cases under examination, four cases out of six concerned people undergoing an operation for thyroidectomy (total or subtotal), one case of laryngectomy, and one of aortic replacement in a patient affected by an aortic dissecting aneurysm. The second step of the analysis of the medical practice showed a relevant number of mistakes concerning a non-isolation of the lower laryngeal nerve during the surgical operation, even though there are many intraoperative techniques able to highlight the nerve frames at issue, and preserve them properly. Medico-legal experts consider this negligent practice, able to identify these mistakes made by doctors implicated in a similar situation, as a result of not keeping to the therapeutic protocols in the specific literature.

Among six cases of phonatory deficiency under examination, four cases have been closed with the admission of the surgeon's responsibility, while in the other two cases any responsibility has been excluded. One case involved the surgical repair of an aortic aneurysm, and it was considered more important to save the patient's life than preserve his nerve. In the other case, the damage was linked to the post-operative behavior of the patient himself.

Laryngeal Nerve, Medical Malpractice, Medical Liability

G28 Electrocution by Arcing: A Non Fatal Case Study

Biagio Solarino, MD, Giancarlo Di Vella, MD, PhD, and Alessandra Arpaio, MD, Sezione di Medicina Legale - Di.M.I.M.P., Università degli Studi di Bari - Policlinico, Bari, 70125, Italy*

The goal of this presentation is to report an unusual case of electrocution by "arcing" from overhead high-voltage power lines.

This presentation will impact the forensic community and humanity in general, as it provides information about a case of accidental electrocution during working activities that occurred due to dielectric breakdown, so that the current from a high-tension overhead cable (30000V) ran down an aluminium pole grasped by a farmer who was thrashing an olive tree.

An ancient rural tradition is called "battitura", whereby farmers in South Italy thrash the branches of the olive trees with a pole or stick, causing the olives to drop into sheets placed under the trees. This is a case of a 25-year-old Caucasian male, who suddenly collapsed while he was thrashing an olive tree in front of him, using an aluminium pole 2 metres long. The olive tree was dangerously situated underneath (but at no less than 7 meters distance) a high-voltage power cable. These cables transmit very high voltages (30000-60000V) and in Italy they are built at least 10 metres above ground level, thus it should not be possible to come in contact with the power lines. The patient underwent loss of consciousness and bleeding from the mouth. He was taken to the ER where, on examination for injuries, he was found to have "electrical burns" with peculiar pits on the hands and on the soles of the feet. He developed cardiac arrhythmia with high levels of CPK and CK, requiring electrical defibrillation. Dental

radiography and CT scan demonstrated fractures of the mandibular symphysis and condyles, along with the left tubercle of the upper jaw, with no evidence of external wounds. Many teeth were injured, with avulsion of the first and second incisors of the upper right jaw (11, 12), the first incisor of the upper left jaw (21), the second pre-molar of the lower right jaw (45), coronal fractures of the first pre-molar of the upper right jaw (14), the second molar of the lower left jaw (37), and the first pre-molar of the lower right jaw (44). At the moment of electrocution, the worker was wearing shoes that were sold as safety footwear, and inspection revealed characteristic burn defects on the sole, which corresponded to the electrical burns of the feet. Therefore, the safety shoes did not prove effective.

A review of the literature reveals few data or case reports specifically addressing the issue of electrocution by arcing, with no direct contact with the wire, especially at so great a distance between the energy source and the victim. In this case the farmer was standing vertically below the power lines in front of the olive tree, grasping the aluminium pole. There was a gap of about 6-7 metres from the upper end of the pole to the high-voltage power lines. It has been reported that a sparking gap larger than 50 cm is sufficient to transmit a voltage of about 30-40000V. However, in the reported case there were behavioral and environmental factors, equally distributed, that can explain the near fatal accident. Firstly, in high voltage accidents it is known that direct contact with the wire is not necessary because when the body is near the voltage lines an electric arc may jump from the lines to the body. Moreover, the resistance opposed by the skin and the air has an important role in electrical conduction. In particular, the humid weather present at the time of the farmer's electrocution, a cloudy and drizzling morning at the end of November, boosted the electric current discharge. Another important environmental factor is the part played by the tree, known to be an excellent energy conductor, which in this case was growing just beneath the cable. This situation allowed the accumulation of energy on every branch, thus representing a potential risk of electrocution in itself. In addition, there were some behavioral aspects to be considered. The tool used by the victim for thrashing is ideal for the conduction of electric power. Aluminium or graphite, used in staff or pole manufacture, both have superconductor qualities. The current flowing from the metal staff through the hands would probably not have been able to electrocute the farmer if he had been wearing good quality safety shoes. Finally, the great human error was that of working under a tree situated so close beneath the high voltage power lines. This is commonly a great hazard for workers, especially those in industrial fields, as this is one of the most common reasons for accidents at the workplace in Italy. Each one of the above described factors likely contributed to dielectric breakdown and conduction of the current from the high voltage power lines to the end of the metal staff and then through the farmer's body. Identification of all behavioral and environmental causative factors may lead to future adjustments in design, to reduce the risk of electrocution in working environments. Photographic documentation illustrates the results of the case investigation.

Electrocution, Arcing, Accident at Work

G29 Abrasion or Gunshot Wound? The Primary Role of Forensic Pathologist

Giancarlo Di Vella, MD, PhD, and Biagio Solarino, MD, Sezione di Medicina Legale - Di.M.I.M.P., Università degli Studi di Bari - Policlinico, Bari, 70125, Italy*

After attending this presentation, attendees will learn about two cases of gunshot injuries that were undiagnosed by the physicians in the ER, posing a great risk of compromising both the victims' health and the Police investigations.

This presentation will impact the forensic community and/or humanity by illustrating the primary role of the forensic pathologist even in the ER, to prevent misdiagnosis of atypical lesions, especially when caused by unconventional firearms.

Although the effects of firearms on the human body are well known, in some circumstances the objective picture of the lesions may be so modest and lead to an incorrect diagnosis, unless there is a forensic expert present. The present work describes two cases in which the correct diagnosis of a shotgun entrance wound was formulated only thanks to the help of a forensic pathologist, who was called in to give an opinion of the unusual lesions observed in the patients. On 13 December 2004, at 09.00 a.m., a 35-year-old male subject, of robust build and about 180 cm tall, was brought by ambulance to the Emergency Room at Bari Hospital (S. Italy). He stated that two robbers had attacked him near his home, and one had grasped him around the neck to immobilize him. The patient was admitted to Intensive Care due to the presence of subcutaneous emphysema of the neck and superior mediastinum, causing severe breathing difficulties. He showed digitiform ecchymoses on the face, neck and upper portion of the chest. The Intensive Care specialist on duty called in the forensic pathologist for a consultation to confirm the traumatic picture and the compatibility of the lesions with the dynamics of the events referred by the patient. The forensic pathologist confirmed the presence of ecchymotic-excoriated areas in the referred sites and pointed out scratches and bruising caused by the robber's hands. An oval-shaped area appearing to be an abrasion was seen, with distinct, slightly retracted margins, 0.6 cm in diameter, with a small eschar in the lower right semicircle. The lesion was localized in the chin region, 2 cm to the left of the anterior median line. After photographing the lesion, the forensic pathologist decided to explore it in depth, introducing a needle cannula for use as a probe, which revealed the presence of an entrance into the body. X-rays of the chest and neck were performed, which demonstrated a foreign body found to be a bullet fragment, retained in the soft tissues of the anterior region of the neck just in front of the spine. After two weeks the patient underwent surgical treatment to remove the fragment, a deformed lead bullet core that was delivered into the hands of the Police. On the basis of the investigations, it was possible to conclude that the victim had been struck in the chin by a slow-moving bullet, which was partly fragmented by impact with the bone. The bullet had been fired from a small calibre firearm, likely a modified toy gun, which still had not been found at the time of this contribution.

On 5 March 2004, a 17-year-old boy accompanied his parents to a small hospital in the province of Bari. He complained of pain in the mandible, stating that he had fallen down the stairs in his home. Orthopantomography demonstrated a fracture of the mandible and avulsion of the lower incisors. Transfer to a clinic with facilities for maxillo-facial surgery was advised and the patient was taken to Bari Polyclinic for necessary care. On arrival, the forensic pathologist was called in to give an expert opinion. HA circular wound, approximately 0.7 cm in diameter, was observed in the chin region with inverted margins and a slight, ecchymotic, excoriated border. The wound was surrounded by powder tattooing and some soot, and these findings, together with the characteristics of the perforation, suggested a gunshot entrance wound. The available X-rays were reviewed and a foreign body was noted, which had not been referred to in the radiological diagnosis. The bullet, localized in the submandibular region, and surgically removed, was a 7.65 mm caliber (FMJ), deformed at the apex and with no markings (class characteristics). These elements led the investigators to conclude that, far from falling down the stairs, the victim had been hit in the face by a bullet from a modified toy gun, shot at intermediate range.

Failure to diagnose a gunshot wound is an exceptional event. Clinical medicine relies more and more on sophisticated diagnostic techniques, and procedures for quality control. However, the previous histories show that when non-conventional firearms are used, and the patient history is not suggestive of their use, clinicians may be unfamiliar with the type of wound they produce, because these events are rarely seen. In these circumstances, consultation with the forensic expert is needed to make a correct diagnosis of the wounds. This is very important to further judicial investigation procedures related to the case. In accordance with the Italian penal law code (penal procedure code, art. 331), health workers (physicians, nurses, etc) treating a wounded patient in a hospital facility are obliged to communicate

the event to the Judicial Authorities without delay, if the lesions were obviously voluntarily inflicted (criminal assault) and recovery will take longer than 20 days (penal code, art. 582-583). This obligation applies even for shorter recovery times if firearms or other potentially lethal weapons were used (penal code, art. 585). Failure to notify the Authorities lays the health workers themselves open to criminal charges (penal code, art. 361 and 362). Photographic documentation of each of the above described cases will be shown during the presentation.

Forensic Pathologist, Gunshot Wound, Modified Toy Gun

G30 Sudden Death in Toddlers Due To Influenza B Infection: A Report of Two Cases and a Review of the Literature

Kristen Landi, MD*, and Andrea Coleman, MD, Office of the Chief Medical Examiner, 520 First Avenue, New York, NY 10016

After attending this presentation, attendees will better appreciate the importance of viral testing in pediatric autopsy cases. Attendees will have better understanding that influenza may present with atypical symptoms such as abdominal pain, vomiting and shock and have a very short duration between onset of symptoms and death.

This presentation will impact the forensic community and/or humanity by bringing attention to the need for specialized testing in pediatric autopsy cases, more specifically the need for viral testing, especially for influenza. Cases of sudden death among children, especially with atypical symptoms for influenza, usually do not get viral studies collected at the time of autopsy and if viral infections are not considered the cause of death may remain elusive. The authors recommend viral screening for cases of sudden death among infants and children in addition to the more standard specialized testing such as bacterial cultures.

Influenza has historically been a cause of considerable mortality world-wide during pandemics as well as small outbreaks, and continues to be a significant cause of death today. The very young and very old are especially vulnerable. Influenza typically appears during the winter months and classic symptoms include fever, sore throat, sweating, nasal obstruction, and cough and malaise. In severe attacks bronchiolitis and pneumonia may be caused directly by the virus or may result from secondary bacterial invasion of the lungs. Influenza is caused by myxovirus influenzae and there are three distinct serotypes (A, B, and C), each containing antigenic strains. Virus A causes pandemics as well as local outbreaks. It affects all age groups and is associated with a high mortality in the elderly, the very young, and those with pre-existing cardiac and pulmonary disease. Virus B causes sporadic cases and limited epidemics, especially among institutionalized young people. It tends to cause a milder disease with a lower mortality rate. Virus C is occasionally detected in local outbreaks.

Two cases of relatively sudden deaths with atypical symptoms due to influenza type B infection in a 4-year-old girl and a 2-year-old boy with no past medical history or predisposing risk factors are described. Both children presented with mild abdominal symptoms of vomiting and abdominal pain starting within two days of death, and were found dead in their beds by their parents. Scene investigation, medical history, autopsy, metabolic screening, toxicology, bacterial cultures, and toxicology were all negative. Histology of the lungs showed a viral type pattern with a chronic inflammatory infiltrate involving the bronchioles, bronchi, and trachea. The girl also had small patchy areas of intra-alveolar mixed inflammation including macrophages and neutrophils consistent with bronchopneumonia. Viral testing on the lungs of both cases was strongly positive for influenza B (by immunohistochemistry in the girl, and RT-PCR in the boy).

These cases illustrate two atypical cases of influenza B infection that would not have been suspected based on the presenting symptoms and rapidly fatal outcomes. Influenza may be found to be the cause of death if viral cultures are done in similar types of cases.

In the literature there are reported cases in adults of influenza A infection with shock like symptoms and high morbidity and mortality. There is ongoing research into the possible role that cytokines play in causing additional injury in a number of infections including influenza associated encephalopathy, streptococcal toxic shock syndrome and RSV respiratory infections. Immune mediated injury may result from the cytokine storm triggered by the initial infection and may spill over into the systemic circulation and cause devastating consequences in a relatively short period of time. There are some studies that suggest that RNA viruses like influenza may be particularly prone to inducing cytokine and chemokine up regulation including numerous interleukins (including IL-1, IL-6, IL-8, IL-11, IL-16) and tumor necrosis factor. It has been suggested that immunomodulators be used as part of the medical treatment of influenza to help prevent cytokine storm.

Influenza, Sudden Death, Toddlers

G31 Neuropathology of Pre-Teen Homicides in the State of Maryland: 1994-2004

Ana Rubio, MD, PhD, State of Maryland Office of the Chief Medical Examiner; 111 Penn Street, Baltimore, MD 21201; Miguel A. Riudavets, MD, Department of Pathology (Neuropathology), Johns Hopkins University School of Medicine, Baltimore, MD 21201; Ling Li, MD, State of Maryland Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201; Christopher Cox, PhD, Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD 21201; David Reisz, BA, and David R. Fowler, MD, State of Maryland Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201; and Juan C. Troncoso, MD, Department of Pathology (Neuropathology), Johns Hopkins University School of Medicine, Baltimore, MD 21201*

After attending this presentation, attendees will appreciate that pre-teen homicides differ from that of other age groups. Brain pathology is a common finding in childhood homicide, especially in cases with a blunt force component. The majority of pre-teen homicides are due to blunt force injuries of the head or head and torso. Detailed, systematic study and documentation of the central nervous system and ophthalmic injuries is essential in determining the nature and timing of the injuries and ruling out natural diseases or accidental injuries.

This presentation will impact the forensic community and/or humanity by demonstrating; (1) a better understanding of the epidemiology of pre-teen homicides; (2) the necessary role of neuropathologic studies in childhood homicides; and (3) an understanding of the pattern of injuries in blunt force head trauma in children.

Background: The State of Maryland (population below 6 million, half rural) has a unified medical examiner system that investigates suspicious deaths following standard protocols. Homicides in pre-teens differ from those in the general population in victim's characteristics (e.g. gender distribution), causes of death (e.g. firearm use), environment of death (e.g. home) and patterns of injuries.

Method: Cases were reviewed and tabulated for demographic characteristics, cause of death, post-injury survival, systemic and brain injuries. Cases with a significant central nervous system component were examined by a single neuropathology's (JCT). The majority of the cases included examination of the spinal cord and eyes. Cases were stored in a centralized database. Data was retrieved and analyzed by nonparametric statistical methods.

Results: From 1994 to 2005 one hundred and eighty five children younger than 13 years of age suffered homicidal deaths in the State of Maryland (7.5 % of all deaths reported to the office for that age group). Blunt force injuries were the most common cause of death (95 cases, 51.1%) followed by firearms (16.7%) and asphyxia (16.2%), each preferentially affecting children of specific ages. Most children with blunt force injuries had significant neuropathology, and this is the focus of the following study.

There was overrepresentation of cases in the Baltimore metro area (60% of the cases; 12% of the State wide population). Girls were slightly more prevalent than boys (52 vs. 48%) and African-Americans represented 64.5% of the total. Median age was 1.1 years. Brain weight ratio (brain weight obtained at autopsy divided by standard brain weight for individual's age) was 1.1. The neuropathologic findings depended on age, survival after injury and mechanism of force. The majority of the cases had external (73.7%) signs of blunt force head injuries, either alone (50%) or in combination with torso injuries (50%), with an average of 4.7 (median 4) head contusions/abrasions identified at autopsy. Injuries included intracranial subarachnoid hemorrhage (61.5%), intracranial subdural hemorrhage (55%), hypoxic injuries (35%), cortical contusions (38.5%), brain swelling (21%), intracranial epidural hemorrhage (17%), and gliding (intermediate) contusions (15.4%). White matter tears and diffuse axonal injuries were rare. Spinal cord was obtained and studied in 70 of 95 cases (73.7%). Intraspinal hemorrhage was seen in 31% (subarachnoid 24.3%, subdural 23% and epidural 17%). Eye pathology was found in 44 of 60 cases studied (73%), and was bilateral in 95% of them.

Summary and conclusions: Brain pathology is a common finding in childhood homicide, especially in cases with a blunt force component. The majority of pre-teen homicides are due to blunt force injuries of the head or head and torso. Age, gender, and race influence specific neuropathologic findings. Brain weight ratio correlates with survival and is influenced by neuropathology. Detailed, systematic study and documentation of the central nervous system and ophthalmic injuries is essential in determining the nature and timing of the injuries and ruling out natural diseases or accidental injuries.

Blunt Force Head Injuries, Pre-Teen Children, Homicides

G32 Transplacental Intrauterine Herpes Simplex Virus Infection Resulting in Cutaneous Calcifications in an Infant

Sam D. Simmons, MD, MBA, Ashley O'Bannon, MD, and Subodh Lele, MD, University of Kentucky, Department of Pathology and Lab Medicine, 800 Rose Street, MS 117, Lexington, KY 40504*

After attending this presentation, attendees will learn about a unique pathologic presentation of transplacental neonatal herpes infection, which may aid in future clinical diagnoses.

This presentation will impact the forensic community and/or humanity by highlighting a distinctive but rare presentation of Herpes Simplex Virus (HSV). By augmenting the relatively scant literature on transplacental HSV infection, this case may expand the differential diagnoses for infant autopsies with similar gross findings, and possibly aid in earlier detection and treatment of intrauterine HSV infection.

Neonatal HSV infection is often associated with liver necrosis, microcephaly, intracranial calcifications, and brain necrosis, and clinical signs may not be apparent until several days after birth. In many of these cases, transmission occurs during birth. More rarely, transplacental intrauterine HSV infection can occur, with life-threatening effects due to earlier onset in the pregnancy. A literature search reveals some isolated case reports of similar cases, most of which demonstrate unique gross presentations. The authors describe the autopsy case of an infant born at 25 weeks gestation with diffuse cutaneous calcifications. There was microscopic evidence of acute chorioamnionitis and acute funisitis. HSV immunostaining was positive on the tissue sections of placental membranes and umbilical cord. Polymerase chain reaction analysis (PCR) on the same paraffin-embedded tissues was positive for HSV. No viral inclusions were identified in any of the tissue sections.

A pregnant 20-year-old female (G1P0) presented to her obstetrician with spontaneous rupture of membranes at 25 weeks gestation. The patient was transferred to a tertiary care center for probable chorioamnionitis, where she was noted to be febrile with uterine tenderness and an elevated

white blood cell count. The fetus began to show signs of distress with decelerations in heart rate, and a caesarean section was planned. However, the infant was delivered vaginally in the operating room, approximately 18 hours after the membranes ruptured. The infant failed to breathe spontaneously and had no heart rate, so resuscitation efforts began, including intubation and 3 doses of epinephrine per endotracheal tube. Resuscitation was discontinued after 15 minutes since the infant could not sustain a heart rate. Apgar scores were 0 @ 1 minute, 1 @ 5 minutes, and 0 @ 10 minutes.

Maternal past medical history was significant for two urinary tract infections during pregnancy, with urine cultures positive for *Escherichia coli*. She was also briefly hospitalized for pyelonephritis one week prior to delivery, with urine cultures again positive for *E. coli*. She was treated with Macrobid and Keflex, and was still taking these medications along with prenatal vitamins at the time of delivery. Prenatal labs were negative for chlamydia, gonorrhea, HIV, and Group B Strep. She denied any history of sexually transmitted diseases. There was no documentation of prenatal HSV testing.

At autopsy, the infant's skin was light tan with extensive areas of dark red discoloration on the back, chest, and head. Additionally, there were irregular, white patchy lesions on the posterior head, back, shoulders, chest, inguinal areas, and over the coccyx. These lesions appeared to be intradermal, were not palpable, and did not scrape off. The remainder of the gross examination was unremarkable. The body was that of a normally formed male infant, consistent with a 25-week gestational age. No other dysmorphic features were noted, and the internal organs were located in their normal anatomic positions. The placenta was significant for a white area on the maternal surface, grossly consistent with an infarct, and encompassing less than ten percent of the maternal surface area.

Microscopically, the skin demonstrated multiple areas of intradermal calcifications, consistent with the white, patchy lesions seen grossly. Hyperkeratosis was present, with amorphous debris visible on the skin surface. However, only minimal inflammation was observed around the calcified areas. The lungs contained multiple areas of lymphocytic infiltration with debris-laden macrophages. The infarcted area on the maternal side of the placenta showed acute inflammation with neutrophilic extravasation and fibrin deposition. The umbilical cord demonstrated funisitis, with neutrophils visible in the walls of the cord vessels, and chorioamnionitis of the placental membranes. Of note, no herpetic viral inclusions were identified in any of the tissue sections.

Sections containing the intradermal calcifications and sections of placental membranes and umbilical cord were sent for special staining. GMS, gram stain, Steiner stain (for spirochetes) and Toxoplasmosis stain were all negative on these sections. However, HSV immunostaining was positive on the placental membranes and umbilical cord. HSV infection was confirmed by PCR at an outside laboratory (ARUP Laboratories, Salt Lake City, Utah). The tissue submitted for HSV PCR was from the formalin-fixed and paraffin-embedded sections of placental membranes and umbilical cord.

Herpes (HSV, Herpes Simplex Virus), Transplacental, Cutaneous

G33 Killer Hairdryer

Francesco Introna, MD, PhD, Section of Legal Medicine (Di.M.I.M.P.), University of Bari, Policlinico - Piazza Giulio Cesare, 11, Bari, 70124, Italy; Simona Corrado, MD, Section of Legal Medicine (Di.M.I.M.P.), Bari University, Policlinico - Piazza G. Cesare, 11, Bari, 70124, Italy; and Vitantonio Amoruso, Dipartimento di Elettrotecnica ed Elettronica, Politecnico di Bari, Via Orabona, 4, Bari, 70125, Italy*

After attending this presentation, attendees will learn about the silent and invisible nature of electric current injury that requires a thorough investigation of the death scene, to aid in accurately determining the cause of death. In a suspected electrocution in water, if the autopsy fails to reveal indications for an electrocution, a check of the bathtub or pool's electrical system is still in order.

* Presenting Author

This presentation will impact the forensic community and/or humanity by assisting the forensic community in understanding the important reasons for vigorous investigations of these deaths in bathtub to prevent further injury.

This case consists of the tragic death of a perfectly healthy 9-year-old girl (Proc. N. 2172 / 2004 Court of Trani), with no history of illnesses, congenital or otherwise, who was found dead by her mother, in the bathtub filled of water. The parents reported to the Judicial Authority that it was an unexpected death, excluding the possibility of an electrocution. The findings of the following forensic investigations were unprecedented, both from a legal perspective, as well as from the point of view of the postmortem and histological data gathered.

The external examination of the child's body revealed no traces of traumatic or violent wounds, although two small unusual areas of skin were detected in the lumbar region, which, when substantially enlarged, appeared to be pale and irregular compared with the surrounding skin. The internal examination revealed only a small myocardial dyschromic area under pericardium, a small area of haemorrhage at the level of the lower part of the uterus and a reddish area in region of the vagina.

The histological examinations excluded acute or chronic pathology, revealing indications for an electrocution on the lumbar skin specimens where a palisade-type appearance of the malpighian layer was noted. Furthermore, in the myocardium specimen's bands of contractions and fragmentation and coagulative haemorrhagic intramyocardial necrosis were observed.

This suspicion of an electrocution was not related with the historical and circumstantial facts of the case. The authors suggested that the Judicial Authority obtain a specialist in electrical engineering to perform an examination of the child's home.

The survey of the bathroom revealed the presence of a glazed metal bath and a hairdryer. The examination of the hairdryer revealed that some of internal parts oxidized. The electrical plant of the house was protected only by a thermomagnetic circuit breaker and there was no differential circuit breaker.

In addition to these findings, suspicion for an electrocution was supported by the results obtained by a finite element method simulation, aiming at determining the electric current distribution inside a human body immersed in a bathtub when an electrically connected hairdryer came into contact with the bath water. The simulation showed that when the water came in contact with the electrical part of the hairdryer, the current lines permeate the bath water and go across the human body. The current flows until the thermomagnetic circuit breaker intervenes (i.e. when the total current reaches about 90 A). On the basis of this study, the authors suggest that a lethal fraction of this current went across the little girl body, and therefore across her heart, resulting in a fatal ventricular fibrillation.

Our investigation having been completed, the judicial authority summoned the parents of the child. The parents withdrew their previous statements, and replaced them with a circumstantial and specific reconstruction of the sequence of events immediately preceding the death, which revealed strong indications of fault. Indeed, the parents of the little girl confessed that her one-year-old brother, who had been left alone with his sister in the bathroom, had thrown the hairdryer into the bath in which his sister was immersed.

The JA therefore asked us to establish the cause or the contributory cause of the lack of differential circuit breaker in the electrical plant. The computer simulation allowed us to confirm that the presence of a differential circuit breaker (i.e. when the electrical plant is in compliance with the law) would not have prevented the death of the little girl, since she was immersed in a highly conductive medium.

In conclusion, the case established a grave 'negligence in supervision' by the parents. The fact that the electrical plant did not meet the Standard requirements did not account either for the cause and / or contributory cause of death. In similar cases the use of hairdryers having a full immersion protection plug against contact with water (either in the "on" or "off" position) should be mandatory. The authors also recommend that hairdryers which are not provided with a full immersion protection device be recalled.

Electrocution, Death in Bathtub, Electric Mark

G34 Pyelonephritis—Sudden and Unexpected Death in Infancy

Cristin M. Rolf, MD*, University of Kentucky, Office of the Associate Chief Medical Examiner; 100 Sower Boulevard, Suite 202, Frankfort, KY 40601-8272; and Bonnie Mitchell, MD, University of Kentucky, Department of Pathology and Laboratory Medicine, 800 Rose Street, UKMC MS 117, Lexington, KY 40536-0298

The goal of the presentation of these two separate cases is to demonstrate that acute pyelonephritis, which may not be detected clinically, is an unusual cause of sudden and unexpected death in infants.

This presentation will impact the forensic community and/or humanity by informing all of the role acute pyelonephritis plays in sudden, unexpected death in infancy, and providing a discussion of the differential diagnosis. This potentially lethal condition can be misdiagnosed clinically or masked by other co-morbid infections such as otitis media and viral illnesses.

This poster presents two cases of infants dying suddenly and unexpectedly from acute pyelonephritis. In the first case the infant had no known risk factors, in contrast to the second infant who had significant risk for the development of pyelonephritis. The authors review the pathogenesis, incidence, and differential diagnosis of pyelonephritis in infants dying suddenly and unexpectedly.

The first case is that of a previously healthy 7-month-old white female with medical history of asthmatic bronchitis. The infant appeared to be in her normal state of health, playing before she went to sleep the night before her death. She was fed a bottle around 3:00 AM and placed on top of her mother's chest, which was the infant's usual sleeping position at night. At around 6:00 AM the mother noted the infant to lifelessly fall limp from her chest onto the couch. The Coroner's investigation disclosed no evidence of maternal intoxication. No wedging or overlay was suspected. The mother stated the infant had a low-grade fever over the preceding 2-3 days. Despite emergency care and ACLS protocol, the infant could not be resuscitated. Gross autopsy findings revealed no evidence of accidental asphyxia or trauma. All other findings were negative except for an enlarged left kidney demonstrating wedge-shaped foci of pink, soft expanded renal cortex and medulla. No stigmata of sepsis were present. No congenital anomalies of the urogenital tract were grossly evident. Microscopic examination of the kidneys revealed acute pyelonephritis of the left kidney characterized by acute inflammatory cell infiltrates involving the renal tubules and interstitium. Tubular abscesses were present. Death in this case was attributed to acute pyelonephritis.

The second case involved a 10-month-old white male infant diagnosed with Ectrodactyly-Ectodermal Dysplasia-Clefting Syndrome complicated by extrophy of the urinary bladder with subsequent hydronephrosis. The infant had undergone multiple corrective surgical procedures for extrophy, epispadias, anteriorly placed imperforate anus, and cleft palate. His course was complicated by bilateral hydroureter and hydronephrosis. Prophylactic Cephalexin was prescribed throughout the last months of his life. On the day before death the infant developed recent onset of fussiness and low-grade fever, and was diagnosed in the local pediatric clinic with otitis media. He was prescribed Amoxicillin clavulanate and discharged to home. The next evening the infant was placed in an infant swing to calm his fussiness. He was found unresponsive in the swing 2 hours later. The body was positioned sitting in the seat with his head extended over the backrest of the seat. Coroner's investigation revealed no evidence of swing malfunction or positional compromise of respiratory excursion. At autopsy, gross examination revealed the facial and appendicular stigmata of Ectrodactyly-Ectodermal Dysplasia-Clefting Syndrome with postnatal operative corrections. The repaired urinary bladder contained numerous stones, and the mucosa was significant grossly and microscopically for chronic cystitis. Bilateral hydroureter and hydronephrosis were present. A perinephric acute inflammatory exudate was present around the right kidney and adjacent right liver lobe. Histopathologically, both kidneys demonstrated chronic interstitial nephritis, and the right

kidney contained acute and chronic inflammatory cell infiltrates within the renal interstitium associated with focal tubular abscesses. Postmortem blood cultures yielded *Proteus mirabilis*, *Citrobacter freundii*, and *Enterococcus faecalis*. Death was attributed to acute pyelonephritis with perinephric abscess and urosepsis. The significant contributing cause of death was Ectrodactyly-Ectodermal Dysplasia-Clefting Syndrome complicated by extrophy of the urinary bladder.

Acute pyelonephritis is an acute suppurative inflammation of the kidney usually caused by a bacterial infection. Routes of bacterial spread to the kidney can be either hematogenous or due to retrograde ascension from the infected lower urinary tract. Risk factors for pyelonephritis include the following: hematogenous septic spread; congenital obstruction of the urinary tract; vesicoureteral reflux; pregnancy; instrumentation; age and sex; renal lesions with scar; or immunodeficiency. Papillary necrosis, pyonephrosis, perinephric abscess, and urosepsis represent complications of acute pyelonephritis. Both cases involve ascending route of infection. Although the first infant had no gross anomalies of the urogenital tract, functional vesicoureteral reflux cannot be excluded. An incompetent vesicoureteral orifice, which is not detectable on visual inspection, could have allowed the reflux of urine and bacteria into the ureter and kidney. The hematogenous route was not deemed likely in either case. The second case involved a physical anomaly of the urinary tract with subsequent chronic traction and obstruction of the ureters.

The clinical diagnosis of pyelonephritis in infancy may be difficult for several reasons. A diagnostic index of suspicion was blunted by the mild febrile presentation in the first case. Clinical focus on otitis media masked the more serious infection in the second case. This poster presents two cases of pyelonephritis, which were neither suspected by parental caregivers nor diagnosed clinically in the presence of a less serious infection. Pyelonephritis constitutes a rare cause of sudden and unexpected death in infancy.

Pyelonephritis, Sudden and Unexpected Death in Infancy, Autopsy

G35 Necrotizing Fasciitis: Manifestations, Microbiology and Connection With Black Tar Heroin

Nancy M. Dunbar, BA*, Carl Wigren, MD, and Richard C. Harruff, MD, PhD, King County Medical Examiner's Office, HMC Box 359792, 325 Ninth Avenue, Seattle, WA 98104

After attending this presentation, attendees will gain knowledge regarding the manifestations and microbiology of necrotizing fasciitis and how it is related to injection of black tar heroin. The hypothesis is that necrotizing fasciitis caused by drug injection differs substantially from the same disease due to other causes.

This presentation will impact the forensic community and/or humanity by showing the relationship of necrotizing fasciitis to injection of black tar heroin and the importance of understanding the manifestations, microbiology, and causes of this infectious disease.

Introduction: Black tar heroin use is pervasive in the Seattle area. When intravenous (IV) drug users exhaust their IV sites, they resort to subcutaneous (SC) and intramuscular (IM) routes. Unfortunately, SC and IM injection promotes infection by introducing contaminated material into the tissue. Infections are common in heroin users, who often believe that the drug rather than the injection method is responsible. From what is known about black tar heroin, it is likely that either the raw drug or diluents contain clostridial spores, which are difficult to kill by the brief heating drug users employ. It is not uncommon for clusters of infections to be associated with a single batch of heroin. Because necrotizing fasciitis is often fatal, this study was initiated to delineate factors responsible for the disease.

Methods: King County Medical Examiner's Office assumes jurisdiction in all reported cases of necrotizing fasciitis, deaths related to drug abuse, and all infections that may represent a public health hazard. For this study, a records review over 7 years yielded 87 total deaths due to necro-

tizing fasciitis. Eliminating those that lacked identification of the infecting microorganisms left 65 cases in the present study. For these 65 cases, disease manifestations were correlated with the source of infection and the microorganism(s) identified.

Results: Of 32 cases due to drug injection, 17 grew cultures isolating a single organism; the remaining 15 were polymicrobial. Of the 17 single isolates, 13 were clostridia (4 *C. sordellii* and 2 *C. perfringens*). Of the 15 polymicrobial cultures, clostridia were present in 11, with *C. sordellii* representing 4 cases. Overall, clostridia accounted for 24 of 32 cases of necrotizing fasciitis due to black tar heroin injection.

All of 13 cases of necrotizing fasciitis developing after other types of trauma grew cultures containing at least one species of streptococci; 7 grew a single isolate, 4 of which were *S. pyogenes*. The remaining 6 cases were polymicrobial with various streptococci predominating.

In 14 cases developing apparently spontaneously, with no known trauma but several with comorbid conditions, 3 had single isolates of clostridia identified, 2 of which were *C. septicum*. Another 7 grew single isolates of streptococci, 5 of which were *S. pyogenes*. Two additional infections were due to *Staphylococcus aureus*, and the remaining 2 were polymicrobial.

In 6 cases complicating integument breakdown, such as ulcers and percutaneous feeding tube sites, all were infected by streptococci; 2 had single isolates of *S. pyogenes* and 4 were polymicrobial.

Conclusions: This study shows convincingly that necrotizing fasciitis due to clostridial infections is a potential consequence of IM or SC injection of black tar heroin. This disease has a high mortality rate. Although black tar heroin is the likely source, clostridia are unlikely to cause infection unless mechanically introduced into an anaerobic environment. Thus, the injection method rather than the drug is primarily responsible for the disease. There is insufficient evidence from this study to say whether clostridial spores came from the raw black tar heroin, from diluents, or from contaminated needles. The microbiology of cases of necrotizing fasciitis originating from other sources of infection differs from those due to drug injection; in these, streptococcal infections predominate. Compared to clostridia, group A streptococci (*S. Pyogenes*) are virulent and can cause fatal disease spontaneously or following superficial trauma. Accordingly, the organism itself is often primarily responsible for disease.

This study supports the conclusion that necrotizing fasciitis caused by injection of black tar heroin is substantially different from the same disease resulting from other causes. Cases associated with heroin injection are predominantly clostridial infections while the others are predominantly streptococcal infections. While all cases of necrotizing fasciitis are potentially fatal, this conclusion indicates that different prevention and treatment strategies are necessary depending on the underlying cause.

Necrotizing Fasciitis, Clostridial Bacterial Infections, Black Tar Heroin

G36 Was the Shawnee War Chief Blue Jacket a Caucasian?

Carolyn Rowland, MS*, Forensic Bioinformatic Services, Inc., 2850 Presidential Drive, Suite 150, Fairborn, OH 45371; Dan E. Krane, PhD, Wright State University, Department of Biological Sciences, 2640 Colonel Glenn Highway, Dayton, OH 43435; Marc S. Taylor, MS, Technical Associates, Inc., 4125 Market Street, Suite 3, Ventura, CA 93003; and Robert Van Trees, BA, 589 Westwood Drive, Fairborn, OH 45324

After attending this presentation, attendees will gain an appreciation for the mutation rate of the paternally inherited Y chromosome with regards to inquiries of male lineage.

This presentation will impact the forensic community and/or humanity by demonstrating the confidence by which male line descent can be ascertained by performing a direct comparison of the Y-STR haplotypes back eight generations.

The paternally inherited Y chromosome contains the largest non-recombining block of nucleotides in the human genome (approximately 50 million base pairs) and has much lower levels of polymorphism than any other region of the human genome (International SNP Map Working Group 2001). It has become an extremely important tool in a variety of areas including forensics (Jobling et al. 1997), genealogical reconstruction (Jobling 2001), molecular archaeology (Stone et al. 1996), nonhuman primate genetics (Stone et al. 2002) and human evolutionary studies (Hammer and Zegura 1996; Underhill et al. 2000, 2001; Hammer et al. 2001). As a direct result of the relatively low mutation rate, 0.23%/STR locus/generation in human pedigrees, concordance of male-line relation can be deduced via direct comparison Y-STRs. This direct comparison of paternally inherited Y-STRs was utilized to explore a centuries old controversial legend that contends that the legendary Shawnee War Chief, Blue Jacket, was not of American Indian descent, however, was a white man of Dutch descent, known as Marmaduke Swearingen. The comparison of twelve Y-chromosome polymorphic markers in six purported male-line descendants of Chief Blue Jacket and four purported male-line descendants of Marmaduke Swearingen, eight generations removed in both families, revealed that male line descendants in each of the families shared the same 12 locus Y-STR haplotype. However, the Swearingen haplotype was distinctly different from that of the Blue Jacket male-line descendants, with consistency at only five of the 12 tested loci therefore, excluding them from an ancestry linked to Chief Blue Jacket.

Y-STRs, Genealogical Reconstruction, Mutation Rates

G37 Using Multiplexed Microsatellite Markers of Cannabis sativa to Determine Genetic Diversity

Maria Angelica Mendoza, MS*, Heather Erek, BS*, and José R. Almirall, PhD, 11200 SW 8th Street, CP194, Miami, FL 33199

After attending this presentation, attendees will understand previously described microsatellite markers known to discriminate between individual plants were multiplexed into a single reaction and validated in 2 separate laboratories with over 30 plant individuals.

This presentation will impact the forensic community and/or humanity by providing the forensic community with a genetic test, which they can use to track origin in order to connect samples to each other to associate distributors.

Cannabis sativa L. (marijuana) plants can be easily identified through morphological examination and chemical analysis; however there is a need for a DNA test for use as a means of association between individual plants and even as a method to track distribution networks.

Cannabis sativa L. is the most frequently used illegal drug in the United States. *Cannabis* has been used throughout history for its stems in the production of hempen fiber for rope and fabric, for its seed for oil and food and for its flowers and leaves as a psychoactive drug. Microsatellite markers have been chosen for a DNA test because these markers have distinct advantages over other genetic methods. STRs have multiple alleles at a single locus, can be standardized such that reproducibility between laboratories can be easily achieved, have a high discrimination power and can be multiplexed.

In this project, seven *Cannabis* primers selected from a set of primers previously described by the group [1] and four *Cannabis* primers from a set previously described by Gilmore's group [2] were multiplexed into a single reaction. The multiplex reactions were independently analyzed in two separate labs for 30 different cannabis plants. Both an ABI 3100 and an ABI 310 were used for the analysis. Trinucleotide repeats were chosen to reduce the incidence of artifacts that may affect interpretation. The forward primers in some of the primer sets were fluorescently tagged with 6-FAM

dye and some of forward primer sets were tagged with HEX dye. Hemp DNA extracts were provided by Tariq Mahmood of the Alberta Research Council in Alberta, Canada. The hemp samples were amplified in a single optimized reaction to determine base pair size for each allele. The primers were then combined into a single multiplexed reaction. The samples were amplified on a 9700 Thermal cycler with the following parameters: a 5-minute incubation at 94°C then twenty-five cycles of 94°C for 30 seconds, 54°C for 30 seconds and 72°C for 30 seconds, eight cycles of 94°C for 30 seconds, 52°C for 30 seconds and 72°C for 30 seconds, a 60 minute extension time at 60°C and a final 4°C chill. The samples were prepared and electrokinetically injected for capillary electrophoresis on the ABI Prism 3100. The data generated was imported into GeneScan 3.7 and the base pair size analysis performed using Genotyper 3.7.

Previous studies using these microsatellite markers were able to distinguish clones from non-clones. Efforts to construct a comprehensive genomic map of *Cannabis sativa*, where the positions of these microsatellite loci on various chromosomes/linkage groups could be defined are presented. Efforts to determine the level of polymorphism and to measure the genetic relationships between different *Cannabis* plants are also presented. There were a total of 30 individual *Cannabis sativa* plants analyzed, 15 with a low Δ^9 tetrahydrocannabinol (THC) content and 15 with a high THC content.

This study determined the practicality of multiplexing primers sets to differentiate individual plants within the *Cannabis sativa* species. Using previously described primer sets the authors were able to produce a working multiplex, which could differentiate fourteen individual Cannabis samples of unique origin. During testing, the authors determined that there was no significant difference in base pair size between alleles typed using the single locus amplification and the multiplexed amplification. Each cannabis sample gave a unique profile showing clear differences between the generated genotypes.

Cannabis, STRs, Multiplex

G38 Co-Amplification of Cytochrome B and D-loop mtDNA Fragments for More Reliable Species Identifications

Dongya Yang, PhD*, Department of Archaeology, Simon Fraser University, 8888 University Drive, Burnaby, BC V5A 1S6, Canada; and Speller Camilla, MA, Department of Archaeology, Simon Fraser University, 8888 University Drive, Burnaby, BC V5A 1S6, Canada

After attending this presentation, attendees will learn a new method for the analysis of degraded DNA samples in wildlife forensics, food inspection, conservation biology and ancient faunal remains analysis.

This presentation will impact the forensic community and/or humanity by demonstrating the co-amplification method, which is a simple, cost-efficient and genomic DNA-saving approach for species identifications from minute and degraded DNA samples.

This study proposed the simultaneous co-amplification of both cytochrome b and D-loop fragments for more reliable animal species identifications. This method uses a conserved cytochrome b sequence to obtain a less ambiguous species indication and a hyper-variable D-loop DNA sequence to obtain other specific information concerning species, population, and even individual specificities. Tests on ancient whale and salmon DNA samples have demonstrated that the co-amplification is a simple, cost-efficient and genomic DNA-saving approach for species identifica-

tions from minute and degraded DNA samples. It is suitable for the analysis of degraded DNA samples in wildlife forensics, food inspection, conservation biology and ancient faunal remains analysis.

Species Identification, PCR Amplification, mtDNA

G39 Sternal Shard From Bystander Bullet: A Rare Mechanism of Homicide

Wendy M. Gunther, MD*, Office of the Chief Medical Examiner, Tidewater District, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510

After attending this presentation, attendees will become aware of unusual locations a bullet may reach in the body, and understand how a gunshot wound can cause death without the bullet penetrating into the chest cavity, or injuring any vital organ.

This presentation will impact the forensic community and/or humanity by making the attendee aware of fractured sternal fragments as possible injuring substances in a death in which a bullet does not penetrate into the chest cavity, and achieve agreement on whether a death in such a circumstance can be considered accidental, or whether the manner is more appropriately to be deemed a homicide.

An 18-year-old senior high school student, who was captain of the local track team, exited an all-night pancake restaurant after two o'clock on a Saturday morning. He passed through the restaurant parking lot at the time that a gun battle was going on between adversaries on the opposite side of a busy six-lane surface street. The adversaries, who were exchanging shots after exchanging words at a nightclub, were unknown to the victim. It is likely that he was not aware of the gun battle on exiting the restaurant.

A bullet from the exchanged fire crossed the highway, and struck the young man in the chest. He collapsed in the parking lot. Emergency medical services both en route and at the local trauma center provided resuscitative efforts for more than an hour, without avail. Emergency thoracotomy revealed a large amount of blood in the chest.

At autopsy, the gunshot wound had a slightly atypical appearance, in that it consisted of a $\frac{1}{2}$ " oval, with a broader than usual central perforation. There were 250 cc of blood remaining in the chest after bilateral thoracotomy; all viscera were markedly pale, and the vascular tree was depleted of blood. In situ thoracic organ dissection revealed the presence of a partially transected right anterior pulmonary vein, with injury to the right atrial appendage. However, despite this clear evidence of an injury path, no bullet could be located for the initial hour of the autopsy.

During the prolonged search for the bullet, a physician, who was observing the autopsy, identified the projectile in the chest plate, which had been set to one side during the dissection, with its undersurface exposed to view. The bullet was clearly visible, impacted in the inner sternum, although it was partially covered by a disrupted shard of fractured bone from the inner cortex of the sternum. This shard of bone, with a triangular shape like a knife blade, projecting at close to a right angle from the inner cortex, had lacerated the pulmonary vein and right atrium. The bullet which caused death had done so without entering the thoracic cavity, and without perforating any vital structures, because it dislocated a sternal shard from the inner cortex of the sternum, at an unfortunate angle which was responsible for death.

The shooter claimed self-defense, in that he was returning fire on a person who, he stated, was firing at him from within a car across the parking lot. The mechanism of death supported his contention that he did not intend to fire at the victim. Three months later, free on bail, he was arrested with three other men after a drug-surveillance related gun battle with police.

The mechanism of this unusual chain of events leading to death will be discussed, utilizing autopsy photographs, with consideration of the appropriate manner of death.

Sternal Shard, Gunshot Wound, Bystander

G40 False Positive Diagnosis of Subarachnoid Hemorrhage and Subdural Hemorrhage by Computerized Tomography

Sangeeta Sandhu, MD*, St. Luke's-Roosevelt Hospital, 515 West 59 Street, #4K, New York, NY 10019; Stephen deRoux, MD, and Beverly Leffers, MD, Office of Chief Medical Examiner (Brooklyn), 520 First Avenue, New York, NY 10016-6402; and Thomas Gilson, MD, Office of Chief Medical Examiner (Manhattan), 520 First Avenue, New York, NY 10016-6402

The goal of this presentation seeks to raise awareness of the potential misdiagnosis of subarachnoid hemorrhage and subdural hemorrhage by computerized tomography. Attendees should understand possible reasons for misdiagnosis as well as their medicolegal and clinical implications.

This presentation will impact the forensic community and/or humanity by presenting three cases of misdiagnosed subarachnoid hemorrhage and one of subdural hemorrhage.

Death investigators should be aware of potential discrepancies between radiologic and autopsy findings.

Subarachnoid hemorrhage (SAH) involves bleeding into the space between the pia and arachnoid membranes and subdural hemorrhage (SDH) is characterized by bleeding into the space between the dura and arachnoid membranes. SDH is generally associated with trauma while SAH has well-recognized traumatic and non-traumatic (e.g. ruptured cerebral aneurysm) etiologies. Computerized tomography (CT) is frequently used in the evaluation of cases of suspected head trauma and has a high sensitivity in the diagnosis of SAH and SDH. Misdiagnosis by CT of SAH has been infrequently reported but may have significant clinical and medicolegal consequences. Potential sources of misdiagnosis include hypoxic encephalopathy, meningitis and reviewer inexperience. This report addresses three adult cases where CT misdiagnosis of SAH occurred as well as a pediatric case where CT misdiagnosed a SDH.

The **first case** involved a 25-year-old man who presented to the emergency department with vomiting and abdominal pain following an alcohol binge. He had altered mental status and went into cardiorespiratory arrest shortly after presentation. He was resuscitated but remained comatose and succumbed to multisystem organ failure three days after admission. A head CT after resuscitation was interpreted as showing diffuse SAH. No SAH was identified at autopsy. Neuropathologic examination revealed changes consistent with hypoxic encephalopathy with cerebral edema. Cause of death was acute liver failure due to acute and chronic alcoholism.

The **second case** involved a 49-year-old man who presented in cardiorespiratory arrest to the emergency department after being found unresponsive at home. Past medical history was notable for a high cervical spine injury approximately one and half years prior to death. Because of the injury the decedent was ventilator dependent. After resuscitation he remained comatose and died one day later. A CT scan of the head after resuscitation was interpreted as showing diffuse SAH but no SAH was identified at autopsy. Neuropathologic evaluation demonstrated hypoxic encephalopathy with cerebral edema. The cause of the decedent's initial cardiopulmonary arrest was related to complications of his remote neck injury and this was listed as the proximate cause of death.

The **final adult case** involved a 33-year-old man with a history of substance abuse who collapsed at a fast food restaurant and was taken unresponsive to the hospital where he was resuscitated. He regained vital signs but had sustained a hypoxic brain insult and never regained consciousness before expiring 14 hours later. A head CT after resuscitation was interpreted as showing diffuse SAH. This was not present at autopsy and neuropathologic examination again showed only signs of hypoxic encephalopathy with cerebral edema. Cause of death was related to acute drug intoxication.

The **pediatric case** involved a 5 week-old infant who was brought to the hospital in extremis by her father after she developed labored breathing. She had been previously healthy but over the preceding hours was

described as progressively lethargic. She was intubated in the emergency department but became profoundly bradycardic during a head CT. She received inotropic support but expired four hours after presentation. Head CT was interpreted as showing a small right frontal SDH with blood at the posterior aspect of the interhemispheric fissure. No SDH was identified at autopsy, which revealed bacterial leptomeningitis and this was given as the cause of death. The father was released from police custody following autopsy as he had been arrested on suspicion of child abuse (shaken baby syndrome).

Forensic Science, Subarachnoid Hemorrhage, Subdural Hemorrhage

G41 TASER-Related Fatalities: Case Report and Review of the Literature

Amy T. Sheil, MD*, and Kim A. Collins, MD, Medical University of South Carolina, Department of Medical and Forensic Autopsy, 165 Ashley Avenue, Suite 309, Charleston, SC 29425

After attending this presentation, attendees will be aware of TASER-related fatalities, understand the pathophysiological effects of TASER stunning, know common comorbid conditions identified in deaths resulting in conjunction with TASER use, and identify important clinical and pathologic information in the assessment of a TASER-related death.

This presentation will impact the forensic community and/or humanity by demonstrating a compilation of information regarding TASER-related deaths and will educate the forensic community (police, coroners, medical examiners, and investigators) regarding use and pathophysiological effects of the TASER. Identification of comorbid conditions and risk factors for poor outcomes associated with TASER stunning may lead to additional studies concerning guidelines for use. Recommendations may inspire the implementation of clinical and histopathological standards in evaluation of future TASER-associated deaths. Finally, understanding the need for cautious use may limit the number of TASER-associated fatalities, and therefore support continued utilization of this non-lethal weapon.

A recent rash of TASER-related fatalities has inspired controversy regarding the use of the touted non-lethal weapon, as well as the exact role the TASER (an acronym for "Thomas A. Swift's Electric Rifle") has played in the deaths of over 100 people since 2001. Most reports have been prominently featured by the media. TASER International, Inc. asserts that the TASER has not been directly responsible for these deaths.

The TASER is an electric stun gun designed to cause incapacitation upon delivery of approximately 50,000 volts of electricity by means of two metal darts. A cartridge containing two barbed darts is loaded in the gun. The darts are attached to the cartridge by means of thin wire (some with ranges up to 21 feet), and are deployed from the cartridge by pressing a trigger button. One press of the trigger causes a five-second delivery of electricity. A longer duration of delivery may be obtained by continuing to press the trigger. Following deployment of the darts, the gun may be used to deliver electricity by direct contact. Delivery of such an electrical stimulus causes intense, immediate, and painful muscle contraction. Many law enforcement agencies throughout the U.S. employ TASER guns; the TASER is also commercially available to civilians. While the TASER likely has been useful in preventing lethal use of force in some situations, a concern is that few standards are in place governing the use of the TASER. Fatalities have occurred during or following TASER stunning. Many perpetrators on whom the TASER has been deployed have been acutely intoxicated by various drugs, including cocaine, methamphetamine, and phencyclidine (PCP). Acute intoxication has generally been ruled as the cause of death in these cases, and TASER use indirectly implicated. In the absence of any evidence of illicit substances, other causes of death have included positional asphyxia, excited delirium, or underlying cardiac disease.

A case of a 29-year-old schizophrenic inmate who died immediately after being tased approximately six times, subsequent to his attack on cor-

rections officers is reported. He collapsed in a supine position, and his hands were cuffed in front of his body. Postmortem examination revealed an anatomically normal heart, normal postmortem vitreous chemistries, and a negative urine drug screen. No obvious cause of death was revealed by autopsy. Focal interventricular cardiac septum subendocardial myocardial contraction bands were identified by light microscopy. The authors concluded that the inmate died of a fatal cardiac arrhythmia, and in light of the temporal relationship to delivery of TASER electrical stimulus, the manner of death was deemed homicide.

The pathology findings in this case are reported, with a review of the existing literature concerning TASER-related deaths.

TASER, Forensic Medicine, Death

G42 A Demographic Analysis of Youth and Teen Suicide in Maryland (1994-2003)

Melissa A. Brassell, MD, Carol H. Allan, MD, Mary G. Ripple, MD, and David R. Fowler, MD, Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201*

After attending this presentation, attendees will be briefed on the analysis of trends regarding youth and teen suicide, which will assist in properly developing, placing and implementing suicide prevention strategies.

This presentation will impact the forensic community and/or humanity by demonstrating the trends regarding age, gender, race and methods of suicide among youth and teen age groups (age 10-19) in Maryland, which may assist in the application of suicide prevention strategies.

Learning Objectives: This is a retrospective epidemiologic survey of youth and teen suicide, ages 10-19, in the state of Maryland. Analysis of trends regarding age, gender, race and methods of suicide within this population may assist in the application of prevention strategies.

Suicide is the 11th leading cause of death in the United States, comprising 7% of all deaths. Adolescent suicide rates have continued to increase over the last several decades. There have been an increasing number of articles focusing on the epidemiology of suicide, showing the majority of suicide victims to be Caucasian males, followed by African American males, Caucasian females and African American females, in decreasing order of frequency. Fewer studies have focused on the trends of suicide in childhood. This report is a retrospective analysis of suicide in youth (age 10-14) and teen (age 15-19) age groups.

Suicide is the third leading cause of death between the ages of 10-19 years, comprising nearly 8% of all deaths, following only unintentional injury and homicide. In the state of Maryland, during the years of 1994-2003, there were 262 deaths between the ages of 10 and 19 in which the manner of death was determined to be suicide. The average age was 16.7 years. Youth suicide (age 10-14) accounted for 19.5% of these deaths.

In this population, 68% of suicide victims were Caucasian and 28% were African American, a ratio of approximately 2.5:1. This ratio is lower than that typically seen in the general population. This may be explained by the larger African American population seen in the state of Maryland when compared to the United States as a whole. Other races comprised 4% of suicide victims. As in prior studies on suicide, the majority of suicide victims were male (81%). The order, in decreasing frequency, remains Caucasian males (55.3%), African American males (24.4%), Caucasian females (14.1%) and African American females (4.6%).

Gunshot wounds and hangings, which steadily increased in frequency over the ten-year period, comprised the majority of methods of suicide (83%), consistent with that seen in the general population. A majority of fatal self-inflicted gunshot wounds occurred in the male population (41.6%), with 71.6% of these deaths resulting from contact gunshot wounds to the head or intra-oral gunshot wounds. 5.7% of female suicides resulted from gunshot wounds, approximately half of these due to contact

or intra-oral gunshot wounds. Females were significantly more likely to commit suicide by drug intoxication than were males, though hanging was the most common method used. While the availability of firearms has significantly increased over the last decade, there did not seem to be a significant upward trend in the use of firearms to commit suicide in the youth and teen population. There did appear to be an upward trend in hangings. Drug intoxication and multiple injuries, falls from a height, accounted for an additional 10%, with carbon monoxide intoxication and drowning making up the remainder.

Regional evaluation of youth and teen suicide occurrence in the state showed a preponderance of cases in Baltimore County (16%) and Baltimore City (15%). Montgomery County and Prince George's County comprised an additional 23% of cases. The remaining 20 more rural Maryland counties had suicide rates ranging from 1-4%. While there has not been a significant increase in the overall number of youth and teen suicide over the last decade, it may be useful to more closely evaluate those counties, which have had a steady rise in suicides in this age group. Knowledge of risk factors and demographics for suicide in this population, and how they differ according to socioeconomic status will assist in appropriately placing and developing prevention strategies.

Teen Suicide, Suicide Methods, Suicide Prevention

G43 Effectiveness of Death Investigation in Cases of Potential Elder Abuse

Diane C. Peterson, MD, and Richard E. Powers, MD, P220 West Pavilion, Department of Pathology, 619 19th Street South, Birmingham, AL 35233; James N. Robinson, BA, University of Alabama at Birmingham Medical School, VH P-100, 1530 3rd Avenue South, Birmingham, AL 35294; and Gregory G. Davis, MD, Jefferson County Coroner/Medical Examiner Office, 1515 Sixth Avenue South, Room 611, Birmingham, AL 35233-1601*

After attending this presentation, attendees will learn a means to examine the effectiveness of a medical examiner system at detecting cases of elder abuse.

This presentation will impact the forensic community and/or humanity by showing a means for evaluating the effectiveness of a medical examiner office at investigating cases of elder abuse.

RATIONALE: A primary means of detecting foul play is the examination by the medical examiner of the bodies of all individuals who die unexpectedly. Death in the elderly, however, is not necessarily unexpected, and it is possible that foul play is more easily hidden in the elderly by a claim that death was expected, thus bypassing the jurisdiction of the medical examiner. The rate of referral to the medical examiner's office of suspected lethal abuse or neglect in the elderly by all reporters or first responders is unknown. Reasonable conservative estimates exist, however, of claims of elder abuse substantiated upon investigation. Researchers wished to assess the effectiveness of the existing medical examiner system in Jefferson County, Alabama at capturing all cases of physical abuse in the elderly. The authors compared the number of cases of suspected elder abuse investigated by the medical examiner office to the number of cases of elder abuse expected to occur in order to determine whether present reporting network and investigative guidelines are sufficient for recognizing cases involving physical abuse in the elderly.

METHODS: The authors conducted a retrospective study of deaths investigated by the Jefferson County Coroner/Medical Examiner Office, Alabama from January 1, 2003 to December 31, 2004 and reviewed the deaths that occurred in decedents 65 years of age or older, looking for evidence of assault or physical abuse. During this time criteria for accepting cases remained unchanged. The findings were compared with an estimate based on the estimated number of cases of physical abuse that should have occurred during this time span. The estimate was made using data from the Adult Protective Services Division of the Alabama Department of Human

Resources, the United States Census estimates for the state and county populations, and the mortality statistics for Jefferson County. During fiscal year 2004 Adult Protective Services conducted 4,754 investigations into allegations of abuse, of which 16% included allegations of physical abuse. Half of these allegations were substantiated upon investigation. Given a random distribution of cases, use of population and mortality data indicate that the Jefferson County Office should expect to investigate about six cases with allegations of physical abuse and three cases of substantiated physical abuse in the elderly per year.

RESULTS: From 2003-2004 the Jefferson County Coroner/Medical Examiner Office examined 198 individuals age 65 years or older, and suspicion of abuse was reported or found in eight cases. In three cases the abuse was not substantiated at postmortem examination, and in five cases the death was a homicide. Based on the estimates given above, the expected number of cases for two years was 12 cases of suspected abuse and 6 cases of substantiated abuse, so the office investigated roughly the number of cases that might have been expected over the course of this study. Because a case more or fewer would make such a large difference when dealing with such small numbers, e looked at the number of homicides in individuals 65 years of age or older by year during the past decade (1995-2004), during which criteria for accepting jurisdiction were identical to the criteria used for the years of review. It was found that the number of homicides in individuals 65 years of age or older per year ranged from a high of 12 (in 1997) to a low of 0 (2004), with a mean of six cases per year.

CONCLUSION: Using published reports of the incidence of substantiated investigations of physical abuse in the elderly, the authors investigated about the number of cases of physical abuse that were predicted by a model. The number of deaths suspicious for elder abuse investigated by the medical examiner is in keeping with the number of allegations and substantiations for elder abuse in Alabama. The authors' approach to case selection and assumption of jurisdiction appears to be adequate for the investigation of physical abuse in the elderly.

Elder, Abuse, Homicide

G44 Use of CT as an Aid in the Recovery of Metallic Foreign Bodies at Autopsy

Edward A. Reedy, PhD, MD, John M. Getz, PhD, Lisa Pearse, MD, Craig T. Mallak, MD, JD, and James L. Caruso, MD, Armed Forces Medical Examiner System, 1413 Research Boulevard, Building 102, Rockville, MD 20850*

After attending this presentation, attendees will learn the practical application of a well-established technology to aid in the recovery of evidence.

This presentation will impact the forensic community and/or humanity by demonstrating the possible introduction of an existing radiology method into the forensic autopsy.

The recovery of metallic projectiles at autopsy can be difficult if the fragments are small, deeply embedded, very few in number or if the entrance wound or wound tract is obscured by burns or tissue loss. The recovery of projectiles is essential for evidentiary purposes. Plain radiographs frequently prove difficult to interpret, and recovery of metallic foreign objects often requires multiple views. The use of CT at autopsy to locate metallic objects is not a new concept, but is impractical when there are large numbers of foreign bodies to be recovered. Software algorithms now provide a means for the subtraction of tissue densities, allowing for: the determination of size, shape, density, and location of metallic foreign bodies in relation to anatomical structures. CT was utilized at the time of autopsy to identify and recover metallic foreign bodies as evidence.

CT, Radiology, Metallic

G45 Antemortem and Postmortem Toxicological Findings in Motor Vehicle Accidents, Maryland (2003-2004): Does Impairment Equal Death?

Sunil K. Prashar, MD, State of Maryland, Office of the Chief Medical Examiner; 111 Penn Street, Baltimore, MD 21201; Jami L. Grant, PhD, University of Baltimore, 1420 North Charles Street, Baltimore, MD 21201; Susan R. Hogan, MD, David R. Fowler, MD, and Mary G. Ripple, MD, State of Maryland, Office of the Chief Medical Examiner; 111 Penn Street, Baltimore, MD 21201; and Mary E. Kramer, RN, R. Adams Cowley Shock Trauma Center, 22 S Greene Street, Baltimore, MD 21201*

After attending this presentation, attendees will understand the potential utility of adding toxicological screening for drugs to the routine testing of alcohol levels in individuals involved in motor vehicle accidents. Furthermore, attendees will better understand the individual, situational and regional factors associated with motor vehicle related fatalities.

This presentation will impact the forensic community and/or humanity by demonstrating a method to assist state officials in setting policy for the testing of substances of impairment involved in serious motor vehicle accidents. In addition, the presentation will impact the design of public alcohol and drug prevention programs by identifying at risk populations and consumption trends, assist law enforcement in the development of improved interdiction programs, and serve as a guide for future research among the forensics community.

In the state of Maryland, law enforcement personnel perform alcohol testing of individuals involved in motor vehicle accidents. The purpose of this research is to determine whether alcohol testing alone is a reasonable marker of impairment in motor vehicle accidents or whether full toxicological screening should also be required. In addition, this research identifies factors associated with use of alcohol and/or drugs in the driving fatality population with the goal of improving public policies and decreasing driving fatalities.

This presentation will assist state officials in setting policy for the testing of substances of impairment involved in serious motor vehicle accidents. In addition, the presentation will impact the design of public alcohol and drug prevention programs by identifying at risk populations and consumption trends, will assist law enforcement in the development of improved interdiction programs, and will serve as a guide for future research among the forensics community.

The research methodology is based on a retrospective study of the motor vehicle accident fatalities that presented to the State of Maryland Office of the Chief Medical Examiner (OCME) and the motor vehicle accident injured population that presented to the University of Maryland Shock Trauma Center (UMSTC) between July 2003 and June 2004. The study sample included motor vehicle operators, passengers, pedestrians, motorcyclists and bicyclists. Outcome variables include the presence of alcohol alone, drugs alone, and both alcohol and drugs. In the fatalities, drugs included are those routinely tested for at autopsy at the OCME and include illicit drugs, prescription medications and over the counter medications. In the injured sample, drugs included the 18 drugs tested for at UMSTC.

Predictor variables include individual factors (e.g., decedent age, race, and gender), situations factors (e.g., vehicle type, single vs. multiple vehicles, driver vs. passenger, at fault vs. not at fault, safety equipment, and road conditions), and regional/geographic factors (e.g., access to trauma care). This approach is similar to that used in public health research, focusing on primary (before event), secondary (during event) and tertiary (after event) factors, as they pertain to injury-causing events.

Using various descriptive and inferential statistical techniques, the following results were derived (for fatalities n=251; for injured n=2,880). The fatality sample was predominately male (n=186), constituting 74%. Caucasians (n=147) and African-Americans (n=78) comprised approxi-

mately 90%. Decedent ages in both populations ranged from 13 to 65 years. Of the fatality sample, 50.6% tested positive for alcohol and/or drugs, 39.4% tested positive for alcohol alone, 12.4% tested positive for alcohol and drugs, and 11.2% tested positive for drugs alone. Of the injured sample, 22.3% tested positive for alcohol and/or drugs, 16.5% tested positive for alcohol alone, 2.6% were positive for both alcohol and drugs, and 5.8% were positive for drugs alone.

The results suggest that alcohol is a good indicator of driving impairment, as approximately 40% of the fatality sample and 16.5% of the injured sample tested positive for its presence. However, nearly half of the fatality sample and 69% of the injured sample that tested positive for drugs would have been missed by alcohol screening only. Therefore, the ability to determine impairment following motor vehicle accidents may be improved by expanded toxicological studies.

Toxicology, Alcohol, Motor Vehicle Accidents

G46 Descriptive Study on the Causes of Death of Residents of Boarding Homes

Andrea L. Dickens, MD, and Richard E. Powers, MD, P220 West Pavilion, Department of Pathology, 619 19th Street South, Birmingham, AL 35233; James N. Robinson, BA, University of Alabama at Birmingham Medical School, VH P-100, 1530 3rd Avenue South, Birmingham, AL 35294; and Gregory G. Davis, MD, Jefferson County Coroner/Medical Examiner Office, 1515 Sixth Avenue South, Room 611, Birmingham, AL 35233-1601*

After attending this presentation, attendees will gain a better understanding of the circumstances surrounding death and the causes of death for disabled residents of boarding homes.

This presentation will impact the forensic community and/or humanity by demonstrating how boarding homes will become an increasingly common source of cases as disabled individuals are moved from institutional care to community housing in compliance with the federal Olmstead Decree.

RATIONALE: In 1999 the Supreme Court issued the Olmstead Decree, which requires that states offer community-based living for individuals with disabilities rather than house these individuals in institutions. Several options are available to states to satisfy the requirements of the Olmstead Decree. Nursing homes, for example, often house individuals disabled by dementia. Boarding homes also play a critical role in providing housing for disabled individuals, and boarding homes have proliferated in response to the increased demand for such housing since the beginning of the movement to deinstitutionalize individuals with disabilities. The quality of care given by nursing homes has been a subject of great interest recently, both in the medical and legal communities. The nursing home industry is tightly regulated by the federal government, and the causes of death for nursing home patients are recorded as a matter of course. Boarding homes, in contrast, are under no regulation, and virtually nothing is known of the outcomes of disabled patients living in boarding homes, including the circumstances in which these individuals die.

METHODS: The authors conducted a retrospective study of deaths investigated by the Jefferson County Coroner/Medical Examiner Office, Alabama from January 1, 2000 to December 31, 2004. Review of the case files revealed 35 deaths during that time that occurred in a boarding or group home. Each case was reviewed, recording the circumstances surrounding death and the cause and manner of death.

RESULTS: Researchers found 35 deaths investigated by the office which occurred in a boarding or group home. The mean age of the decedents was 59 years, with a standard deviation of 15 years (minimum age 25 years, maximum age 91 years). Twenty-one decedents were black and fourteen were white. Twenty-two decedents were male and thirteen were female. The reasons for living in a boarding home were divided between two broad categories – a history of substance abuse (12 cases) or a history

of debilitating illness (17 cases, with 7 cases of schizophrenia or other psychiatric disorder, 2 cases of mental retardation, and 8 cases due to chronic illness such as diabetes mellitus, loss of mobility due to gunshot wounds, etc). In six cases the cause for living in a boarding home was unclear from the chart. The manners of death were distributed as shown in Table 1.

Table 1. Distribution of deaths by manner in decedents from boarding homes.

Manner of Death	No.	(%)	(Overall % of office)
Natural	20	(57)	(34)
Accident	3	(9)	(31)
Suicide	5	(14)	(12)
Homicide	0	(0)	(20)
Undetermined	7	(20)	(3)

The natural deaths were due to ischemic heart disease (7 cases), hypertension (3 cases), and one case each of pneumonia, cardiomyopathy, and alcoholism. The remaining seven natural deaths were due to undetermined natural causes, a situation that most often arises when a physician refuses to sign a death certificate after the body has already been buried or cremated. The three accidental deaths were due to intoxication related to substance abuse. Two suicides were a gunshot wound of the head, two a hanging, and one an overdose. In the seven cases where the cause of death was undetermined, four were undetermined in part because the office received the case after a physician refused to sign the death certificate, and three were undetermined following an autopsy. Decedents with a history of substance abuse tended to be intoxicated at the time of death; toxicology testing revealed an intoxicating substance in nine of the 11 decedents with a history of substance abuse who were tested. Thirty-two of the decedents were not married, whether because of death of their spouse, divorce, or never having married. The factors that led to the assumption of jurisdiction of a case were lack of a physician to sign the death certificate, history or scene evidence to suggest substance abuse, or concern on the part of the decedent's family about foul play or poor care. No evidence of physical abuse was found in any of these cases.

CONCLUSION: Federal law requires that states offer community-based living for individuals with disabilities rather than house these individuals in institutions. Boarding homes are the community-based housing available to these disabled persons. Residents of boarding homes are likely to be disabled by substance abuse or by a mental disorder. Research indicates that abuse of the elderly is more likely in individuals with short-term memory problems, any psychiatric diagnosis, substance abuse, or poor social support. Most residents of boarding homes in this study were socially isolated and either mentally disabled or prone to substance abuse, leading us to conclude that deaths that occur in boarding homes merit forensic investigation.

Group Home, Boarding Home, Disabled

G47 The Death of an Italian Soldier in Iraq: Murder or Fatality?

Margherita Neri, MD, Marianna Di Padua, MD, Cristoforo Pomara, MD, and Emanuela Turillazzi, MD, PhD, Department of Forensic Pathology, University of Foggia, Viale Pinto 1, Foggia, 71100, Italy*

The death of an Italian soldier in Iraq is presented. The goal of this study is to present a relatively quick and easy method for evaluation of gunshot residues, useful for interpreting gunshot wounds in cases where the circumstances of death are not clear. A specific histochemical stain with sodium rhodizonate and an analysis using a confocal type laser profile microscope was performed in order to clarify the exact death scenario.

This presentation will impact the forensic community and/or humanity by providing a relatively quick and easy method for evaluation of gunshot residues, using sodium rhodizonate staining on histological

samples, that may help determine range of fire in cases of death caused by firearm, and in this particular case, in order to clarify whether it is an accident, homicide or a suicide case. This histochemical data may be supported by the use of a confocal microscope.

A young Italian soldier in Iraq, at 01:00 p.m. was discovered wounded in a shooting range, where he was training with his rifle, a "MINIMI" cal. 5.56 mm. The rifle was found near the man and was seized. He was quickly taken by helicopter to the nearest military hospital in serious clinical condition, but he continued getting worse, so was transferred and hospitalized to Kuwait City, and died at 4:27 p.m. The body was transferred to Italy to the Department of Forensic Pathology of Foggia. A Military Prosecutor arranged the autopsy on the body because the circumstances of the wound suggested that the death could be an accident or, alternatively, a murder.

A complete autopsy was performed. The head injury was massive with partial evisceration of the brain. A large gaping tear of the scalp was present. The exact sites of the entrance and the exit of the bullet were not apparent. Careful re-approximation of the scalp and the examination of the tear showed an irregularly circular wound with irregular margins, surrounded by a wide zone of raw abraded skin in the forehead. A large, V-shaped scalp laceration (18 x 15 centimetres) radiated from this circular area up to the parietal and occipital bones. Gross identification of the entrance site was not possible. The brain was edematous, and the bilateral frontal and right parietal regions were lacerated with lost brain parenchyma.

The brain was sectioned with coronal cuts according to the Adams technique and showed right to left shift of the midline structure.

In the bilateral frontal region a small foci of hemorrhage was present and characteristic petechial hemorrhages continued throughout coronal cuts and affected the corpus callosum. Furthermore, in the right hemisphere, superficial subcortical hematomas extended into the parenchyma and the right lateral ventricle.

The cerebellum the subarachnoid space was affected by moderate hemorrhage, and the brainstem showed characteristic petechial hemorrhages.

The examination of the other organs was unremarkable. Routine histological investigation of skin specimens applying hematoxylin and eosin staining revealed a detachment of the upper epidermal areas mainly extending through the basal cell layers with flattened and stretched epidermis. The deeper parts of stratum papillare and underlying upper layers of the corium were homogenized. In these areas wide erythrocyte accumulation was present in the dermis and sub-epidermic adipose tissue. In superficial and deep layers of skin and dura mater were black foreign bodies. Brain sections showed intraparenchymal diffuse haemorrhages.

Frontal wound skin and dura mater samples were also stained with Rhodizonate dye technique. Rhodizonate acid exists as needle-shaped crystals of a dark orange colour and forms a sodium salt, which reacts with heavy metal ions (barium, antimony, lead, tin) contained in gunshot residues (GSR) with a red precipitate. On histological tissue sections, Rhodizonate reacts with heavy metal particles from the primer by generating a finely granular scarlet red pattern. The specimens were examined with a light microscope, in transmitted brightfield illumination and phase contrast mode.

In the samples collected from skin of the frontal region the Na-Rhodizonate reaction was positive for the presence of gunshot residues (GSR), showing dotted, non-contiguous, coarsely granulated deposits of rhodizonate, positive not only on the surface of skin, but also appearing within the gaps between connective tissue fibers. The same findings were observed in the dura mater specimens.

The GSR-positive samples were examined with confocal microscope using fluorescence emission of skin and antimony, a heavy metal contained in gunshot residues. A three-dimensional reconstruction was performed that confirmed the presence of GRS - positive granules on skin and dura mater surface.

Gunshot residue findings, their morphological aspects, and their location were indicative for a shooting distance less 40 centimetres.

In this reported case, the careful histological investigation of the wound skin through specific staining made the circumstances of the death clear, leading to the assessment of entrance site and firing distance. Furthermore the circumstantial data confirmed the hypothesized death scenario, that it was an accidental self-inflicted gunshot while the soldier was trying to unblock his rifle.

Soldier Death, Gunshot Wound, Shooting Range

G48 Prevention of Accidental Strangulation of Children in Their Sleeping Bags: Development of a New Sleeping Bag

Kathrin Gerlach, MD, Department of Legal Medicine, Pestalozzistrasse 22, Basel, 4056, Switzerland; Beat Horisberger, MD, Department of Legal Medicine, Rue du Bugnon 2, CH-1005 Lausanne, Switzerland, Walter Bar, MD, Department of Legal Medicine, Winterthurerstrasse 190, CH-8091 Zürich, Switzerland; and Volker Dittmann, MD, and Daniel Wyler, MD, Department of Legal Medicine, Pestalozzistrasse 22, CH-4056 Basel, Switzerland*

The goal of this presentation is to draw your attention to the dangers of accidental strangulation of children in their sleeping bags. Dr. Gerlach will also introduce a newly developed model of a sleeping bag, which prevents fatal incidents of that kind.

This presentation will impact the forensic community and/or humanity by aiming to sensitize the audience to the problem, to critically discuss the prototype as well as to show how to avoid such fatalities, which should also be accomplished by marketing the new sleeping bag.

In the last few years, researchers analysed several fatalities of children who had strangled themselves at the neckline of their sleeping bag due to their own movements while sleeping. Those sleeping bags can be purchased on the market and should be suitable to fix children.

Types of sleeping bags currently available on the market with their safety advantages and disadvantages are presented.

After this analysis, these fatal incidents appear to be avoidable, and it is possible to adopt measures to prevent these deaths. A simple means to resolve the problem would be a revision of the cut patterns in the current sleeping bags, which fixes the main hazard of these sleeping bags.

A prototype was developed with a cut to prevent these fatal incidents. This prototype sleeping bag is being tested for its functionality and handling and is registered for marketing. This prototype will be presented to an audience of experts.

Sleeping Bag, Strangulation, Prevention

G49 VIRTopsy (Virtual Autopsy) - Past, Present, and Future

Michael J. Thali, MD, University of Berne, Institut Forensic Science, Buehlstrasse 20, Bern, Switzerland; Peter Vock, MD, University of Berne, Radiology Department, Berne, 3005, Switzerland; and Richard Dirnhofer, MD, University of Berne, Institut of Forensic Medicine, Berne, Berne 3012, Switzerland*

After attending this presentation the attendee will get an upgrade of the cutting edge technologies in forensic imaging/radiology.

This presentation will impact the forensic community and/or humanity by providing an actual overview of upcoming imaging technologies in forensic medicine.

The aim of the VIRTopsy project (www.virtopsy.com) is utilizing 3D body-surface documentation and minimal-invasive, image-guided virtual autopsy utilizing optical and radiological scanning to push low-tech

documentation and autopsy procedures in a world of high-tech medicine in order to improve scientific value, to increase significance and quality in the forensic field. The Institute of Forensic Medicine, University of Berne is, in collaboration with a well selected national and international research team, evaluating and validating several cutting-edge technologies such as 3D optical and photogrammetric surface scanning, computed tomography (CT), magnetic resonance imaging (MRI), magnetic resonance (MR) spectroscopy, micro-CT, micro-MR, postmortem biopsy, postmortem angiography and synthetic body models. The term VIRTOPSY was created from the terms virtual and autopsy: Virtual is derived from the Latin word ‘virtus’, which means ‘useful, efficient, and good’. Autopsy is a combination of the old Greek terms ‘autos’ (=self) and ‘opsomei’ (= I will see). Thus autopsy means ‘to see with ones own eyes’. Because the goal was to eliminate the subjectivity of “autos”, the two terms virtual and autopsy were merged - deleting “autos” - to create VIRTOPSY. Today the project VIRTOPSY combining all the research topics under one scientific umbrella, is characterized by a trans-disciplinary research approach that combines Forensic Medicine, Pathology, Radiology, Image Processing, Physics and Biomechanics to an international scientific network. The paper will give an overview of the Virtopsy change process in forensic medicine.

Virtopsy, Virtual Autopsy, Forensic Radiology

G50 Professional Quality in a Forensic Medical Setting: The Singapore Experience

Paul P.S. Chui, MBBS, DMJ, MBA, and Clarence T. Tan, MBBS, Health Sciences Authority, 11 Outram Road, Singapore, 169078, Singapore*

After attending this presentation, attendees will 1. Understand the need for Professional Quality in a forensic medical setting; 2. Gain an insight in how CFM, HSA has approached the subject of Professional Quality; and 3. See the need to implement quality systems suitable to their own operating environment.

This presentation will impact the forensic community and/or humanity by encouraging implementation of quality systems and promoting more emphasis on assuring quality of services of the forensic medicine community; and encouraging dialogue between practitioners as to best practices that would engender the above.

In many different industries, including the healthcare sector, the pursuit of quality has become an essential element in both assuring consumers a consistency of standards in the products and services delivered as well as delivering a competitive marketing advantage. Indeed, this also applies to many public agencies around the world.

Forensic medical practices/consultancies are typically small “enterprises” with limited budgets and they operate within a limited legal/geographical jurisdiction, in a typical single seller (the forensic practice) and single buyer/payer (State/Law Enforcement agency) environment. Some of these “enterprises” are one-man-operations (OMO).

Professional accountability is mostly limited to challenge within a courtroom environment or is non-existent outside of the courtroom in some instances. Peer review is not a norm. The weight placed on personal professional independence, expertise and experience creates an milieu amenable to development of a prima donna culture where forensic opinion is no longer largely a question of science but of the weight of persona and charisma in court and the public eye, where the risk of errant practices and practitioners may remain undetected for a long time. Failure to deliver good quality results can pervert the course of natural justice and damage public confidence in the law enforcement and judicial systems.

Considering the impact of the professional work in influencing judicial outcomes, it is important, in the authors' view that while one cannot wholesale adopt practices from the industry, efforts nonetheless need to be made to identify relevant and appropriate measures for adoption, to assure the stakeholders (the Prosecution, the Courts, Law Enforcement, the

Public, the Politicians, the funders) that high standards in professional forensic practice are delivered consistently with accountability. The paper will discuss the experience of the Centre for Forensic Medicine, Health Sciences Authority Singapore, in its journey towards assuring professional quality.

Quality, Forensic Medicine, Accreditation

G51 Insects of the Grave: A Cold Case History Involving Insects 27 Years After Death

Richard W. Merritt, PhD, Michigan State University, Department of Entomology, 243 National Science Building, East Lansing, MI 48824; Mark E. Benbow, PhD, Department of Biology, DePauw University, Greencastle, IN 46135; Ryan K. Kimbrauskas, MS, Michigan State University, Department of Entomology, East Lansing, MI 48824; Joyce L. deJong, DO, Sparrow Hospital, 1215 East Michigan Avenue, Lansing, MI 48909; and Richard Snider, PhD, Michigan State University, Department of Zoology, East Lansing, MI 48824*

After attending the presentation, attendees will understand the biology of a relatively small group of insects (Collembola) rarely mentioned as an insect frequenting decomposing remains, especially following exhumation 27 years after death. They also will be exposed to the environmental factors that may have led to this occurrence.

This presentation will impact the forensic community and/or humanity by presenting case that provides important information to entomologists and biologists on the biology of Collembolan as it relates to human decomposition. The case also will add to the biological information of this insect group as to their movement in the soil and apparent niche at this soil depth. This is information that will rarely ever be collected in normal crime scene investigations, and it is a rare occurrence in nature to find insects inhabiting a cadaver 27 years after death.

This presentation will make forensic entomologists and other biologists aware of insects and other arthropods associated with decomposing bodies far beyond the normal postmortem interval. It also will make forensic pathologists aware of what types of arthropods may be encountered during investigations when bodies have been exhumed after several years.

The cadaver of a 28-year-old female was exhumed in January 2005 from a cemetery in Battle Creek, Michigan. She had sustained a gunshot wound to the head and was found dead in her home on November 15, 1977. An autopsy was performed and the manner of death was termed as a homicide. The body of the victim was subsequently embalmed and then buried at a depth of 6 feet in an unsealed casket that was placed inside an unsealed cement vault. Information leading to the perpetrator of the crime became known in 2004 and the investigating agency was unable to locate an autopsy report. Therefore, law enforcement officials requested the body be exhumed and a second examination be performed.

The current exhumation yielded thousands of live specimens of a single species of Collembola or spring tails, *Sinella (Coecobrya) tenebricosa*. This species is considered to be a “tramp” species, cosmopolitan in the United States and Canada. It is usually collected in protected areas such as caves, wood piles, and greenhouses. Based on their occurrence in soils, small size, and given the damp conditions present in the casket, this species probably made use of soil pores and tunnels made by worms and other burrowing arthropods in searching for food. Over time, some individuals moved down further into the soil into the moist vault and eventually the casket where cadaver tissues and clothing provided a suitable substrate for fungal/yeast/mold growth as a food source. At this site the species had ideal conditions and the population exploded. Collected with the Collembola were large numbers of Acarina (mites) of the Family Glycyphagidae, and phorid fly puparia, known as coffin flies.

Insects, Burial, Collembola

G52 Seasonal Effects on Blow Fly Species Composition and Behavior

Jennifer Y. Rosati, BSc*, and Sherah L. VanLaerhoven, PhD, University of Windsor, Rm 119 Bio, 401 Sunset Avenue, Windsor, Ontario N9B 3P4, Canada

After attending this presentation, attendees will learn about blowfly species and behavior and how it relates to decomposition and PMI determination.

This presentation will impact the forensic community and/or humanity by recognizing the importance regarding the effects of habitat and season on blowfly species composition and behavior.

Blowfly species composition is an important aspect to consider in the determination of the postmortem interval (PMI). Presented here are some preliminary results from the first year of a 2-year decomposition study. The effect of habitat (sun and shade) and season (spring, summer, and fall) on the successional patterns of carrion insects were investigated using the domestic pig. Each season, 2 freshly killed pigs (approximately 23kg) were placed in each habitat type in 6 test sites located throughout Windsor/Essex County, Ontario (n=12 pigs/season). Insects were sampled using a combination of pitfall and malaise traps as well as direct sampling. Internal carcass temperatures and ambient temperatures were recorded for each pig using Smartbutton data loggers and biomass loss was determined through weekly weighing. The effect of habitat and season can play a significant role in determining the species composition and successional patterns of the blowfly community. Observations and differences concerning maggot feeding and wandering behavior for each habitat and season were recorded. The research is currently on going with the second year beginning in April 2006.

Blowfly Species Composition, Blowfly Behavior, Habitat and Seasonal Effects

G53 Improving Postmortem Interval Estimates in Forensic Entomology: Blowfly Gene Expression and Development

Aaron M. Tarone, BS*, Department of Zoology, 203 Natural Sciences Building, Michigan State University, East Lansing, MI 48824; and Kimberly C. Jennings, BS, and David R. Foran, PhD, School of Criminal Justice, 560 Baker Hall, Michigan State University, East Lansing, MI 48824

After attending this presentation, attendees will learn about the use of gene expression information to assist in making entomology based PMI estimates.

This presentation will impact the forensic community and/or humanity by improving the precision of entomology based PMI estimates.

Investigators often use the presence and age of blowfly larva on a carcass to estimate the postmortem interval (PMI). Currently, morphological traits, including larval instar and length and weight are used to approximate larval age. Likewise, pupae can be dissected and morphological features observed. However, the precision of these estimates is always in question, particularly for the longer third instar and pupal stages.

The goal of this project was to produce a more objective, genetic-based assay of juvenile fly age, and thus PMI, focusing on the widely distributed and forensically useful blowfly, *Lucilia sericata*. The foundation for this assay was the wealth of developmental data already available from the model fly system *Drosophila melanogaster*, as well as from a *sericata* sister species, *L. cuprina*, a sheep parasite that has been studied in Australia and New Zealand. In both systems, a variety of developmentally important genes have been shown to undergo changes in expression levels throughout the immature stages (egg, larva, and pupa). Using known sequence from *D. melanogaster* and *L. cuprina*, a suite of genes (white, scalloped wings,

resistance to organophosphate 1, acetylcholine esterase, ultraspiracle, ecdysone receptor, wingless, slalom, aminopeptidase 1, bicoid, chitin synthase, and heat shock proteins 60 and 90) was isolated and sequenced in *L. sericata*. The expression levels of these genes were profiled throughout the juvenile life cycle at two temperatures. They were also assayed in larvae that failed to pupate.

Gene expression profiles were obtained for replicate time series, as were the distributions of gene expression levels. Examples of informative transcripts at a specific stage include resistance to organophosphate-1, which became the most common transcript in mid pupal samples, and scalloped wings, which decreased dramatically at the same time. Through replicate analysis of many individuals from each developmental stage, a confidence interval could be assigned to the expression level of each gene throughout the life cycle. Further, by analyzing the expression levels of a number of genes, confidence levels could be assigned to the estimate of developmental stage of the flies. Finally, expression profiles of larvae that failed to pupate were examined, which indicated aberrant gene expression lay at the root of this phenotype.

Current research in forensic entomology includes investigation of error rates for PMI estimates, as well as improved use of environmental information, in an attempt to increase the accuracy of PMIs generated in this way. The developmental gene expression research presented here addresses the biological side of the same issue. The method allows for a quantitative analysis of age using many different traits, and represents a promising approach for improving entomology based PMI estimations.

This project was supported by Grant Number 2004-DN-BX-K005 awarded by the National Institute of Justice, Office of Justice Programs, U.S. Department of Justice. Points of view in this document are those of the author and do not necessarily represent the official position or policies of the U.S. Department of Justice.

Forensic Entomology, DNA Expression Levels, Postmortem Interval

G54 The Developmental Studies of The Green Bottle Fly, *Phaenicia coeruleiviridis* (Diptera: Calliphoridae)

Kc L. Deaver, MS*, 2704 72nd Avenue, SE, Mercer Island, WA 98040; and Jerry Cook, PhD, Sam Houston State University, Department of Biological Sciences, 300 Lee Drain, Box 2116, Huntsville, TX 77341

After attending this presentation, attendees will learn the developmental growth times of *Phaenicia coeruleiviridis* in this preliminary study of this species.

Insects collected at crime scenes are often used to estimate PMI (Postmortem Interval). Developmental growth curves of individual species are used in these estimations. To date, there is very little information on the species *Phaenicia coeruleiviridis*. This presentation will impact the forensic community and/or humanity by helping in creating a more accurate PMI estimate when *Phaenicia coeruleiviridis* is used.

Despite its obvious presence and abundance in the south and southeastern parts of the United States, there is little information on the growth and development of the green bottle fly, *Phaenicia coeruleiviridis* (Macquart). Growth curves were determined for the egg, larva, and pupa stage of this species under constant temperatures of 21.1, 23.8, and 26.6°C. Development from egg to adult under all temperatures ranged from 608 to 844h. Length and mass measurements for each development stage at each temperature regime were reported, giving investigators an option for analysis of age and postmortem interval estimations using *P. coeruleiviridis*. Although the genus *Phaenicia* (=*Lucilia*) is small and the species appear similar, developmental data varies greatly within this genus, indicating a need for further study.

Developmental Growth Curve, Forensic Entomology, *Phaenicia coeruleiviridis*

G55 Effects of Fluctuating Temperature and Larval Density on *Calliphora dubia* (Diptera: Calliphoridae) Implications for Postmortem Interval Estimation

Ian Dadour, PhD*, and Sasha Voss, BSc, University of Western Australia, Centre for Forensic Science, 35 Stirling Highway, Nedlands, 6009, Australia

After attending this presentation, attendees will be briefed on this part of a series of research papers, which revisits fly life histories and examines them in the environment lived in, rather than the constancy of the laboratory. Entomologists involved in case-work need to understand developmental rates of insects.

This presentation will impact the forensic community and/or humanity by reminding forensic entomologists to be careful in their assessment of fly life histories and their application in case work.

The accuracy of any entomological estimation of postmortem interval (PMI) depends on the thermal history of the larval samples investigated and the availability of comparative developmental reference data. At present, there is a paucity of data relating to larval development under geographic-specific climatic conditions and the influence of micro-environmental temperature produced by larval aggregations on development.

Most entomological PMI estimates are based on reference data compiled from larvae reared at constant temperatures. These estimations have the potential to be erroneous where ambient temperatures at the crime scene fluctuate over time, or where larval aggregations are present on the cadaver during development. High larval density can alter the temperature of the microenvironment experienced by the larvae above that of the ambient temperature used in the PMI estimation.

In this study, the rate of larval development of the forensically significant blowfly, *C. dubia*, was investigated under both constant and fluctuating temperature regimes. Temperatures investigated approximated the summer (24°C; 19/30°C) and autumn (19°C; 13/25°C) seasonal temperatures of southern Western Australia. The influence of larval aggregation on the development rate of *C. dubia* was also investigated using larval densities of between 50 and 5000 larvae. This presentation will discuss the influence of larval aggregation size and fluctuating temperatures on the development rate of *C. dubia* and the implications of this for PMI estimation.

Development, Flies, PMI

G56 The Composition and Succession of Soil Microbial Communities Following Cadaver (*Rattus rattus* L.) Burial

David O. Carter, PhD*, Department of Plant Pathology, University of Nebraska-Lincoln, 406 Plant Sciences Hall, Lincoln, NE 68583-0722; David Yellowlees, PhD, School of Pharmacy and Molecular Sciences, James Cook University, Douglas, QLD 4811, Australia; and Mark Tibbett, PhD, School of Earth and Geographical Sciences, University of Western Australia, Crawley, WA 6009, Australia

After attending this presentation, attendees will understand fundamental principles concerning the composition and population dynamics of soil microbial communities associated with cadaver decomposition in soil.

This presentation will impact the forensic community and/or humanity by demonstrating the potential for microbial succession as a basis for estimating postmortem interval.

Recent research has shown that the soil microbial biomass can respond positively to the burial of a juvenile rat (*Rattus rattus*) cadaver.

However, it is unknown what components (bacteria, fungi) of the soil microbial biomass are associated with this increase in microbial abundance. It is well understood that the amendment of soil with an organic resource (such as a cadaver) can result in a shift in the composition of the soil microbial community. Furthermore, the composition of microbial communities can also change as a resource decomposes and these successional changes may provide a basis to estimate postmortem interval.

The current experiment aims to demonstrate the concentration and succession of Gram-positive bacteria, Gram-negative bacteria, and fungi associated with cadaver breakdown. In order to investigate this, a field experiment was conducted at two disparate field sites during the dry season (March 2003). Site 1 comprised a loamy sand soil (84% sand, 11.1% silt, 4.9% clay) and was located in Yabulu, Queensland, Australia. Site 1 receives an average rainfall of 140 mm during the dry season (March–October) and average maximum/minimum temperature equals 22.9 °C/16.7 °C. Site 2 comprised a sand soil (97.7% sand, 1.3% silt, 1% clay) and was located in Pallarenda, Queensland, Australia. On average, site 2 receives 120 mm of rainfall during the dry season and the average maximum/minimum temperature is 26.9 °C/16.4 °C. The resulting vegetation at the two sites was dominated by grasses with scattered trees. These characteristics are typical of a tropical savanna ecosystem.

Juvenile rat (*Rattus rattus*: ~18 g) cadavers were buried (2.5 cm) in the center of a 2 m² plot. Cadaver mass loss and phospholipid fatty acid (PLFA) concentration of soil directly surrounding each cadaver were measured at 7, 14, and 28 days following burial. To measure PLFA concentration soil was amended with a chloroform:methanol:phosphate buffer, shaken and centrifuged. Supernatant was removed, placed in a clean glass culture tube, and dried under nitrogen (N₂). Dried lipids were resuspended in chloroform and phospholipids were eluted with methanol through a silicic acid column and dried under N₂. Dried phospholipids were amended with acidified methanol, incubated for 12 hours at 60 °C, and amended with purified water and petroleum ether. The ether layer was transferred to a clean culture tube and dried under N₂. Standard (19:0) and hexane were added to the dried ether layer and PLFAs were separated by capillary gas chromatography using an automated procedure developed by MIDI (MIDI, Inc. Newark, DE). PLFAs were used as markers of Gram-positive bacteria (15:0, i15:0, i16:0, 17:0, i17:0, a17:0), Gram-negative bacteria (cy17:0, cy19:0, 16:17c, 16:17t) and fungi (18:26c). This experiment was replicated four times and controls (soil without cadaver) were used.

After one week's burial cadaver decomposition at Site 2 (1/3 mass loss) was greater than at Site 1 (1/4 mass loss). All cadavers lost approximately ¼ of mass after two weeks at which time the larger soil microbial community was found at Site 1. At this site, the microbial community was dominated by bacteria throughout, and Gram-positive and Gram-negative bacteria comprised equal fractions of the population. Fungal PLFAs were detected after two and four weeks only. The microbial community at Site 2 was also dominated by bacteria for the first two weeks after burial, and Gram-positive and Gram-negative bacteria also comprised equal fractions of the bacterial population. In contrast to site 1 however, the microbial community was dominated by fungi on day 28.

These findings are not surprising considering the introduction of a high-quality; complex resource (such as a juvenile rat cadaver) tends to result in the proliferation of bacteria. As these resources are depleted bacteria are commonly replaced by fungi, which are more tolerant to moisture stress and can be indicators of low soil nutrient status. The difference in succession between soils may be because cadavers buried at Site 2 reached skeletonization prior to cadavers buried at Site 2. These successional sequences may be used as a basis to estimate postmortem interval of cadavers that have progressed into the skeletonization stage of decomposition. The dynamics of specific PLFAs will be presented in relation to cadaver decomposition stage.

Taphonomy, Succession, Phospholipid Fatty Acid Analysis

G57 Nematode Community Dynamics Associated With Cadaver (*Sus scrofa* L.) Decomposition and Insect Activity on the Soil Surface

David O. Carter, PhD*, Department of Plant Pathology, University of Nebraska-Lincoln, 406 Plant Sciences Hall, Lincoln, NE 68583-0722; Timothy E. Huntington, MSc, and Leon G. Higley, PhD, Department of Entomology, University of Nebraska-Lincoln, 202 Plant Industry, Lincoln, NE 68583-0816; and Thomas O. Powers, PhD, Department of Plant Pathology, University of Nebraska-Lincoln, 406 Plant Sciences Hall, Lincoln, NE 68583-0722

After attending this presentation, attendees will understand the relationships between the composition of belowground nematode communities and cadaver decomposition as well as how these relationships are influenced by insect activity.

This presentation will impact the forensic community and/or humanity by demonstrating the potential for nematode succession as a basis for estimating postmortem interval.

Soil-dwelling nematodes are microscopic invertebrates that play a key functional role in soil processes of decomposition and nutrient cycling. Nematodes are generally the most abundant and diverse metazoans living in the soil and respond rapidly to disturbance, such as the decomposition of a body. The investigation of nematode community structure can reflect decomposition status because nematodes exhibit a sensitive relationship to their environment by responding to the spatial and temporal dynamics of resources. Thus, a localised succession of nematode trophic groups (bacterial-feeder, fungal-feeder, herbivore, omnivore, and predator) occurs as a resource decomposes. Nematodes are readily sorted into trophic groups because feeding behavior can be deduced from the structure of the mouth cavity and pharynx. This makes nematodes an efficient indicator of decomposition status. In addition, nematodes may be transported to a decomposition site by insects. This may have implications for forensic science because nematodes can establish phoretic relationships with many insects associated with cadaver decomposition (Calliphoridae, Coleoptera, and Silphidae).

This study was based on the understanding that (1) insects respond rapidly to the placement of a cadaver on the soil surface and (2) a proliferation of soil microorganisms is associated with cadaver decomposition in soil. This work aimed to test the hypothesis that nematode community composition is related to the stage of cadaver decomposition and insect activity.

Six 10-week-old pig (*Sus scrofa* L.) cadavers (~45 kg) were killed by trauma (gunshot) to the head and placed inside a 2 m² plot on the soil surface within 30 minutes of death. Three cadavers were exposed to insects, three were excluded from insects using Lumite (18 x 14 mesh) exclusion cages (6 ft³), and controls (plots without cadavers) were used. Thus, four treatments were used: + cadaver + insects, + cadaver - insects, - cadaver + insects, - cadaver - insects. Cadaver decomposition was measured using a decomposition scoring system at intervals of 24 hours for the initial seven days and at intervals of seven days thereafter. Cadaver decomposition was designated as being in one of four stages: Fresh, Early Decomposition, Advanced Decomposition, and Skeletonization. Soil samples (0 cm -10 cm depth) were collected from soil adjacent to the cadavers at intervals of seven days using a soil probe (2.5 cm diameter). Following transportation to the laboratory nematodes were extracted from soils enumerated and identified morphologically. DNA sequencing was used for identification when nematodes could not be identified morphologically.

The exclusion of insects had a significant negative effect on cadaver decomposition. Cadavers exposed to insect activity reached Early Decomposition by day 2, Advanced Decomposition by day 4 and Skeletonization by day 21. In contrast, cadavers excluded from insect

activity reached early decomposition by day 3, Advanced Decomposition by day 21 and had not reached Skeletonization by day 49. Insect activity also had an effect on belowground nematode abundance that was characterized in a delay in peak nematode abundance. In the presence of insects nematode abundance reached peak levels on day 14. Nematode abundance in the absence of insects reached peak levels on day 21 to day 28 and a second peak was observed on day 49. The nematode community in association with insect activity could be dominated by phoretic nematodes while the nematode community in exclusion cages could be dominated by native soil-dwelling species. Nematode species identification is currently underway and results will be presented.

Taphonomy, Nematode, Succession

G58 Characterization of Adipocere Formation in Animal Species

Shari L. Forbes, PhD*, University of Ontario Institute of Technology, Faculty of Science, 2000 Simcoe Street, N, Oshawa, Ontario L1H 7K4, Canada; and Barbara H. Stuart, PhD, and Boyd B. Dent, PhD, University of Technology, Sydney, Department of Environmental Sciences, PO Box 123, Broadway, NSW 2007, Australia

After attending this presentation, attendees will understand the chemical process by which adipocere forms, the requirements for its formation, the types of animal species it has been observed on, and an example of a case study in which its identification was required.

This presentation will impact the forensic community and/or humanity by discussing the value of adipocere as evidence and the limits associated with confirming its human origin in cases of homicide or human rights issues.

The aim of this presentation is to demonstrate the importance of identifying the species origin of adipocere samples collected as evidence. After attending this presentation, attendees will understand the chemical process by which adipocere forms, the requirements for its formation, the types of animal species it has been observed on, and an example of a case study in which its identification was required.

Adipocere is a soft white substance formed postmortem from fatty tissue in a decomposing body. Its formation is characterized by the hydrolysis and hydrogenation of the neutral fats into a mixture of predominantly saturated fatty acids. Under suitable conditions adipocere may form on both human and animal remains. The majority of research investigating adipocere formation has focused on either human remains or porcine remains, as a model for human decomposition. However, no studies of the nature of adipocere formation in other animal species have been reported. This study was conducted as a result of two enquiries from independent forensic laboratories to assist with the identification of adipocere collected as evidence in homicide cases. In both instances, the species origin of the adipocere fragments was in question.

Adipocere was formed in a controlled soil environment by burial of fatty tissue samples of several different animal species. Infrared spectroscopy was used to provide a lipid profile of the fatty tissue and adipocere samples. Gas chromatography-mass spectrometry was employed as a method for the identification of fatty acids in the original tissue and adipocere. Of the six species investigated, adipocere did not form on two of the species due to their reduced fat content. The adipocere that formed from the other species' tissue could not be visually discriminated between species.

The chemical characterization demonstrated identifiable differences in the fatty acid content of the original adipose tissue. Characterization of the adipocere samples also demonstrated differences in fatty acid content however this was determined to be a result of the different rates of formation of each species. The results suggested that the fundamental composition of adipocere is similar regardless of the species on which it formed. There was no evidence to suggest that the chemical composition

of adipocere is species-dependent. This conclusion highlights the difficulty associated with determining the species origin of adipocere, whilst also demonstrating the caution, which must be taken when attempting to link adipocere fragments to human remains.

Further studies are presently on-going to determine the feasibility of extracting DNA from adipocere. Extraction of DNA may provide the necessary information for determining species origin, as well as providing further evidentiary value in human identification. This presentation will impact the forensic community and/or humanity by discussing the value of adipocere as evidence and the limits associated with confirming its human origin in cases of homicide or human rights issues.

Adipocere, Species Origin, Characterization

G59 Maggot Development During Morgue Storage and the Effects on Estimating the Postmortem Interval

Timothy E. Huntington, MS, Leon G. Higley, PhD, and Frederick P. Baxendale, PhD, University of Nebraska, Department of Entomology, 202 Plant Industry Building, Lincoln, NE 68583*

The goal of this presentation is to present to the forensic sciences community research which demonstrates the potential for insect development during pre-autopsy morgue storage which may in turn affect estimates of postmortem intervals by forensic entomologists.

This presentation will impact the forensic community and/or humanity by demonstrating the need to consider insect development during morgue storage.

Forensic (or medicocriminal) entomology, the use of arthropods in legal investigations, is most frequently employed to estimate the post-mortem interval (PMI) of victims of violent crimes or suspicious deaths. The most commonly used method of PMI estimation employs temperature-dependent developmental rates of blow fly larvae (Diptera: Calliphoridae). Retrospective scene temperatures, those temperatures, which the insects experienced during development, are used in combination with known developmental rates of the species involved to estimate the age of the larvae, which often correspond closely with the time of death of the victim. When insect evidence is obtained during autopsy, forensic entomologists often need to make decisions regarding the effects of low temperature (-1°C to 4°C) storage of the body and associated insects when estimating the PMI. Some have argued that development ceases during refrigeration, while others suggest that maggot mass temperatures go unchanged.

During the course of a 2003 homicide investigation, temperatures experienced by the insects associated with the victim were recorded from the time the body was removed from the scene until autopsy using an Onset Hobo H8 data logger. During the intervening time the body was kept in a standard morgue cooler and the temperatures which were recorded showed that the insects were able to maintain high enough temperatures to be able to continue development despite the cold storage temperature. Consequently, subsequent experiments with decomposing pigs were conducted to confirm observations on maggot development in morgue coolers and to establish the magnitude of temperature differences.

Seven porcine cadavers were used: "small pigs" (approx. 11 kg) and "big pigs" (38 kg avg.). Pigs were placed in the field for up to 14 days to allow for insect colonization and maggot mass formation, which were defined as aggregations of feeding third stage blow fly larvae. Upon removal from the study site, each pig was wrapped in a clean sheet and placed in a medium-duty body bag, as is standard procedure for human remains. Thermocouples were attached to each replicate and temperatures inside and outside of body bags were measured during storage in a morgue cooler. Temperatures remained significantly higher ($P < .05$) inside of the body bags relative to the cooler, and remained at levels sufficient for maggot activity (feeding and development). Maggot development was slowed, but not enough to discount insect development between removal of the body from the scene and autopsy. If the assumption is made that no

insect development takes place during pre-autopsy refrigeration, potential error rates in PMI estimation of 8.6 – 12.8% occur. The potential for blow fly larvae to undergo significant development, including stadia transitions, while being stored in the morgue is a real possibility. Forensic entomologists must consider this continuing development during the course of an investigation involving samples collected at autopsy.

Forensic Entomology, Postmortem Interval, Autopsy

G60 An Unusual Postmortem Change in a Child Homicide—Leaching

Paul P.S. Chui, MBBS, DMJ, MBA, Health Sciences Authority, 11 Outram Road, Singapore, 289160, Singapore*

After attending this presentation, attendees will learn about an unusual form of decomposition change through leaching (loss of fluid from the body).

This presentation will impact the forensic community and/or humanity by creating awareness of such a finding and discussion of mechanism by which such a change occurred.

A child came to Singapore with her mother to study in a primary school. Her mother went back to China and left her on her own. The child went missing and sparked off a nationwide search. In the local hot and humid climate, bodies outdoors decompose quickly and early putrefaction begins within two to three days leading to early skeletonization in a week when the body is left in the open. Police investigations led to the arrest of a friend of the mother's whom the child was familiar with. After 3 weeks, the child's body was finally recovered, packed in nine plastic bags within a cardboard box in the undergrowth of a local hill-park. The case attracted much media sensation as well as outpouring of public sentiment.

At autopsy, the body was found to be much better preserved than expected. Bruises were well-defined and internal organs were well preserved. The condition of the body permitted better recovery of evidence of injury for determination of injuries resulting from allegations of sexual assault. It was also noted that after the autopsy was completed, signs of mummification became evident very quickly.

The presentation will discuss the cause of death, an unusual form of decomposition change, which has not been previously described in the literature, and the mechanism for such a postmortem change.

Decomposition, Child-Homicide, Leaching

G61 Comparison Study of Various Protocols to Release Maximal Amounts of Amplifiable DNA From Decomposed Soft Tissue Exposed to Different Environmental Conditions

Daniel E. Katz, MFS, Delaware Office of the Chief Medical Examiner, 200 South Adams Street, Wilmington, DE 19801; Timothy McMahon, PhD, Armed Forces DNA Identification Laboratory, 1413 Research Boulevard, Building #101, 2nd Floor, Rockville, MD 20850; Arthur Young, BS, National Medical Services, 3701 Welsh Road, Willow Grove, PA 19090; Rebecca A. Kennedy, Cedar Crest College, 100 College Drive, Allentown, PA 18104; Michelle Malley, MSFS, Armed Forces DNA Identification Laboratory, 1413 Research Boulevard, Building #101, 2nd Floor, Rockville, MD 20850; and Rebecca E. Wallman, BS, MS, Delaware Office of the Chief Medical Examiner, 200 South Adams Street, Wilmington, DE 19801*

After attending this presentation, attendees will understand what protocols are most suitable for certain decomposed tissue remains based on type of soft tissue and the environmental conditions from which it came.

This presentation will impact the forensic community and/or humanity by providing guidance to the pathologist and DNA analyst in

obtaining the maximum quantity and quality of DNA from decomposed soft tissue samples.

The protocols investigated were compared using five different tissue types (brain, heart, kidney, liver, lung) exposed to three different environmental conditions (fire, submersion in water, and bog/swamp).

This presentation will benefit the forensic community by providing guidance to the pathologist and DNA analyst in obtaining the maximum quantity and quality of DNA from decomposed soft tissue samples.

At autopsy, questions are often raised regarding what type of tissue to send off for DNA analysis when the body is in a state of decomposition. While the standard answer has routinely been deep muscle tissue, anecdotal evidence from the Delaware OCME DNA Unit and Armed Forces DNA Identification Laboratory (AFDIL) have suggested that this is not always the case and that in fact, organ tissue is often preferable. Historically, the research regarding decomposed tissue samples and associated DNA yields has been somewhat limited because the typical DNA laboratory does not have access to such samples. The fact that Delaware's forensic DNA laboratory is located at the Office of the Chief Medical Examiner and, therefore, has access to such samples, allowed for this much needed study to be performed. Decomposition is a cumulative consequence that naturally occurs over time once a body is no longer living. Decomposition originates from the activity of microorganisms/bacteria and internal biodegradative enzymes, including DNases that cause autolysis of the body. The concentration levels of bacteria and enzymes vary amongst organs during decomposition based on the organ's function and location within the body. This variation results in some organs degrading DNA at a faster rate than other organs. Additionally, decomposition can be altered by external stimuli associated with different environmental conditions because different conditions have different effects on factors such as temperature, moisture, pH, and partial pressure of O₂.

Four extraction protocols were investigated in a collaborative effort between Delaware OCME, AFDIL, and National Medical Services (NMS) to develop the most successful extraction procedure from various organ tissues exposed to different environmental conditions. The four different extraction protocols were an organic extraction using a non-ionic detergent based digestion buffer, an organic extraction using an ionic detergent based digestion buffer, a non-organic extraction using standard columns, and a non-organic extraction with paramagnetic beads. In addition, variations in reagent amount as well as variations in reagent amount plus sample amount were studied. The tissue sample extracts were then quantitated, amplified, and analyzed. Data and conclusions will be presented and discussed at the meeting.

DNA, Decomposition, Tissue

G62 Eagles Syndrome: Case of an Elongated and Ossified Stylohyoid Ligament in an Elderly Female

William C. Rodriguez III, PhD, Office of the Armed Forces Medical Examiner, 1413 Research Boulevard, Building 102, Rockville, MD 20850; and Jack M. Titus, MD, and David R. Fowler, MD, Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201*

After attending this presentation, attendees will be able to recognize cases involving Eagles Syndrome and have a basic understanding of the mechanisms, which may result in this bony anomaly, and associated symptoms.

This presentation will impact the forensic community and/or humanity by providing death investigators with information to ascertain the presence of the skeletal anomaly Eagle Syndrome and how it may or may not be involved in the death of the deceased.

The case presented is that of a 72-year-old Negroid Female whose badly decomposed and, partially skeletonized remains were recovered from her residence in Baltimore, Maryland. Local police were called to the res-

idence of the deceased, by neighbors who reported a foul smell. Investigation of the scene found the deceased lying in her bed clothed. Police found no evidence of forced entry into the residence, or other evidence indicative of foul play. Relatives of the deceased reported that she was last seen alive approximately one month prior, during the summer months. Examination of the body at the Office of the Chief Medical Examiner in Baltimore, Maryland, found it to be in an advanced state of decomposition with partial exposure of the skull and upper thoracic cavity. Inspection of the chest and abdominal cavity revealed the absence of the internal organs as a result of decomposition. No injuries or notable defects were observed on the remains with the exception of an extraordinarily long, and irregularly shaped left styloid process of the skull.

The extremely large and lengthy styloid process was recognized as "Eagle syndrome" which is described as the elongation of the styloid process and stylohyoid ligament calcification. Eagle syndrome has been named under several other synonyms including stylohyoid syndrome, hyoid syndrome, styloid elongation syndrome, styloid process syndrome, and carotid artery syndrome. The syndrome is well documented in the dental and otolaryngology literature however it has not been widely reported in radiological and general pathological literature. Multiple symptoms are associated with Eagle syndrome, which includes cough, dizziness, recurrent throat pain, voice alteration, dysphasia and /or facial pain, and sensation of a foreign body present in the throat. It has also been reported that that approximately 4% of the general population is thought to have elongation of the styloid process, and that only a small percentage of those individuals 4% to 10%, are thought to be symptomatic.

Anthropological studies have documented the prevalence of elongated styloid process, in particular the high frequency of occurrence among various Mongoloid populations. The average length of the styloid process in adult is approximately 2.5 cm, and in most individuals there is little variation in length between left and right process. Eagle syndrome has been documented as occurring unilaterally or bilaterally. Recognition of Eagle syndrome is rare among the forensic case population unless it is noted during detailed radiographic examination of lateral views of the head and neck, or during gross examination of skeletonized remains. Most cases are picked up by dentists or oral surgeons during routine panoramic radiographs, or by physical examination involving palpation of the elongated styloid process in the tonsillar fossa, of those individuals who are symptomatic.

In the case of the elderly Negroid female, the recognition of Eagle syndrome was made during removal mummified and decomposed tissues surrounding the skull. The left styloid process measured approximately 8 cm in length, and had an average circumference of approximately of approximately 2.5 cm. Not only did the left styloid process look extremely large, but it had the appearance as if three medial phalanges had been fused together. Examination of the right side of the skull found the right styloid process to be near non-existent, measuring less than 5 mm in length. Close inspection of the left carotid foramen revealed evidence of significant narrowing resulting from the enlargement of the base of the styloid process. A review of the deceased medical records obtained by investigators later in time, provided documentation of Eagle syndrome which had been noted during a dental panoramic exam in 2003 to access periodontal disease. According to the medical records, the elderly woman was asymptomatic at the time of the exam. Documentation of Eagle syndrome provided a means of positive identification of the deceased. In regards to cause and manner of death, the absence of trauma, and documented history of heart disease, and negative toxicology, the case was signed out as hypertensive atherosclerotic disease -natural.

The cause of the elongation of the styloid process is not well understood. Multiple theories have been forwarded including congenital elongation, growth of osseous tissue at the insertion of the stylohyoid ligament, and calcification of the stylohyoid ligament by an unknown process. Pathophysiological mechanisms of symptoms is also contested which include irritation of pharyngeal mucosa by post-tonsillectomy scarring or by direct compression, traumatic fracture of the styloid process resulting in

proliferation of granulation tissue, inflammatory or degenerative changes in the tendon, and impingement of the carotid vessels thus irritating the sympathetic nerves of the arterial sheath.

Eagle syndrome can be treated by surgical and no surgical intervention. No surgical treatment includes steroid injections and other anti-inflammatory medications. Surgical treatment involves removal of the elongated portion of the styloid process.

Anthropology, Eagles Syndrome, Skeletal Pathology

G63 Where is the Head? A Case of Homicidal Decapitation

Sabina Di Donato, MD, Carmela Fiore, MD, and Emanuela Turillazzi, MD, PhD, Department of Forensic Pathology, University of Foggia, Viale Luigi Pinto, n.1, Foggia, 71100, Italy*

The goal of this presentation is to present the case of a complete homicidal decapitation. Investigation of the scene where the body was discovered, autopsy findings, and DNA analysis are described. In particular, the primary importance of histological and immunohistochemical study to evaluate the vitality of wounds is underlined.

Only a few cases of homicidal decapitation are reported in the forensic literature. Sometimes the forensic pathologist faces the particular case, which may be difficult to distinguish between a vital or a postmortem beheading, especially when the circumstantial data is insufficient. This presentation will impact the forensic community and/or humanity by showing how histological and immunohistochemical investigations play a decisive role in forensic medicine.

Cases of complete decapitation have been sporadically reported in the forensic literature. In spite of high suicide rates all over the world, this particular mode of death is a relatively rare finding in violent suicidal deaths. Suicides by self decapitation have been reported, like those where individuals deliberately put their neck onto the track while a train is approaching or those where subjects use a ligature tied between the neck and a stationary object while attempting to drive a vehicle away, or even cases where individuals use a guillotine. Also unintentional decapitations are possible in suicidal cases, as after hangings. Accidental decapitation may also occur, for example, in cases of train pedestrian fatalities, industrial accidents, and unusual injuries during road accidents regarding either cars or motorcycles. Even more rare is the homicidal decapitation. This manner of death has been used for centuries for execution all over the world, and today is still used in some countries to carry out a death penalty. In recent years beheadings have also been registered in those homicides perpetrated by satanic sects, serial killers, or even in hostage killings. The forensic pathologist may meet some difficulties in evaluating cases of decapitation. A relevant problem, which the forensic pathologist has to face, may be the differentiation between a real decapitation and post-mortem mutilation of the body.

Here is presented the case of a 32-year-old Italian woman murdered by her Romanian partner and found dead under a bridge in a country of South Italy. The man himself, who in the meantime had escaped abroad, phoned the police indicating the place where he had left the lifeless body of the woman, and he also confessed to having strangled her. When the police officers arrived at the suggested place, they found the lifeless body of a woman, tidily dressed, with the upper regions of the body completely wrapped in her jacket. When they lifted it they discovered that the body was completely decapitated. Numerous locks and shards of the scalp were scattered all around the body, abundantly stained with dried blood. Some locks held her earrings and necklace. On the ground beneath the body there was only a small amount of blood. Notwithstanding the careful examination of the scene where the body was discovered and the adjacent countries, neither the severed head nor the injuring tool was found. Only a metal bar, 66 cm in length and 2 cm in diameter, was recovered near the body, showing on its surface some blood spots. The postmortem examination

showed that the neck was completely cut 3 centimeters above the jugular fossa; the wound margins were clear-cut, which led the examiner to assume that the head had been cut off with a sharp tool. The vertebral column was disconnected on the level of the seventh cervical-first dorsal vertebra. Numerous superficial linear wounds, of different length, and many excoriation zones with soft tissue bleeding underneath were present on the cutis adjacent to the neck lesion. No relevant injuries were detected in the remaining body parts. The lack of the severed head didn't allow analysis to injuries in this site. Massive blood aspiration, soft tissue hemorrhage surrounding the neck lesion and the pallor of inner organs as signs of bleeding out, were present. Histological investigation applying hematoxylin and eosin staining revealed massive hemorrhages in the cutaneous and subcutaneous tissues. Immunohistochemical studies were performed on the cutis specimens collected from the neck lesion for the determination of the vitality of the neck wound. The expression of Fibronectin, α_1 -antichimotrypsin, antitryptase, CD 31, and collagen type IV was analyzed. The positive results lead us to conclude that the neck lesion was vital, identifying homicidal decapitation as cause of death. Two months later a countryman discovered the skeletal remains of a human head on the back of his homestead, about 200 m from the place where the body was discovered. The skull showed no fractures. DNA analysis established that those skeletal remains belonged to the same woman.

Homicidal Decapitation, Vitality, Immunohistochemical Study

G64 Simple Tissue Preservation Methods That Result in Reliable DNA Analyses

Corinne L. Michaud, BS, and David R. Foran, PhD, Forensic Science Program, School of Criminal Justice, 560 Baker Hall, Michigan State University, East Lansing, MI 48824*

The goal of this presentation is to inform attendees of several simple tissue preservation methods that are conducive to obtaining a quality DNA sample. The procedures outlined can be applied to many situations, since the methods examined were developed for use in situations where time, materials, and facilities are limited.

This presentation will impact the forensic community and/or humanity by demonstrating providing valuable information on how to successfully preserve tissue samples for subsequent DNA analysis. The methods examined for this study required minimal materials, storage space, and temperature considerations. For these reasons, the results of this research can be useful to many factions of the forensic community, from mass disaster response teams, to conservation officers, to crime scene technicians. By having a simple tissue preservation method available in the field, samples can be preserved immediately, which increases the potential for a successful DNA analysis in the laboratory.

This presentation provides an evaluation of on-site tissue preservation methods, examining the success of each in yielding high quality DNA. The research examined factors such as availability and portability of materials, tissue storage life at room temperature, ease of use, ease of subsequent DNA extraction, and the quantity and quality of DNA obtained from preserved samples. Attendees will gain an understanding of the range of tissue preservation methods available, as well as the efficacy of each method in preserving DNA. The goal of this study was to develop a rapid, reliable method for storing tissue samples that can be easily employed in the field.

In the event of a mass disaster, where a large number of victims must be located and identified, it becomes difficult to process the site in a timely and orderly manner. Due to extensive injury or decomposition, many victims may only be identified through DNA analysis; therefore, obtaining viable tissue samples is of great importance. Amidst the rush of locating survivors, making anthropological identifications, and gathering other information about the victims of the disaster, tissue collection for subsequent DNA testing is often delayed. Likewise, tissue preservation of remains discovered in very remote areas can also be hindered. The goal of

this study was to examine protocols for on-site tissue preservation that would undergo later DNA analysis. Through development of simple, portable, and readily available methods for preserving tissues in the field, robust DNA results are more likely to be obtained.

Testing was conducted on tissues taken from recently killed pig carcasses that had been placed in a field during the summer; samples were collected regularly over a one-month period. Six preservation methods were evaluated: storage of tissue in ethanol, isopropanol, RNAlater (Ambion, Inc.), and silica desiccant, as well as hot air drying and freezer storage. Muscle, skin, and brain samples were collected in triplicate from each animal, and ca. 0.25 g placed in each storage medium. DNA extractions were performed after two weeks and after three months for each storage method. DNA quality and quantity were assessed using quantitative PCR of three species-specific single-copy nuclear genes. Results were analyzed in order to determine which preservation methods were the most successful in yielding a viable DNA sample after a period of storage.

Although DNA quantity and quality were the most significant factors in the evaluation, many other issues were addressed. Tissue type and level of decomposition, portability of materials, toxicity of the preservative, shelf life of preserved samples, and ease of subsequent DNA extraction were also factored into the analysis. By considering all of these interdependent variables, an optimized, reliable procedure for preserving tissue samples when adequate storage and DNA processing facilities are not readily available can be developed and implemented.

DNA Extraction, Mass Disaster, Tissue Preservation

G65 Quantification and Amplification of MtDNA From Chemically Treated Hair

Rayna L. Hebard, BS, and Bruce R. McCord, PhD, Florida International University, International Forensic Research Institute, 11200 SW 8th Street, Miami, FL 33199; and DeEtta K. Mills, PhD, Florida International University, Forensic DNA Profiling Facility, 11200 SW 8th Street, Miami, FL 33199*

After attending this presentation, attendees will learn of some of the techniques used to extract, quantify, and amplify mtDNA from telogen hair shafts that have been chemically treated. The attendee will also be aware of how these chemical treatments affect the quantity and quality of DNA amplified.

This presentation will impact the forensic community and/or humanity by providing knowledge of whether chemical processes cause degradation to DNA in hair shafts and to what extent that damage may be. This knowledge can help the forensic community to establish ways in which to overcome this difficulty so as to enhance mtDNA extraction and amplification from hair so that genetic profiles can be more sufficiently attainable, as hair forensics is becoming increasing significant in forensics and law.

Evidentiary collection at crime scenes and mass disaster typically include hair strands that later undergo DNA typing that can identify victims and assailants. This presentation will impact the forensic community and/or humanity by demonstrating the effect that various beautification processes have on the quantity and quality of amplifiable mtDNA extracted from hair shafts.

Millions of people, both men and women, subject their hair to different chemical treatments, such as bleaching, coloring, and perming. As such, it is reasonable to assume that hair recovered from a crime scene may have come from a person who utilizes one or more of these popular processes.

Nuclear DNA extraction is typically done on hair strands with growing root tissue. However telogen hairs, hair strands that are naturally shed, do not contain roots. The shafts of hair are not suitable for nuclear DNA due to the degradation that occurs because of the keratinization process. However, mitochondria are present in abundance in hair shaft. Therefore, mitochondrial DNA is typically extracted from the myriad of

mitochondria that are still present in cells. There have been several studies on the efficiency of mtDNA extraction from hair. While the consensus among these studies is that adequate amounts of mtDNA can be extracted from hair and other types of degraded samples, the quality and quantity of the genetic material recovered has not been directly addressed. Within some of these same studies, researchers agreed that damage to hair caused by fire or environmental conditions can significantly affect the amount of DNA extracted. However, there has not been any published research that examines how normal chemical conditioning of hair affect DNA recovery. With the advent of real time PCR, this DNA can be quantified at the picogram level and by examining the effect of amplicon size, the level of degradation can be evaluated.

In this research project, DNA was extracted from telogen hairs from volunteers who used chemical treatments and those who did not. Ten to fifteen hairs, approximately 2-3 cm long, were extracted from each volunteer using the published phenol chloroform separation method and purification of the DNA. The recovered DNA was quantified with real time PCR. Amplification was done using published mtDNA primers and primers specifically designed for this research. The primers utilized amplified conserved areas of the coding region of mtDNA, as these areas have the least amount of variability. Sequencing was done on selected samples with non-coding, control region primers for the hypervariable 1 and 2 regions. The resulting electropherograms were compared to the known reference samples to determine if adequate amount of quality mtDNA was amplified in order to yield a genetic profile.

The amount of mtDNA recovered varied from person to person, but preliminary results revealed that the quantity and quality of mtDNA recovered from individuals without chemical hair treatments exceeds that which comes from treated hair. However, those hairs subjected to treatments can undergo successful mtDNA amplification and sequencing which can then be used to obtain a genetic profile.

Mitochondrial DNA, Real Time PCR, Telogen Hair

G66 What is Forensic Informatics?

Gilbert E. Corrigan, MD, PhD, East Baton Rouge Coroner's Office, 4030 T.B. Herndon Road, Baton Rouge, LA 70808; and Sarah P. Corrigan, MS*, Reliagene Technologies, Inc., 5525 Mounes Street, Suite 101, New Orleans, LA 70123*

After attending this presentation, attendees will gain an understanding of the precise meaning of forensic informatics, knowledge of its many dimensions, its role in the progress of the forensic sciences, and the current challenges of the discipline.

This presentation will impact the forensic community and/or humanity by demystifying the boundaries and contents of the concept of forensic informatics and allow forensic scientists an understanding of the dimensions of forensic informatics.

Forensic Informatics is the systematic application of information and computer science and technology to forensic practice, research, development, and learning. It is a major discipline of the forensic sciences and encompasses many other scientific disciplines, which have reached maturity at a first generation level. As a major or covering discipline it has the responsibility for establishing performance standards and ideological goals for the component parts. The forensic responsibility entitles the application of sound computer engineering and scientific principles in an open, introspective, and universal manner applicable to the judicial system. The goal of utility in the solution of crimes, the search for the criminal act, the discovery of the criminal, and the analysis and retention of evidence is obvious; the boundaries of informatics extends into the civil affairs of government additionally and extends into property, taxation, public health, and inheritance; the detailed review of the fine details and codes of computers and computer software entitling long hours of study are not easily obtained, but required. Forensic informatics has practical utility in the solution of complex problems and the retention for review of the detailed data arising

from the solutions of the problems. Importantly, forensic informatics not only records the past in its archival function, and solves problems with its present capabilities, but necessarily provides a key to the future as vacancies in disciplinary content and theory are discovered and programs developed to encompass the missing details.

Current challenges in forensic informatics are immense and include the development of operational and proficiency standards for all forensic software and information systems including the error rate of the system, operator deficiency recording, output errors, logic error detection in software, security requirements for forensic systems, acceptable decay rates, the mathematics of the database, specialized forensic informational databases, data mining of criminal patterns, three dimensional forensic images, the schooling of new scientists in forensic informatics with the development of educational standards and professional employment opportunities, and dimensions in informatics. Guidance to the judiciary in forensic informatics seems of major operational import.

Involvement of the forensic sciences in these initial stages of the “computer revolution” is a major activity of the current membership of the American Academy of Forensic Sciences.

Formal models of forensic informatics and its dimensions are presented in relation to the other recognized disciplines of information and computer science, including medical informatics, pathology informatics, chemical informatics, public health informatics, digital evidence, and bioinformatics.

Forensic Informatics, Forensic Computer Science, Forensic Science Models

G67 Death in Custody: A Historical Analysis

Jami R. Grant, PhD, University of Baltimore, Forensic Studies, 1420 North Charles Street, Baltimore, MD 21201; Pamela E. Southall, MD*, and David R. Fowler, MD, Maryland State Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201; and Shauna R. Scott, University of Baltimore, Forensic Studies, 1420 N Charles Street, Baltimore, MD 21201*

After attending this presentation, attendees will understand the historical evolution of death in custody, be familiar with the various types of and the agencies that experience death in custody, and recognize the need for conceptual specification of death in custody.

This presentation will impact the forensic community and/or humanity by delineating the historical evolution (both qualitative and quantitative) of death in custody. Few analyses have examined death in custody from a historical perspective. An understanding of the history of death in custody may provide insight that would enhance the development of intervention protocols.

A substantial amount of controversy generally surrounds deaths that occur in custody, especially in this era of instant media coverage and communication. Often, allegations of brutality are launched and community relations are notably compromised. Exacerbating the situation, medical examiners are often presented with minimal physical findings at autopsy. To understand the phenomenon and minimize its occurrence, the medical-legal community has conducted a considerable amount of research. However, few analyses have examined death in custody from a historical perspective. The purpose of this research is to delineate the historical evolution (both qualitative and quantitative) of death in custody. An understanding of the history of death in custody may provide insight that would enhance the development of intervention protocols.

To identify the frequency and type of deaths in custody occurring over time, a retrospective, exploratory analysis was conducted. Using data from Maryland's Office of the Chief Medical Examiner, a sample of approximately 15,000 cases, dating from 1939 to 2004, was examined. Employing a general definition of the phenomenon, all deaths that occurred

in custody were included for analysis. Custodial agencies were operationalized to include law enforcement, correctional, psychiatric and emergency medical. Study variables include, incident location, decedent demographics, behavioral, medical and toxicological indicators, and the cause and manner of death.

Results indicate that death in custody is a multi-faceted phenomenon, subsuming a variety of qualitative types. All manners of death were identified; however natural deaths and suicides comprised the vast majority of cases. Similarly, while all custodial agencies experienced death in custody, most cases occurred in correctional and psychiatric facilities, respectively. Results also suggest that there have been substantive, qualitative changes in death in custody. For example, during the 1940s and 1950s a significant portion of deaths occurred during police transport. This finding reflects the unique role of law enforcement during those decades: prior to the establishment of a formalized emergency medical system, police transported the sick and injured to local hospitals. “Sudden unexpected death in custody,” especially those occurring after a violent struggle with police, emerged during the 1980s and 1990s, concomitant with widespread, recreational stimulant drug abuse.

Generally defined, death in custody is an “umbrella” concept that subsumes a variety of unrelated manners of death and that occurs in disparate custodial agencies. To understand deaths that occur in custody, further conceptual specification is required. Such specification would allow for better methodological precision and improve theoretical/conceptual uniformity.

Death in Custody, Sudden Death, Law Enforcement

G68 Simultaneous Diabetic Ketoacidosis and Neuroleptic Malignant Syndrome in a Patient on Olanzapine

Erik D. Christensen, Office of the Greenville County Medical Examiner, 890 West Faris Road, Suite 110, Greenville, SC 29605*

After attending this presentation, attendees will understand how neuroleptic malignant syndrome and diabetic ketoacidosis are well-described phenomena in conjunction with the use of antipsychotic medications. They can independently cause sudden death and this case report documents their first simultaneous occurrence in a patient taking olanzapine.

This presentation will impact the forensic community and/or humanity by documenting and reporting the first simultaneous occurrence of DKA and NMS in the same patient taking olanzapine.

Learning Objectives: To present to the forensic and psychiatric communities the historical, clinical and laboratory findings in a patient who was diagnosed postmortem as having concomitant diabetic ketoacidosis (DKA) and neuroleptic malignant syndrome (NMS) as the cause of his sudden death.

Case Report: A 32-year-old black male taking olanzapine for a long history of psychiatric illness (variably diagnosed as schizophrenia and schizotypal personality disorder) was found unresponsive. On arrival at the hospital he was afebrile with symptoms and lab findings consistent with DKA. During his stay in the emergency room he developed a progressive decline in mental and clinical status and subsequently developed clinical and laboratory findings of NMS, which were diagnosed postmortem. His condition continued to deteriorate and he expired despite aggressive resuscitative measures approximately 6 hours after being found unresponsive. Body temperature at the time of death was 108 degrees Fahrenheit.

Methods: Medical records and autopsy protocol with laboratory studies were reviewed for this patient and are presented. The medical literature was searched using the keywords *olanzapine, diabetic ketoacidosis, and neuroleptic malignant syndrome* for citations relating to NMS and DKA in the setting of neuroleptic use and relevant citations are reviewed and discussed.

Results: Poor glycemic control is a well-described phenomenon in the setting of neuroleptic use and new-onset DKA has been reported in patients taking many different neuroleptics, including olanzapine. Neuroleptic malignant syndrome, which was reported with much greater frequency on older neuroleptics, has also been reported to occur with newer antipsychotic agents, including olanzapine. A single case of the simultaneous occurrence of NMS and DKA was previously reported in a hospitalized patient on Thorazine. This case report is the first reported case of the simultaneous occurrence of both conditions in a patient taking olanzapine.

Conclusions: While both NMS and DKA are well-known occurrences in patients on neuroleptics and equally well-known causes of death in forensic practice, their simultaneous occurrence has not been previously reported in the era of newer antipsychotics.

Diabetic Ketoacidosis, Neuroleptic Malignant Syndrome, Olanzapine

G69 An Unusual Case of Child Head Injury by Coat Hanger

Biagio Solarino, MD, Sezione di Medicina Legale - Di.M.I.M.P.
Università degli Studi di Bari - Policlinico, Bari, 70125, Italy; Amy M.
Burrows-Beckham, MD, Office of the Chief Medical Examiner, 810
Barret Avenue, Louisville, KY 40204; and Kathy Recktenwald, RN,
Clinical Forensic Medicine, University of Louisville, 810 Barret Avenue,
Louisville, KY 40204*

After attending this presentation, attendees will understand the value of a multidisciplinary team, composed of clinical forensic medicine specialists, and law enforcement, in the management of injured children.

This presentation will impact the forensic community and/or humanity by demonstrating the value of crime scene reconstruction coupled with the evaluation of physical evidence in determining the factors in equivocal child abuse and neglect investigations.

The question of natural disease process versus accidental injury versus inflicted injury is the central issue involved in a clinical forensic investigation. The physical findings in the infant or child must be correlated with the history provided by the caretaker, as well as milestones achieved by the infant or child. Injuries affecting specific frontal locations, such as the forehead, nose, chin, palms, and knees, are often the result of accidental events secondary to children playing or falling. For these kinds of injuries, the examiner must have an open mind that the injury could be the result of an unintentional event, instead of a horrible episode of domestic violence.

The Clinical Forensic Medicine team in Louisville Kentucky is routinely consulted in a variety of cases of presumed child abuse and neglect. The authors present a case of a 2-year-old female who was brought to the Emergency Department with a large stainless steel hanger embedded in her left frontal region, between the orbit and the bridge of the nose. She was conscious, alert and moved all extremities. A lateral radiograph of the head demonstrated a foreign body embedded in the frontal region of the skull for approximately 2cm. A CT scan of the head demonstrated a U shaped body entering the frontal bone with probable fractures of the cribriform plate and crista galli, a small interhemispheric subdural hemorrhage and a left frontal subdural pneumocephalus. There was no injury to the left globe or nasolacrimal duct.

She was taken to the operating room where the curved part of the hanger was removed and the injured brain was derided. The ethmoid bone and shredded galea were repaired. After a five-day admission, she was discharged to home with a CPS approved caretaker. After examination by the Clinical Forensic Medicine team, coupled with home inspection and interviews by the local police, it was possible to reconstruct the child's injury.

The parent's, who are not married, were reported to be arguing. The child's mother stated that when she had her back turned to the father, he is reported to have thrown a hanger, with the intention of hitting the mother. Instead, the hanger hit his daughter, who was playing on the floor.

The investigators were uncertain whether the hanger was thrown from several feet across the room or if it was directly applied to the child's skull. The tool was a large caliber, stainless steel hanger measuring approximately 4 by 4 millimeters in thickness, while the U-Shaped angle measured approximately 3 centimeters. Experiments conducted by the police using a similar hanger and double-up pieces of cardboard demonstrated the U-shaped portion of the hanger penetrated the cardboard six inches deep or more, when thrown from the same distance the father stated he was from the child. The crime scene investigation pointed out that there were other hangers on the floor, manufactured of plastic material, and the one used was the only stainless steel, large caliber hanger present in the room.

The findings of the physical examination, the scene investigation with interviews of the parents, and the reconstruction of the incident support the conclusion that the injury to the child was inflicted.

In conclusion, diagnosing child abuse is a complicated issue. When the injuries are uncommon and involve specific parts of the body, such as the frontal plane, the examiner has to eliminate the potential of an accident. The combined efforts of a multidisciplinary team serve a primary role in the management of domestic violence and child abuse cases.

The present case represents a very unusual case of domestic violence, with child head injury using a stainless steel hanger. Unfortunately, this is only another incredible report about how abusers carry out their harmful acts.

Coat Hanger, Child Abuse, Pediatric Head Injury

G70 Adolescent Suicide Trends in the Third Largest County in the United States

Andrea J. Harrison, BSN, RN, Harris County Medical Examiners Office, 1885 Old Spanish Trail, Houston, TX 77054; Sharon M. Derrick, PhD, Harris County Public Health and Environmental Services, 2223 West Loop South, Houston, TX 77027; and Stacey A. Mitchell, MSN, RN, and Luis A. Sanchez, MD, Harris County Medical Examiners Office, 1885 Old Spanish Trail, Houston, TX 77054*

After attending this presentation, attendees will gain knowledge and awareness of the epidemiology of suicide and suicidal trends in Harris County, Texas, the third largest county in the United States.

This presentation will impact the forensic community and/or humanity by providing the audience with an understanding of the scope of the adolescent suicide problem and relevant risk characteristics of adolescents in a large urban setting.

Introduction: Harris County accounts for 17% of the adolescent population in Texas and has a growing adolescent suicide rate, ranking first in the number of youth suicides reported to the Texas Department of State Health Services. Harris County, the home of the fourth largest city in the nation (Houston), is also the third largest county with 3.6 million residents and an area of 1,778 square miles. The Houston/Harris County Child Fatality Review Team (HHCCFRT) recorded a rise in the suicide rate for children aged 10-17 from 2.1 per 100,000-population size in 1999 to 3.3 in 2003. The Harris County Medical Examiners Office (HCMEO) has identified adolescent suicide as a public health problem, and has conducted a collaborative retrospective study to identify those most at risk for suicidal injury. The results of this study can be used to drive prevention and intervention programs in Harris County.

Purpose: This collaborative study between the HCMEO, Harris County Public Health and Environmental Services, the Houston-area Suicide Prevention Coalition, and the HHCCFRT was implemented to identify and describe the number and relevant characteristics of adolescents who died by suicide from 2000 through 2005.

Results: The Harris County Medical Examiners Office classified the manner of death as suicide for 154 adolescents aged 10-19 years who were autopsied in the HCMEO from January 2000-July 2005. The majority of

these adolescents (79%) were male. White teens comprised the majority of these cases at 52% but a notable 34% were of Hispanic ethnicity, followed by 13% Black and only 1% Asian teens. Gunshot wounds were the cause of death in 55% of the cases. Hanging (34%) was the second leading cause of death. The remaining 10% of the cases were comprised of overdose deaths, blunt force injuries, and carbon monoxide poisonings. The most recent HHCCFRT data from 2002-2003 (N=34) cases demonstrates that older teens (15-17 years) most often used a gun as the mechanism of injury but the majority of younger (10-14 years) adolescents used hanging as a mechanism. A suicide note was recovered in only 21% of the reviewed cases. The most common precipitating factors to the injury were prior attempts/suicidal ideation (37%), argument with a parent or girlfriend/boyfriend (19%), documented depression or mental illness (17%), substance abuse (10%).

Implications: The results of this study are an important foundation for establishing prevention and intervention efforts in Houston and Harris County. The rising suicide rate among adolescents makes it imperative that the HCMEO and HCPHES mobilize to reduce risk in the adolescent population. The scope of the adolescent suicide problem and the characteristics of at risk adolescents will be disseminated to area agencies and community organizations for use in obtaining funding for effective, best practice suicide programming.

Adolescent Suicide, Epidemiology, Trends

G71 Intraspecific Competition in the Blowfly *Chrysomya megacephala* (Diptera: Calliphoridae) Reared at Different Densities

Sandra Pearson*, Criminal Justice Program, Chaminade University of Honolulu, 3140 Waialae Avenue, Honolulu, HI 96816-1578; and M. Lee Goff, PhD, Chaminade University of Honolulu, 3140 Waialae Avenue, Honolulu, HI 96816-1578

After attending this presentation, attendees will learn the effects of population densities on the rates of development and subsequent effects on the calculations of postmortem interval estimates using entomological techniques.

This presentation will impact the forensic community and/or humanity by demonstrating the calculation of an estimated minimum postmortem interval estimate using entomological techniques depends on correct developmental data for the species involved. Understanding the effects of density and intraspecies competition will serve to gradually increase the accuracy of these estimates.

Larvae of *Chrysomya megacephala* are major factors in the early decomposition of remains in tropical habitats. This study was undertaken to determine the effects of larval density on rate of development, larval and puparial mortality and adult size for this species under laboratory conditions. Larvae were collected from a pig (*Sus scrofa* L.) carcass in a mesophytic habitat on the Island of Oahu, Hawaii. Colonies were established with limited food resource (15 gms of beef liver) at densities of 1:1, 5:1, 10:1, 15:1, and 20:1. All colonies were reared at a constant temperature of 24°C, with light/dark cycles of 13/11 hours. In one section of the study, total lengths of 10 larvae per day were recorded to determine rate of development based on increase in size. In the other section of the study, colonies were left undisturbed for the duration of larval development. Larval mortality and puparial mortality and total mortality were recorded. Of the densities studied, the 10:1 ratio appeared most favorable for development. Larvae reared in these colonies were significantly larger than those in other colonies, reached the puparial stage 24 h ahead of other colonies and had the lowest larval mortality.

Entomology, Competition, Postmortem Interval Estimation

G72 Comparison of Early Decomposition Between Domestic Pig Carcasses Hanging and in Contact With the Ground on Oahu Island, Hawaii

Reupena Sheck*, and M. Lee Goff, PhD, Chaminade University of Honolulu, 3140 Waialae Avenue, Honolulu, HI 96816-1578

The goal of this presentation is to document the differences in early decompositional changes in carcasses that are in contact with the ground and hanging.

The patterns of decomposition observed in hangings are quite different from those observed for bodies in contact with the ground. This presentation will impact the forensic community and/or humanity by demonstrating how the accurate estimation of the postmortem interval is dependent on an understanding of these differences in insect invasions, temperature generation, and biomass removal.

This study was conducted on the campus of Chaminade University on the island of Oahu, Hawaii. Carcasses of two domestic pigs, *Sus scrofa* L., were used. One carcass was placed in contact with the ground on a wire mesh platform and the other suspended from a tree, not in contact with the ground. Carcasses were observed twice daily for a period of two weeks. Weights were recorded daily using a hand-held scale to determine rate of biomass removal. Internal temperatures were recorded using telemeter probes of the mouth, abdomen, and anus. Ambient temperatures were recorded at each visit. During the study period, both carcasses passed through four of the five stages of decomposition established by Goff (1993): Fresh, Bloated, Decay, and Post decay. The skeletal stage was not reached during this study. Differences in decomposition patterns were noted between the two carcasses. The hanging carcass demonstrated an initial rate of biomass loss greater than the carcass on the ground. After the first week, the rate became more equal. Internal mouth temperatures for the pig on the ground were uniformly higher than for the hanging carcasses, probably due to the mediating effect of the air. Abdominal temperatures, as well as anal temperatures were more similar, although still higher for the carcass on the ground.

Decomposition, Temperature, Biomass Removal

G73 A Preliminary and Pilot Study About Mitochondrial DNA Deletion in Sudden Infant Death Syndrome: An Endemic Study in Taiwan

Tsun-Ying Huang, MS*, Institute of Forensic Medicine, Ministry of Justice, 16, Lane 175, Tong-Hwa Street, Taipei, 106, Taiwan, Republic of China; Chia-Tung Shun, AP, National Taiwan University, College of Medicine, No. 1, Jen Ai Road Section 1, Taipei, 100, Taiwan, Republic of China; Jui-Ming Li, BS, Institute of Forensic Medicine, Ministry of Justice, 16, Lane 175, Tong-Hwa Street, Taipei, 106, Taiwan, Republic of China; and Shu-Huei Kao, PhD, Institute of Biomedical Technology, Taipei Medical University, 250, Wu-Xing Street, Taipei, 110, Taiwan, Republic of China

After attending this presentation, attendees will gain an understanding whether there is a relationship between mitochondrial DNA deletion and sudden infant death syndrome. This presentation will impact the forensic community and/or humanity by demonstrating how although some change of genetic markers in mitochondrial DNA may not be the real etiological cause of death in SIDS cases; it could be a contributing factor to an infant's death within a critical medical condition or situation.

Sudden infant death syndrome (SIDS) is a leading cause of post-neonatal infant mortality and a serious and challenging issue confronting the medical and legal professions. Many hypotheses have been proposed

and studied, however, a consensus on the causes of SIDS is still lacking. Although a number of coding region mitochondrial DNA (mtDNA) mutations involving SIDS have been reported, the role of mtDNA deletion or depletion in SIDS victims is still unknown. This study was designed to investigate whether mtDNA deletions exert any effect on the etiology of SIDS. Statistical data have shown that infants dying from SIDS score lower in activity tests and appear to be sleepier and less reactive than control subjects. These behavioral characteristics may have been the result of ATP depletion attributable to mutations or deletion in mtDNA.

Seven SIDS and 19 non-SIDS fatalities were included in this study to determine the relative amount of mtDNA copy number and the occurrence of mtDNA deletion in blood, skeletal muscle, and cardiac muscle specimens. Analytical approaches included real-time quantitative PCR, primer-shift PCR analysis and DNA sequencing. Breakpoints of the three types of mtDNA deletions (4977, 5335, and 7599 bp deletions) observed in the population were identified by sequencing methods.

Only one specimen (cardiac muscle) from a congenital heart malformation subject was found to have 4977 bp mtDNA deletion. Fisher's exact probability test and Spearman's correlation coefficient were applied to the analysis of the observed data on 5335 bp and 7599 bp mtDNA deletions and found no statistically significant difference on the occurrence frequencies of 5335 bp and 7599 bp mtDNA deletions between SIDS and non-SIDS victims. However, the observed data indicate: (a) for blood specimens, the occurrence frequencies of 5335 and 7599 bp mtDNA deletion observed in the SIDS were 4- and 2-fold, respectively, higher than the non-SIDS victims; (b) for skeletal muscle specimens, the occurrence frequencies of 5335 bp mtDNA deletion in SIDS victims was 1.8-fold of the non-SIDS victims. No significant correlation was observed on the relative amount of mtDNA copy number and the occurrence frequencies of mtDNA deletions between the SIDS and non-SIDS groups; however, the occurrence frequencies of 5335 bp and 7599 bp deletions and the relative amount of mtDNA copy number in the skeletal and cardiac muscle specimens from the SIDS group were much higher than that from the non-SIDS group.

The increase in mtDNA content in mtDNA deletion cases correlates with mitochondrial proliferation that might have been a compensatory mechanism of defective mitochondria. These defects in mtDNA may result in impaired production of ATP and bioenergetic crisis. mtDNA deletions in themselves do not cause SIDS but may cause energy deficiency or hypoxia in stressful situation during a vulnerable developmental stage. These preliminary results show that mitochondrial DNA deletion might predispose an infant to death in a critical medical situation.

Sudden Infant Death Syndrome, SIDS, Mitochondrial DNA Deletion

G74 Expression of Heat Shock Protein (hsp) 70 in Tissue of Different Human Organs After Burn Fatalities

Heike Klotzbach, MD, PhD*, and Johanna Preuss, MD, Institute for Legal Medicine, Stiftsplatz 12, Bonn, 53111, Germany; Eberhard Lignitz, MD, PhD, Institute for Legal Medicine, Kuhstrasse 30, Greifswald, 17489, Germany; and Burkhard Madea, MD, PhD, Institute for Legal Medicine, Stiftsplatz 12, Bonn, 53111, Germany

After attending this presentation, attendees will gain some understanding of the regulation of the early inflammatory response in humans, specifically regarding the initial response of heat shock proteins (hsp).

This presentation will impact the forensic community and/or humanity by providing some understanding of the regulation of the early inflammatory response in the human organism after burning fatalities, and contributing to the clinical understanding of the development of the serious septic or sepsis-like processes in these cases.

Heat shock proteins play an important role in the early response to various physical or chemical alterations and contribute to the up-regulation of numerous other stress-related mediators such as cytokines. To enhance

the knowledge regarding the complex regulation of these inflammatory mediators, 18 cases of burn fatalities were evaluated immunohistologically after autopsy. Paraffin embedded tissues were investigated for expression of hsp 70 on the protein level related to survival time and further complications, such as pneumonia or sepsis). A tendency toward the early expression of hsp 70 in respiratory epithelium, inflammatory cells, and in the epithelium of renal tubuli was revealed. In the cases with longer survival time, hsp was increasingly expressed in other organs.

Heat Shock Proteins, Burn Fatalities, Inflammatory Response

G75 “Coca-Cola Man”: Sudden Death in a Jailed Mentally Retarded Man After an Altercation Involving Police

Wendy M. Gunther, MD*, Department of Legal Medicine, Virginia Commonwealth University, Medical College of Virginia, 1101 East Marshall Street, Richmond, VA 23298-0568

After attending this presentation, attendees will have an increased index of suspicion for diabetes insipidus in unsuspected cases, familiarity with the four types of diabetes insipidus, and gain an understanding of the mechanism of diabetes insipidus in psychogenic polydipsia.

This presentation will impact the forensic community and/or humanity by providing recognition, postmortem diagnosis and classification of diabetes insipidus, and exploring the medical, legal, and media ramifications of death from dipsogenic diabetes insipidus in a mentally retarded inmate.

A 58-year-old inmate of an institution for the mentally retarded, who bore a number of additional psychiatric diagnoses including undifferentiated schizophrenia, violently assaulted a fellow resident, as well as two nursing home workers who attempted to restrain him. He was subdued with the assistance of police. He was arrested for the assault, and taken from the group home to jail, where he received a medical evaluation, and was noted to be in good health. He was jailed for ten days, during which he received ongoing medication with oxcarbazepine. At 0310 hours on the eleventh day, he was found dead on the floor of his cell.

At autopsy, the oral cavity was noted to be full of vomitus. When the vomitus was rinsed away, white foam appeared. An 11" x 8" fading green-brown bruise occupied most of the right side of the chest, extending across the midline. Two smaller, more recent-appearing bruises were noted on the chest and abdomen. Healing abrasions and almost completely faded bruises were noted on both sides of the upper back, and on the left side of the chest. Multiple bilateral rib fractures appeared, by their freshness, location, and lack of hemorrhage, to have been incurred during cardiopulmonary resuscitative efforts. Natural disease at gross autopsy was restricted to pulmonary emphysema, slight heart hypertrophy, and minor renal changes consistent with hypertension. There was no coronary artery disease, and no coronary thrombosis or pulmonary embolism. It was noted that the urine was root beer colored.

Vitreous electrolytes, analyzed the following day, exhibited a severe deviation from expected values. The BUN was 127 mg/dl, and the creatinine, 1.2 mg/dl. The sodium level was 180 mmol/L, and the chloride level, 150 mmol/L. Potassium, CO₂, and glucose showed a postmortem pattern.

Significant social history included moderate mental retardation, a variety of psychiatric diagnoses, and a noted addiction to soft drink products. At the hospital where he underwent occasional treatment for exacerbation of psychiatric symptoms, the inmate was referred to as “Coca-Cola man,” due to his nonstop consumption of as much of this soft drink as he could obtain. Psychiatric treatment notes had documented a recommendation that he be switched from caffeinated and sugar-containing soda to decaffeinated and diet soda, to control some of his behavior problems.

Death was due to marked hemoconcentration. Consultation with a local endocrinologist suggested the disorder diabetes insipidus.

Diabetes insipidus is a disorder of excessive urination, which may be traced to four types of inciting cause. One type, gestagenic, occurs only in association with pregnancy. Another, neurogenic, is due to a pituitary lesion, which may be acquired or congenital. A third, nephrogenic, may be congenital, but may also be drug-associated. Certain commonly administered drugs are well known to be associated with diabetes insipidus, including lithium, foscarnet, and clozapine, as well as many cytostatic drugs and antimicrobials. No record of administration of any of these drugs could be found. Trileptal is not associated with diabetes insipidus.

The fourth category of diabetes insipidus is dipsogenic, or caused by psychogenic polydipsia. In this disorder, excessive drinking of any fluid, over a prolonged period of time, causes excessive urination, which may become independent of normal feedback mechanisms. What was originally a psychological compulsion then becomes an organic condition. This disorder could be produced by a protracted indulgence in very large quantities of soft drinks.

As diabetes insipidus was not suspected at autopsy, the opportunity to examine the pituitary was lost. So it cannot be definitively stated whether this was in origin a neurogenic diabetes insipidus, or dipsogenic. A mentally retarded and schizophrenic person with a strong drive to imbibe as much soft drinks as possible may not have recognized water available in his cell as a source of rehydration. Nor could he likely explain his symptoms in terms, which would convey his condition to corrections personnel.

The postmortem diagnosis and classification of diabetes insipidus, and the ramifications of dipsogenic diabetes insipidus in a mentally retarded inmate, will be discussed, along with a consideration of how to deal with newspaper interest in the cause and manner of death.

Diabetes Insipidus, Psychogenic Polydipsia, In-Custody Deaths

G76 Estimating Time-of-Death by Body Temperature Analyses - A New Mathematical Strategy

Anthony T. Paganini, PhD, Michigan State University, A519 East Fee Hall, Division of Anatomy, Department of Radiology, East Lansing, MI 48824; and Thomas Adams, PhD, Michigan State University, Department of Physiology, 2240B Biophysical Sciences Building, East Lansing, MI 48824*

After attending this presentation, attendees will learn of a revised curve-fitting method of postmortem estimation of time-of-death by body temperature.

This presentation will impact the forensic community and/or humanity by presenting a new way of analyzing temperature data without making a priori assumptions regarding postmortem cooling rates or involving measurement of complex heat transfer parameters.

Accurate determination of a patient's time-of-death is routine in a hospital, nursing home, hospice, or other well-monitored setting. It is more difficult when death occurs alone at home, at an isolated hunting site, in a vehicle in a remote area, at a crime scene or at some other unsupervised site. Time-of-death (TOD) nonetheless provides crucial information required in many clinical and forensic investigations.

Numerous techniques have been used for the past fifty years to estimate TOD, including quantitative analysis of body tissue and fluids or qualitative staging of rigor mortis, postmortem lividity, putrefaction, or mummification of the decedent's remains (6). Sequential and precise measurements of the change in deep body temperature during the postmortem period have been also been employed by numerous investigators (3). The amount of postmortem temperature data collected is practically limited by the amount of time the medical examiner is allowed access to the body by police and the stability of the environment in which the body was found.

Previous investigators have developed equations (2, 4) or intricate finite-element computer simulations (5) to predict postmortem body

cooling from analyses of empirical data collected from the recently deceased and from tests on manikins. In most cases these analyses use three or fewer postmortem data points and impose, a priori, a multi-exponential curve fit. Data presented here are a first-order attempt using a thermodynamic model and non-linear regression with at least ten postmortem data points.

We are developing mathematical and curve-fitting techniques to construct an analytical model for which body cooling rate is deduced and from which time-of-death is estimated. Data for this model require measurements of internal body temperature during postmortem cooling at matched clock times, although not necessarily at regular intervals. Inexpensive, portable temperature monitoring and logging devices facilitate making these measures are currently available. An estimate of the person's body temperature at death and ambient temperature are also required, as are data about body weight and the quality of clothing or other body covering. Data about the person's physical activity immediately prior to death, medication history, environmental conditions, and exposure circumstances provide useful ancillary, but not essential information. The analyses are equally valid for people whose bodies are found in water or in air. Data analyses are made either with programmable calculators or with standard spread sheet programs. Time-of-death is reported as a range depending on the strength of the correlation coefficient revealed by curve-fitting data for the fall in multiple postmortem body temperatures. Interpretations of preliminary analyses for people whose postmortem cooling rate is recorded in a monitored environment as well as bodies found at crime scenes are providing important information to amend the mathematical model, increase its validity and improve the precision for estimating time-of-death by temperature.

G77 Photography of Abuse: Is There a Best Method?

Lynette Landon-Chellemi, PO Box 523, 59-076 Pupukea Road, Haleiwa, HI 96712; and Wilson T. Sullivan III, MPA, Chaminade University of Honolulu, Forensic Science Department, 3140 Waialae Avenue, Honolulu, HI 96816*

The goal of this presentation is to discuss methods of recording photographically injuries both visible and invisible to the unaided eye.

This presentation will impact the forensic community and/or humanity by demonstrating how there is a need for further research in the development of a standardized protocol for photographing injuries that are not immediately visualized. A standardized protocol for documentation of old injury patterns would be useful in elder and child abuse cases.

Historically, documentation of bruising of abuse victims was accomplished using standard film cameras, recording injuries visible to the naked eye. Presently documentation of abuse has advanced to include both infrared and ultraviolet imagery using both fast black and white film and high-speed infrared film. This research will attempt to establish standardized parameters and techniques for optimum light source and filtration together with an ideal photographic protocol for documentation of fresh and older patterned injuries. When developing a photographic protocol for this research, specific attention is given to techniques appearing in past literature concerning UV and IR imaging of bite marks and bruising. Several methods appearing in the literature on the documentation of pattern injuries are explored and tested. In the research the authors are attempting to determine if any one of those selected protocols explored proves more beneficial than the others, ultimately determining a "best method" if one exists. Since this is a time of technological shift from film to digital media, both types of cameras are examined for compatibility, advantages, and limitations. Photographs were taken for six weeks at two-day intervals using numerous filters with both digital and film capabilities in an attempt to discern if the digital camera is comparable for this type of forensic work. Different alternate light sources are tested during ultraviolet and infrared digital photography. The digital camera has advantages and limitations when working with infrared and ultraviolet photography.

Abuse, Ultraviolet, Infrared

G78 The Cave Man in the 21st Century: Chronicle of an Announced Tragedy: Preventive Measures and Repeating Risk

Cristoforo Pomara, MD, Stefano D'Errico, MD, Sabina Di Donato, MD, Marianna Di Padua, MD, Francesco M. Morreale, MD, Irene Riezzo, MD, and Margherita Neri, MD, Institute of Forensic Pathology, Foggia University, V.le Luigi Pinto 1, Foggia, 71100, Italy; and Giulio Zizzo, MD, Radiology Department Ospedali Riuniti, V.le Luigi Pinto 1, Foggia, 71100, Italy*

The goal of this presentation is to describe a building collapse with fatalities in a typical southern Italian location. According to the common definition of a disaster, the authors want to warn against complacency and the underestimation of the appropriateness of certain environmental structures, and underscore the social impact of such a dramatic event, that upon review was truly a predictable tragedy.

This presentation will impact the forensic community and/or humanity by demonstrating how in spite of the tragic event, people continue to live in "the caves", in a condition of absolute poverty and in contrast of every safety rule. In all likelihood, just a few precaution safety measures could have avoided the dramatic event and could prevent a repeat collapse of these types of buildings.

A human made, level I disaster, occurred with the collapse of a building in the historical center of Foggia, a city in the South of Italy. In this location, some families still live in small, tall, and rundown buildings of usually two floors tall. These buildings were built in the very early 20th century, usually above a basement, three meters underground, named by the town citizens as "the caves." These basements are composed of one or two rooms and a small bathroom, with poor lighting and even worse ventilation, with just a small window for an entrance, accessed by stairs. The "caves" were generally intended for storage, but have often hosted people, usually elderly.

During the night of the 20th of November 2004, at 3:15 a.m., a one-floor building over one a "cave" suddenly collapsed. Of the 14 people living in the building at the time, six were found alive within a few hours after the collapse and were immediately transported to the local hospital. Eight bodies were recovered lifeless from the building, and none were missing.

Soon after the disaster, the local legal authority engaged a team composed of forensic pathologists and engineers to investigate the causes of death and the cause of the building collapse. Engineers' investigations discovered that the cause of the collapse was due to the accidental explosion of a domestic gas cylinder originating from a cave. Scene investigations also revealed irregular gas network connections in spite of standard safety rules.

Three working areas were designated early as medicolegal facilities. A provisional holding area was used to receive dead bodies coming from site of collapse prior to examination allowing family members to be able to identify the victim. A second private viewing area was designated to let family members and friends see photographs of the bodies, objects pertaining to the deceased (jewelry, clothing or identifiable objects found), and finally, the bodies themselves, carried from the holding area. An examination space was designated to conduct a more detailed exterior assessment of the body to provide a careful external examination, and to perform a complete autopsy in order to determine the cause of death, documenting injuries sustained, and determining activities at the time of the collapse.

According to the most advanced disaster preparation guidelines, injuries were coded using the Abbreviated Injury Severity Scale and its derivative Injury Severity Score (ISS). The AIS is a comprehensive taxonomy of individual injuries, which denoted body region, type of anatomic structure and severity of injury. The severity index ranged from 0 (no injury) to 6 (unsurvivable injury), the ISS estimated overall body trauma and was calculated by squaring and summing the single highest AIS score in each of the three most severely injured body regions. An ISS score of 76 was indicative of unsurvivable injury. A complete radiographic study of each body was performed.

Cranio-facial injuries, cranial fractures, sternum and multiple ribs fractures, upper and lower limbs fractures, spine fractures and vertebral subluxations, multiple diaphragm lacerations, multiple lacerations and contusion of internal organs (heart, lungs, kidneys, liver and spleen) were detected in a first group of persons represented from the "cave man" group, and the family living immediately above the cave. The second group was composed of three persons in the family living very close to the source of explosion, and presented with only mild to no traumatic injury. People belonging to the first group died quickly, due to the severity of their injuries. The people in the second group died from mechanical asphyxia.

Cave, Building Collapse, Injury Severity Score

G79 Hypothermia-Related Deaths in Cook County, Illinois From November 2000 to February 2005

Wendy A. Lavezzi, MD, Clare H. Cunliffe, MD, and Edmund R. Donoghue, MD, Cook County Medical Examiner's Office, 2121 West Harrison Street, Chicago, IL 60612*

The goal of this presentation is to identify common risk factors in cases of hypothermia death.

This presentation will impact the forensic community and/or humanity by presenting epidemiological data on deaths due to hypothermia in Cook County, Illinois, including scene investigation, medical history, and toxicological studies.

Deaths due to hypothermia are a significant public health problem in cold climates in the United States. Cook County, IL, has a population of over 5 million people, and includes Chicago and 120 surrounding suburbs. Winter month temperatures in Illinois can reach below zero degrees Fahrenheit.

Risk factors for death during cold exposure are infancy, advanced age (? 65 years), inadequate shelter, mental impairment, substance abuse, and serious medical conditions. Cold-related deaths have received increased media attention in recent years in Cook County, Illinois, aimed in part at increasing public awareness of the deaths in order to decrease future deaths from hypothermia.

This retrospective study examined 129 cases of death related to hypothermia from the Office of the Medical Examiner in Cook County from November 2000 through February 2005, encompassing five winter seasons. Data examined included age, race and sex of decedents, location found, concomitant medical conditions, outdoor low temperature when found, the presence of paradoxical undressing, the presence of alcohol or other drugs, body temperature (when available), whether or not the decedent was homeless, and any other significant conditions that contributed to the death.

Three of the 129 cases were excluded from the study. In these three cases, the decedent suffered low body temperature due to sepsis during prolonged hospitalization; none were exposed to low ambient temperatures.

Of the 126 remaining cases, 34 occurred in the winter season of 2000-01, 27 from 2001-02, 26 from 2002-03, 20 from 2003-04, and 19 from 2004-05. Eighty-three cases (66%) listed hypothermia or cold exposure as the primary cause of death, and the remaining cases listed hypothermia or cold exposure as a contributing factor to death. Manners of death were listed as accident in 123 cases, suicide in two cases, and undetermined in one case, which involved an unwitnessed drowning with a high post-mortem alcohol level. The group consisted of 65 white males (52%), 26 white females (21%), 25 black males (20%), 9 black females (7%), and 1 Asian male (<1%). In 52 cases (41%), the decedent was of advanced age. In 31 cases (25%), the decedent was homeless. The youngest decedent was 28 years old. Forty-seven cases (37%) involved alcohol, and 12 cases (10%) involved other drugs. In 67 cases (53%), the decedent had one or more significant medical problems, including heart disease, diabetes mellitus, dementia, or a seizure disorder. In six cases (5%), a significant injury contributed to the death. Body temperature was taken in 26 cases (21%), and ranged from less than 70°F to 94.5°F. Outdoor temperatures ranged from -9°F to 49°F on the evening before or day found. Mean temperatures per winter season were: 11°F in 2000-01, 21°F in 2001-02, 18°F in 2002-03, 20°F in 2003-04, and 25°F in 2004-05. Seventy three decedents (58%) were found outdoors, 39 (31%) were found indoors with no heat, 13 (10%) were found in various unheated areas, including motor vehicles, porches, and garages, and one was dropped off at the hospital with a high alcohol level and low body temperature by an unknown person. Paradoxical undressing, often cited as a hallmark of hypothermia, was observed in only seven cases (6%).

Autopsy findings in cases of death due to hypothermia may be absent or nonspecific. Correlation with the circumstances surrounding the death and the medical and social history of the subject is important in order to determine the correct cause of death.

Deaths due to hypothermia have decreased in Cook County over the last five years, possibly due to milder winters, but still remain a significant public health problem. The forensic community needs to be aware of the possibility of a cold-related contribution to cause of death.

Forensic Sciences, Hypothermia, Cold Exposure

G80 Analysis of Gene Expression Patterns to Identify Tissue and Body Fluid Specific mRNA Species Using Real Time PCR Assays

Rixun Fang, PhD, Christine Shulse, BS, Pius Brzoska, PhD, and Manohar R. Furtado, PhD*, Applied Biosystems, 850 Lincoln Center Dr., Foster City, CA 94404; and Chitra F. Manohar, PhD, Lawrence Livermore National Laboratory, 7000 East Ave, Livermore, CA 94550

After attending this presentation, attendees will learn that it is possible to test for specific mRNAs that serve as markers for tissue and body fluid identification. Attendees will be informed about pre-amplification protocols that can be employed to simultaneously amplify and detect multiple targets when the amount of material available is limiting.

This presentation will impact the forensic community and/or humanity by teaching the forensic community that gene expression profiles and specific mRNA can be used to identify a large number of body parts and fluids. Attendees will understand that this can be done with very small amounts of material and therefore useful in forensic investigations when sample available is limiting.

This presentation proposes that by screening microarray and SAGE based tissue expression data in multiple databases, both public and internal, it is possible to identify candidate mRNA species that would show tissue specific expression. Additionally, this would select highly expressed messages for use in forensic applications.

In this presentation, and from the screening of human tissue and body fluids, it is possible to define specific markers that can be used for identification. Identification of tissue parts and body fluids is frequently required in crime scene investigations. Conventional methods are often labor-intensive, not confirmatory and employ a diverse range of methodologies. Several forensic laboratories have pioneered the selection of specific protein or mRNA markers for identification of tissues and body fluids. Some laboratories have designed and tested real-time PCR based assays that target the detection of mRNAs encoded by > 20,000 genes in identified in the human genome. The presented methods employ proprietary methods to design assays specific to a target transcript avoiding amplification of related gene transcripts. It also allowed for the development of methods for pre-amplification of hundreds of targets present in a single sample preserving relative quantification information. These methods will be useful when dealing with heterogeneous mixtures.

In this study, the performance of assays targeting saliva specific markers was analyzed such as Statherin, Histatin Ge3, PRB1, PRB2, PRB3, menstrual blood markers like metalloproteinases, and semen specific markers like protamines. These were targets selected based on literature reports. A total of 480 genes from the analysis of microarray data from specific tissues were selected. TData was used to further limit this to a set of 130 genes. Next, RNA from 48 tissues was selected and converted to cDNA by reverse transcription reaction using random primers and commercially available kits. Initially, cDNA was tested using six endogenous controls (GAPDH, GUSB, 18S RNA and ACTB, HPRT and B2M) for normalization purposes. Next, assays targeting transcripts from these genes were used to analyze gene expression relative to endogenous controls across 48 tissues. HeatMap views of gene expression patterns were constructed to identify tissue specific patterns. Based on these expression profiles researchers identified ~20 genes, not reported in the literature as specific markers that are highly expressed in single tissues. Additionally, the authors identified some genes that were expressed in a few (2 to 3) tissues and could still serve as specific markers when used in specific combinations. This research also shows that pre-amplification protocols can be used to detect mRNA when the sample is limiting. Detection of saliva specific markers was demonstrated following pre-amplification.

This study demonstrates that, in many instances, single markers can be defined as specific for a given tissue. These include SEMG1, SEMG2, KLK3, and PRB4/HGNC that have not been reported in the literature as tissue specific markers. In some instances, using a combination of targets will provide identification. This research has shown that if the sample is limiting, pre-amplification of a large set of mRNAs in a single reaction is useful for identification.

Tissue Identification, Gene Expression, Real Time PCR

G81 Caveat Emptor: A Series of Deaths Related to Subcutaneous Silicone Injections in Transgender Males

Morna L. Gonsoulin, MD, Ashraf Mozayani, PhD, Terry Danielson, PhD, and Luis A Sanchez, MD, Harris County Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054-2098*

After attending this presentation, attendees will learn about the history and consequences of the practice of illicit subcutaneous silicone injections as well as the circumstances, findings and available methods of testing in cases involving subcutaneous silicone injections in the forensic setting.

This presentation will impact the forensic community and/or humanity by alerting forensic professionals about the circumstances, findings and available methods of testing in cases involving subcutaneous silicone injections, as well as informing or increasing awareness of a largely underground, poorly documented and dangerous trend which may be gaining popularity despite the potentially significant morbid and lethal risks.

This presentation highlights a series of three deaths resulting from subcutaneous silicone injections obtained illegally outside the medical setting for cosmetic purposes. The goal of this presentation is to review the circumstances and findings of the cases in light of the general characteristics of the typically utilized silicone-containing compounds, their legal and illegal uses, the methods and procedures used during the injections and the complications of subcutaneous silicone injection as a result of inadvertent systemic siloxane exposure. The presentation will impact the forensic community and/or humanity by alerting forensic professionals about the circumstances, findings and available methods of testing in cases involving subcutaneous silicone injections, as well as informing or increasing awareness of a largely underground, poorly documented and dangerous trend which may be gaining popularity despite the potentially significant morbid and lethal risks.

In Houston, Texas, a series of three deaths within a three-month period in 2003 due to pulmonary silicosis were caused by the illegal practice of subcutaneous silicone injection for cosmetic enhancement of the hips and breasts among local transgender males. Gas chromatographic / mass spectrometric analysis indicated the presence of the cyclic siloxanes, hexamethylcyclotrisiloxane, octamethylcyclotetrasiloxane and decamethylcyclpentasiloxane, in fluids collected from hip and breast injection sites, and from syringes and containers of silicones seized during the investigations. These low molecular weight siloxanes may serve as chemical marker substances in the confirmation of siloxane injection.

This unusual cause of death occurred with alarming frequency over a relatively brief period of time due to a sporadic surge in popularity of the practice of subcutaneous siloxane injection among the local transgender community. The injections had been administered by two independently operating agents with no medical training who were soliciting in bars frequented by transgender males. Although ethnically diverse, the three individuals involved were young transgender males who had received several injections on at least one previous occasion, and their clinical presentations, hospital courses and autopsy findings were similar.

Siloxanes are used in preparations such as hair conditioners, skin care products, and industrial lubricants. While their topical use is common, siloxanes are not intended for internal use. Subcutaneous injection of siloxanes (silicone) presents the risk of direct introduction of silicone compounds into the systemic circulation, where they can accumulate in the pulmonary macrophages (pulmonary silicosis), resulting in hemorrhage, respiratory failure and death. Because of the potentially lethal consequence, injection of siloxanes into subcutaneous tissue is illegal in the United States.

Isolated case reports documenting the sequelae of subcutaneous silicone injections have been presented since the 1970's due to occasional trends, particularly in the transgender subculture, where silicone injections

are sought as an easily accessible, non-surgical cosmetic procedure to create a more feminine appearance. The materials required for the injections are easily obtained through cosmetic supply companies (non-medical grade silicone), medical supply companies (medical grade syringe lubricants) or any supplier of viscous liquid silicone (including brake fluid), and the injections are commonly administered in large veterinary syringes. The substance is injected into the dermis and superficial subcutaneous fat, usually in a circular cluster of small punctures. There it accumulates as filler, distending the tissue with the objective of creating a more tense and rounded outline.

Multiple injections are usually required for contour enhancement of the hips and breasts, in particular. Most individuals require additional applications to maintain the enhanced appearance over time. No estimates are available for the number of individuals who have received such injections or for the effects of cumulative silicone exposure of a given individual who has been repeatedly injected. The clandestine nature of the practice and the pervasive social stigma associated with transgender community does not lend itself to obtaining accurate statistics. The persistence of the practice worldwide and anecdotal evidence would suggest, however, that the reported incidence of lethal sequelae of subcutaneous silicone injection is infrequent relative to the number of individuals who have received these injections.

Increased public awareness appears to have had a significant effect in the Houston area. After the local authorities began publicizing the dangers of subcutaneous silicone injections and prosecuting the individuals administering them, no more deaths related to the practice have been reported as of July 2005.

Pulmonary Silicosis, Silicone, Transgender

G82 Anogenital Anatomy: Colposcopy to Study the Appearance and Changes During the Postmortem Interval

Sharon R. Crowley, MN, RN, Forensic Clinical Nurse Specialist, 122 Emeline Avenue, Santa Cruz, CA 95060*

After attending this presentation, attendees will be able to describe the nature and appearance of the anogenital tissues at various postmortem intervals, and evaluate the efficacy of a previously described system of mobile technology for postmortem genital examinations.

This presentation will impact the forensic community and/or humanity by increasing the diagnostic acumen of forensic examiners, increasing the reliability and consistency of both examination techniques and documentation via improved methodology and an efficacious taxonomy, and to eventually allowing reliable comparisons between the anogenital findings in cases of sexual homicide to normative postmortem controls.

Text/background: A paucity of data exists on the "normal" appearance of the anogenital anatomy during the postmortem interval. Data from scrutiny and photodocumentation of these tissues are lacking. Detailed observations of the usual anatomic sites, which have been carefully studied in living sexual assault victims, are lacking in postmortem examples. Thus, the interpretation of genital findings in the deceased remains a vital and timely issue. In addition, techniques that are often employed by some examiners for the medical-legal examination of living sexual assault victims, such as the application of the nuclear stain, toluidine blue dye, have been insufficiently studied in the postmortem arena.

In order to accomplish this, postmortem cases presenting from various causes of death from natural, accidental, suicide, and homicide of non-sexual etiology, are the focus of the present discussion. These cases will comprise a normative, core group of baseline cases, and the first study of "normal" postmortem genital anatomy.

Materials and methods: Baseline examples of genital anatomy during the postmortem interval are selected based upon availability and accessibility. Female cases from the representative causes of death will be clinically evaluated, using the mobile system of technology described by Crowley (JFS, 2004).¹ Colposcopic technique includes inspection at 7.5X, 15X, or both, and photodocumentation via a 35 mm SLR camera. Colposcopy was chosen because it is a well-established technique for the evaluation of sexual assault in both child and adult victims. The range of postmortem interval categories are \leq 24 hours (fresh), 48-72 hours, 73-96 hours, \geq 5 days, and unknown. Reproductive status is categorized as pre-pubertal, reproductive age, perimenopausal, and post-menopausal. Some of the variables to be collected and entered into a sexual homicide database include age, ethnicity, race, date/time body found, date/time of examination, cause of death, past medical history, reproductive status, exam techniques, and any known past medical history, especially gynecological history. Routine inspection, visualization, and photodocumentation of the salient anatomic sites includes the labia majora, peri-clitoral area, peri-urethral area, labia minora, hymen, vagina, cervix, perineum, fossa navicularis, posterior fourchette, anus, and rectum. Any concomitant gynecological condition or benign lesions are noted. Examination techniques such as labial separation, labial traction, use of vaginal speculum, anoscopy, and the degree of fixed magnification (e.g., 7.5X, 15X), used for colposcopic documentation, are also documented.

Discussion: The use of colposcopy is well documented in living sexual assault victims. The obvious benefits of improved visualization via magnification, photodocumentation, and the capacity for peer review are equally germane to the postmortem arena. For living victims, the sexual assault examiner is asked to determine if the physical examination is consistent or inconsistent with the history as provided by the victim. In the deceased, the lack of a history provided by the victim makes the need for reliability and accuracy paramount. The examiner must consider the usual benign factors, gynecological conditions, and concomitant anatomical variations often present in antemortem cases. The examiner of postmortem cases must have the ability to reliably and accurately assess the nature and appearance of anogenital tissues at all major anatomic sites and at various postmortem intervals, while the normal changes of decomposition are simultaneously superimposed on the anatomy. For both the normative, baseline controls and suspected cases of sexual homicide, it is vital that meticulous attention be paid to technique, taxonomy, and interpretation.

The most compelling argument for the use of the colposcope in this setting is the dearth of information available on what is “normal.” In the field of postmortem sexual anatomy, the pivotal issue is that “normal” has never been defined. Postmortem changes that are routinely recognized by the adroit examiner of deceased victims such as mucosal autolysis, skin slippage, dilatation, and lividity, may be mistaken for traumatic changes by even experienced sexual assault examiners, whose prior experience is limited to antemortem cases. The entire perineum including the vagina and rectum can be removed en bloc for dissection and microscopic evaluation by the Forensic Pathologist. However, there may be valuable information gleaned by initial *in situ* examination via colposcopy of the anogenital site.

A high degree of photographic detail and careful analysis of related sample variables will also facilitate categorization of anogenital findings, using an expanded version of the taxonomy described by Crowley and Peterson (AAFS, Dallas, 2004). Continued study may require that the initial taxonomy be modified or expanded.

Colposcopy, Forensic Nurse, Postmortem Anogenital Anatomy

G83 Unusual Suicide With Chain Saw: A Case Report

Gilles Tournel, MD*, Fabrice Dedouit, MD, Anne Becart-Robert, DDS, PhD, Nicolas Pety, MD, Valéry Hedouin, MD, PhD, and Didier Gosset, MD, PhD, Institut de Médecine Légale, Faculté de Médecine, 1, place de Verdun, Lille, 59000, France

After attending this presentation, attendees will learn the importance of a careful observation of the crime scene. This presentation will impact the forensic community and/or humanity by reminding the forensic pathologist that a careful analysis of both the death scene and the findings of the autopsy are essential in reaching the proper conclusion, especially in a very unusual death.

Only a few cases of suicide with a chain saw exist. The reports of these cases are never a complex system, such as presented in this case report. It is interesting to know of this type of a complex system.

A case of suicide using a chain saw is presented. A female suffering from schizophrenia committed suicide through an ingenious system leading to the sectioning of her upper cervical spine involving the cervical spinal cord. The findings of the resulting investigation are described and the mechanism of suicides with the use of a chainsaw is reviewed. The damages to organs and soft tissues are compared to the kinds of chainsaw used.

Case report: Death scene findings: A 32-year-old woman was found dead in her living room. The decedent was a female Asian engineer. She had a significant medical psychiatric past history. She was found dead by her family members ten days after her death. The head was disposed under a material of pulleys and bags filled with water bottles. The material and the appliance are detailed. The chain saw had a 1600 W, 220-240 V, 50-60 Hz engine, and weighted 3 kg. The length was 50 cm including the projecting rim of the chain. The chain’s number of revolutions was 9.5 per second. The stains of blood were located on the floor without splatter on the walls.

Postmortem findings: The wound extended 7 cm deep into the neck and involved the posterior muscles and the posterior side of the third and fourth cervical vertebrae. A complete section of the spinal cord was noted. A study of the cervical bones was performed to compare with the characteristics of the chain saw and to explain all wounds on the cervical vertebrae. Bone injuries were compatible with the use of a large width cutting edge instrument consistent with known chain saw toolmarks. The edges were regular and no hesitation lesion was seen. Because the cadaver was decomposed, the dentist performed identification. The dental comparison of antemortem records and postmortem examination confirmed her identity.

Discussion: Suicides or suicidal attempts with saws are rare but sensational, due to the unusual patterns of injury and sometimes, because of the unusual death scene. Cases reports exist in the forensic literature of this type of suicide. The injuries are almost always inflicted to the head or the neck but in some cases are visceral, and tissue damage occurs because of strong vibrations of the chain saw applied directly to the body. In this case, the young female had significant psychiatric disorders, conceived, and completed a complicate scene of suicide. The wounds inflicted to the neck confirmed the observation of other authors.

The findings of the scene of death were very important to understand the mechanism of the additional material used in the complex manner. No typical hesitation injuries were observed in the neck, and these findings were compatible with the situation of the cadaver and the device. The dry bone study confirmed the regular and sharp limits of the bones injuries.

The authors discuss and compare this case to the literature in consideration of her occupation with possible cultural influences to explain the invention of this efficient and complex deadly system.

Initial autopsy study of the decomposed body were not sufficient enough to characterize the chain saw wounds on her neck, and therefore a dry bone analysis was important and subsequently performed in order to objectively study and understand the mechanism and the physiopathology of her death.

The presentation will illustrate the complex deadly system at her scene of death, in addition to the autopsy findings and the dry bone study.

Chain Saw, Suicide, Complex System

G84 Suicidal Hangings: A Growing Trend in Northern Virginia

Erin E. Falconer, MFS, Danielle L. McLeod, MFS, and Todd M. Luckasevic, DO, Northern Virginia Office of the Chief Medical Examiner, 9797 Braddock Road, Suite 100, Fairfax, VA 22032*

The goal of this presentation is to identify trends present in suicidal hangings.

This presentation will impact the forensic community and/or humanity by providing information on the findings associated with suicidal hangings with emphasis on injuries to the neck, ligature device, presence of a suicide note, and history of mental illness/life event.

Introduction: Suicide is one of the most important public health issues in the United States. Suicide represents the eleventh leading cause of death in the United States. Nearly 20% of the caseload of the Northern Virginia Office of the Chief Medical Examiner in Fairfax, Virginia is suicide. Suicide rates for this country have been relatively stable over the past decade with approximately 10 suicide deaths per 100,000 people. The most common method of suicide in the United States for both males and females is the use of a firearm. The second most common method of suicide in males is hanging.

Materials and Methods: This is a retrospective review of case files from the Northern Virginia Office of the Chief Medical Examiner in Fairfax, Virginia. Inclusionary data for this pilot study included the cause of death from hanging and the manner of death ruled as suicide for autopsy cases from the years 2003 thru 2004. A total of 320 suicides were autopsied during this 2-year study period. Of these 320 suicides, 52 (16%) were due to hanging. These 52 cases were reviewed for the following information: injuries to the neck, type of ligature device, history of mental illness/life event, the presence of alcohol, the presence of a suicide note, past ideations/attempts, and the demographics of the decedent. The case information was organized into a spreadsheet and the data was analyzed for any trends or interesting correlations.

Results: Between the years 2003 and 2004, the Northern Virginia Office of the Chief Medical Examiner in Fairfax, Virginia investigated 320 suicides. Of these 320 suicides, 52 (16%) were reported as hanging. Males comprised 81% (42), while females accounted for the remaining 19% (10) of all suicidal hangings. Caucasians accounted for 71% (37) of the cases, followed by Asians with 13% (7). Case files will be reviewed for a history of depression, mental illness, or life event, and past suicide attempt(s). The presence of alcohol and/or suicide note will be reported.

Conclusions: This pilot study emphasized the increasing rate of suicidal hangings in Northern Virginia. Sixteen percent of the suicides in Northern Virginia are due to hanging. In 2003, 20 individuals died as the result of suicidal hanging. The rate of suicidal hangings increased to a total of 32 cases in the year 2004 and the rate continued to rise in the first half of 2005. This study will report the correlation between type of ligature used and pathologic trauma to the neck. A history of depression, mental illness, or life event, and/or past suicide attempt(s) by the decedent will be analyzed, and the presence of alcohol and/or suicide note will be reported.

Suicide, Hanging, Ligature

G85 DNA Done Right: Manner of Death Determination, Based on Evidence Obtained From a Belt at a Complex Scene Involving a Decomposed Body

Leah L. Bush, MD, and Wendy M. Gunther, MD, Office of the Chief Medical Examiner, Tidewater District, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510*

After attending this presentation, attendees will learn the appropriate methods for handling of evidence at complex scenes; learn about the use of DNA analysis in cases where manner of death is not evident from forensic autopsy; and learn about the value of DNA analysis in cases involving decomposed bodies.

This presentation will impact the forensic community and/or humanity by demonstrating an expanding awareness of the usefulness of DNA touch preparation analysis on items such as ligatures in scenes involving decomposed bodies, and to influence the collection and handling of relevant items at scenes where the manner of death appears undetermined.

A 32-year-old man was found dead in his home at Christmastime, in a state of moderately advanced decomposition. His car was missing from his home, as it had been towed away after an interstate crash days before. The house was secure. There was no suicide note.

The body at the scene was face down on the bedroom floor, lying prone between the bed and a chest of drawers. He was clad only in bikini underwear and socks, with some clothes draped over his lower legs. He was partially suspended by a belt ligature tied to a drawer handle. The belt was looped twice around his neck, with one end of the belt pulled through the buckle behind his left ear. The opposite end of the belt was tied in an overhand knot to the brass drawer handle.

Significant social history included homosexuality, with a history of depression over his sexual orientation, as reported by his mother. There was no known history of autoerotic asphyxia. He had no significant medical history.

Scene investigation included leaving the ligature intact for the autopsy pathologist, bagging the hands in clean paper bags, leaving the clothing undisturbed to allow for a physical evidence recovery kit at autopsy, and wrapping the body in a clean white sheet prior to placing it in a body bag.

Autopsy procedures included photography and close examination of the hands, clipping of the fingernails for DNA analysis, physical evidence recovery kit for sexual activity, removal of the ligature by division away from the buckle, and complete visceral dissection. Autopsy findings included a $\frac{1}{2}$ " horizontal ligature furrow with no upslope, and the following pertinent negative findings of no internal neck injuries, significant blunt force or penetrating injuries, obvious sexual assault, or significant natural disease processes, as far as could be determined in his state of moderate decomposition. Postmortem toxicology on bloody purge fluid yielded only an ethanol level of 0.07 mg%, which most likely was due to postmortem bacterial production.

The cause of death was evident at autopsy as ligature strangulation. The manner of death was not evident. Manners considered included either suicide, supported by the Christmas season and history of depression, accident due to autoerotic asphyxia, or homicide by another person. Autopsy findings could not distinguish between these manners of death. After discussion of this fact with the responsible detective, he elected to submit the entire ligature for touch DNA determination of the tied belt ligature end.

This case report will discuss how the DNA evidence from the end of the belt determined the manner and solved the case, with examination of relevant procedures by forensic personnel at scene and forensic pathologists at autopsy, with recommendations for future similar scene investigations.

Touch Preparation DNA, Scene Investigation, Manner of Death Determination

G86 Guns That Fire Themselves: Report of Three Cases

Elizabeth L. Kinnison, MD, and Wendy M. Gunther, MD, Department of Legal Medicine, Virginia Commonwealth University, Medical College of Virginia, 1101 E Marshall Street, Richmond, VA 23298-0568*

After attending this presentation, attendees will be able to recognize characteristics of unusual gunshot wound fatalities that suggest accidental misfires from dropped guns.

This presentation will impact the forensic community and/or humanity by increasing awareness of gunshot wound fatalities due to accidental misfires from dropped guns, recognition of typical characteristics of such cases, and familiarity with pistol types which are associated with accidental misfires on dropping.

Most unwitnessed deaths due to distant gunshot wounds are homicides. Most unwitnessed deaths due to close range or hard contact gunshot wounds are suicides. This report discusses three cases in which dropped guns accidentally took the lives of their owners, in unwitnessed events which had to be pieced together by the examining forensic pathologist.

A 21-year-old man was found shot beside his bed, with a .44 caliber revolver beside him. He had no history of depression, strife, worries, or alcohol abuse. A trail of blood led to the body from the bathroom, where there was a narrow gouge in the vinyl flooring. There was no soot or stippling on the skin or the clothing. The bullet entered the right chest, and was retrieved from the soft tissues of the back, with an angled trajectory through all three lobes of the right lung. The gouge in the vinyl flooring was measured, and was found to correspond in size to the hammer of the gun.

A 30-year-old man was found shot inside a locked residence. Earlier in the evening, a 911 call had been placed from the residence, but operators only heard an open line, with no talking. Attempts to re-establish communication were unsuccessful. Police arrived to find him dead inside of his locked residence. A .22 caliber pistol, knife, and telephone were nearby. Autopsy revealed a single gunshot wound to the back of the right inner thigh. While it had minimal marginal darkening, there was no soot or stippling. Microscopic examination of the entrance showed evidence of a close range of fire. Firearms examination of the clothing revealed a range of fire estimated between 6 and 30 inches. The bullet had a steep upward trajectory through the body, ending its course anterior to the lumbar vertebrae, after lethal iliac artery injury. The gun had marks on the hammer spur, and could be fired without pulling the trigger if the hammer was resting against the firing pin.

A 22-year-old man, seated on his front porch with his friend, and in possession of an illegal gun, observed a police cruiser passing by. Deciding to return the gun to his house, he left the porch, and entered the small anteroom that led to his apartment, with an additional exit in the form of stairs to the upstairs apartment. His friend heard a single gunshot report. He was found dead in front of his door, with his keys beside him in a location that suggested he had been about to unlock the door. Autopsy showed a single distant (more than 3 feet) gunshot wound of the abdomen, with visceral injuries on a sharply rising course, exiting the back of his neck. Significant history included his involvement in an altercation five days previously, resulting in a fracture in his hand, which had been cast at a local emergency room. It proved to be important that the gun was a Takharov pistol.

Characteristics of these cases include unusual, sharply angled trajectories, no evidence of hard contact gunshot wounds in victims with any documented suicidal ideation, frequent absence of powder soot or stippling, and guns which may be known to misfire on impact. Case discussions highlight these and other useful findings in similar cases.

Gunshot Wounds, Dropped Guns, Accidental Misfires

G87 Handgun to the Head: Suicide Trends in Northern Virginia

Erin E. Falconer, MFS, Danielle L. McLeod, MFS, and Todd M. Luckasevic, DO, Northern Virginia Office of the Chief Medical Examiner, 9797 Braddock Road, Suite 100, Fairfax, VA 22032*

The goal of this presentation is to identify trends present in suicidal handgun wounds to the head.

This presentation will impact the forensic community and/or humanity by providing information on the findings associated with suicidal handgun wounds to the head. Emphasis will be focused on the location and characteristics of the wound, caliber of the handgun, result of gunshot residue (GSR) testing, presence of a suicide note, and history of mental illness/life event.

Introduction: Suicide is one of the most important public health issues in the United States. Suicide represents the eleventh leading cause of death in the United States. Nearly 20% of the cases autopsied at the Northern Virginia Office of the Chief Medical Examiner in Fairfax, Virginia are ruled suicide. Suicide rates for this country have been relatively stable over the past decade with approximately 10 suicide deaths per 100,000 people. The most common method of suicide in the United States is with the use of a firearm.

Materials and Methods: This is a retrospective review of case files from the Northern Virginia Office of the Chief Medical Examiner in Fairfax, Virginia. Inclusionary data for this pilot study included the cause of death as gunshot wound to the head with a handgun as the lethal device and the manner of death ruled as suicide for autopsy cases from the years 2003 thru 2004. A total of 320 suicides were autopsied during this 2-year study period. Of these 320 suicides, 113 (35%) were due to handgun wounds to the head. These 113 cases were reviewed for the following information: the location and characteristics of gunshot wounds, the caliber of weapon, underlying psychiatric illness/depression or life event, GSR results, the presence of alcohol, the presence of a suicide note or past ideations/attempts, and the demographics of the decedent. The case information was organized into a spread sheet and the data was analyzed for any trends or interesting correlations.

Results: Between the years 2003 and 2004, the Northern Virginia Office of the Chief Medical Examiner investigated 320 suicides. Of these 320 suicides, 113 (35%) were caused by shooting oneself in the head with a handgun. Males comprised 87% (98), while females accounted for the remaining 13% (15). Caucasians accounted for 87% of the cases. Ethanol (>.02% by weight by volume) was present in postmortem toxicology samples in a total of 39 (35%) of the decedents. Gunshot residue (GSR) was present in 61 (87%) out of 70 samples analyzed. Suicide notes were present in 44 (40%) cases. The location of the gunshot wound in decreasing frequency: right temple 61 (55%), intraoral 34 (31%), left temple 8 (7%), forehead 6 (5%), submandibular 4 (4%), and back of head 1 (<1%). Two cases involved multiple gunshot wounds to the head. A .38 caliber revolver was the most common handgun used. There was no known or documented history of depression, psychiatric illness or life event in only 7 (6%) of the decedents. Finally, 6 (5%) of the decedents had a previously documented suicide attempt.

Conclusions: This pilot study emphasized the role handguns play in suicide. In the years 2003 thru 2004, thirty-five percent of the suicides in Northern Virginia were due to handgun wounds to the head with the right temple region being the most common location. Interestingly, when handedness of the decedent was known and reported, only 3 gunshot wounds of entry were located on the opposite side of the decedent's dominant hand. Also, 2 cases involved multiple (2) gunshot wounds to the head. There was only 1 case where the gunshot wound of entry was located to the back of the head. GSR was positive in 87% and a suicide note was present in 40% of the cases. Finally, only 7% of the cases had no known/reported history of depression, psychiatric illness, or life event.

Handgun, Head, Suicide

G88 Evaluation of Less-Lethal Impact Munitions

Richard T. Wyant, MS, Washington State Patrol, 2203 Airport Way South, Suite 250, Seattle, WA 98134; and Chris Myers, and Tom Burns, Seattle Police Department, 810 Virginia Street, Seattle, WA 98101*

After attending this presentation, attendees will learn about the types of less-lethal munition systems available, their relative safety, and forensic considerations.

This presentation will impact the forensic community and/or humanity by providing a further understanding of the relative safety of less-lethal impact munitions that will assist forensics examiners in the study, analysis, and reconstruction of events associated with serious injury or death.

Law Enforcement is embracing the concept of less-lethal weaponry. Less lethal options are demonstrating their worth in reducing injury to officers, and often suspects while providing alternatives to higher force options. The function of these less lethal devices is often misunderstood. When a negative outcome or even death results from the use of a less lethal option, the forensic examiner is often called upon to analyze and reconstruct the incident.

There is currently a lack of independent data useful for the comparison of the various products available on the market. Police agencies and trainers often have to rely on manufacturer and marketing data to select munitions and tools for their agencies.

A study was devised in an attempt to develop a more objective standard.

Six basic types of specialty impact munitions were examined for this initial study; 12 Gauge bean bags, 40mm bean bags, 40mm sponge type rounds, 37mm ARWEN/Sage variants, FN303, and Pepperball products. The ordinance was fired at 10 feet and 35 feet into bare and covered ballistic gelatin. The ballistic gelatin was used to observe energy distribution and relative injury potential across the spectrum of munitions tested.

Less-Lethal, Impact, Bean Bag

G89 A First Time for Everything: Homicide Involving the Brenneke® Super Sabot Shotgun Slug

Amy Tharp, MD, and Donald Jason, MD, JD, Department of Pathology, Wake Forest University Baptist Medical Center, Medical Center Boulevard, Winston-Salem, NC 27157*

After attending this presentation, attendees will understand the physical characteristics of the Brenneke SuperSabot shotgun slug as it pertains to the practice of forensic pathology, including injury patterns and scene interpretation.

This presentation will impact the forensic community and/or humanity by introducing a novel projectile, including its physical characteristics that have never before been reported in a homicide.

Sabot shotgun slugs are not a new projectile, but the Brenneke® Super Sabot shotgun slug has never been reported in a homicide. The authors present the case of a 28-year-old man killed with multiple gunshot wounds during an alleged “drive-by” shooting. At autopsy, a 496.2 grain slightly deformed projectile with a base diameter of 5/8” (1.7 cm) was found within the decedent’s clothing. Six distinct bullet tracks were identified. An entrance of the anterior right thigh was 3/4 x 5/8” and ovoid, having only passed through the decedent’s jeans. This bullet track passed through the soft tissue of the right thigh, exiting out the medial aspect and partially transecting the right greater saphenous vein, re-entering the medial left thigh and re-exiting out the posterior left upper thigh. With the exception of an irregular entrance on the sole of the left foot, which passed through the decedent’s shoe, all other entrances were less than 1/2” in greatest dimension. Investigating officers recovered an additional pro-

jectile of the same type, which had undergone more extensive deformation after striking and penetrating the tailgate of a truck. Further investigation identified the projectiles as the Brenneke® Super Sabot shotgun slugs.

Homicide, Shotgun, Sabot

G90 Death by a Radio-Controlled Helicopter

Ana E. Lopez, MD, Harris County Medical Examiner, 1885 Old Spanish Trail, Houston, TX 77054; Luis A. Sanchez, MD, Harris County Medical Examiner, 1885 Old Spanish Trail, Houston, TX 77054*

The goal of this presentation is to report an unusual death by a radio-controlled helicopter and to discuss the safety issues concerning model helicopters with the forensic community.

This presentation will impact the forensic community and/or humanity by providing awareness of the dangers in the recreational use of radio-controlled aviation models by detailing the types of fatal injuries that can occur with these aircrafts.

This case involves a 41- year- old, white male who was instructing another man on how to operate a radio-controlled helicopter. The scene was a five-acre, grassy field, designated as an area for model aeronautic recreation. The instructor had five years of experience with flying radio-controlled helicopters, whereas his student had just three months of experience. The instructor demonstrated to his student how to hover the helicopter, an older model PHI Tornado radio-controlled, and then passed the controls to his student. The student hovered the helicopter for a few minutes and was attempting to land it, when it tilted and came straight toward them. The student immediately threw himself to the ground and was uninjured; however, the instructor was struck by the helicopter blades and died at the scene.

At autopsy, the decedent had a 7 by 2 inch, gaping chop wound of the right side of the neck and chin. The wound injured the sternocleidomastoid muscle, the strap muscles, the salivary gland, and the right jugular vein. The mandible was exposed, and the transverse processes of the 4th and 5th cervical vertebrae were palpable through the wound. He also had linear-patterned abrasions on the right shoulder, right upper arm, and right upper back. Toxicology for alcohol was negative. An examination of the helicopter showed fragmentation of the main rotor blades with blood spatter on the frame and on the rotor blades. The rotor blades were made of fiberglass composite and had an interior metal wire along the leading edge. The helicopter measured approximately four feet in length, two feet in height, and had a main rotor span of five feet.

Based on the circumstances of death and type of injury in this case, there seems to be an inherent danger in the design and rotational movement of the blades used in radio-controlled helicopters. The use of radio-controlled aircraft is restricted to designated flying fields, and a license is not required to operate them. Flying fields also have designated areas for the aircraft operator with separate areas for spectators.

The recreational use of model helicopters and airplanes is guided by the Academy of Model Aeronautics, which publishes an official national model aircraft safety code. In addition, there are many local model airplane clubs that establish their own rules and regulations about the use of radio-controlled aircraft, based on the official national code. Local clubs usually have their own posted safety guidelines at their flying fields. The Academy of Model Aeronautics recommends that qualified instructors should teach beginners how to use these aircrafts, as was the case in this situation. Instructors, however, are not required for beginners, who can instruct themselves on their use. It is also recommended that people learn to fly airplanes before flying helicopters.

This case illustrates an unfortunate accident where the recreational use of a radio-controlled helicopter by an inexperienced person led to the death of another individual.

Accidental Death, Radio-Controlled Helicopter, Safety Issues

G91 A Fatality Due to Atomoxetine - The First Known Case

Kathryn Haden-Pinneri, MD, 21827 Hollow Field Lane, Katy, TX 77450*

The goal of this presentation is to alert the forensic community to the first known fatality associated with Atomoxetine, a non-stimulant medication utilized for the treatment of Attention Deficit Hyperactivity Disorder (ADHD).

This presentation will impact the forensic community and/or humanity by alerting forensic scientists and the medical community of the potentially deadly combination of atomoxetine and paroxetine and to inform them of the first known fatality due to atomoxetine.

Attention Deficit Hyperactivity Disorder (ADHD) is a diagnosed condition in which a child exhibits symptoms of inattention, hyperactivity, and impulsivity. As these behaviors are part of most developing children at one time or another, the diagnosis requires that such behavior be demonstrated to a degree that is inappropriate for the person's age. Diagnostic guidelines exist to aid clinicians in determining if the symptoms displayed represent ADHD or are just part of normal development. This diagnosis can be quite controversial amongst physicians, with some feeling that the diagnosis is fictitious and over-used and others who feel that it is a medically justified disorder and have documented improvement in children with treatment. This paper serves to provide basic information on ADHD, without bias towards one view or the other.

Treatment for ADHD includes behavioral therapy and medication management. Stimulants are typically the class of medication used for ADHD treatment, and include amphetamine, methylphenidate, and dextroamphetamine. These medications work on the dopamine receptor. Atomoxetine is the first and only non-stimulant medication approved by the FDA for the treatment of ADHD in children, adolescents, and adults. Atomoxetine works differently than the stimulants in that it is a norepinephrine reuptake inhibitor. Evidence to date indicates that over 70 percent of children with ADHD who take Atomoxetine manifest significant improvement in their symptoms. Over 2 million prescriptions have been filled since the FDA approved it in 2002. It is not a controlled substance like the amphetamines; therefore refills may be phoned in, rather than having to pick up a refill prescription in person.

Because it is a relatively new medication, postmortem blood and tissue levels are not well established. Prior to this case, there have been no known fatalities associated with the use of the medication. There have been deaths due to other factors (motor vehicle accidents, hanging, etc) where atomoxetine has been identified, but in low levels. One factor in the lack of information regarding postmortem levels is that not all the toxicology laboratories have the atomoxetine standard to run the samples against.

This case is a 17-year-old male with a history of ADHD, depression and one prior suicide attempt with medications. His social history is negative for alcohol and tobacco use, but positive for prior recreational marijuana use. At the time of his death, he had not used marijuana in approximately one year. He presented to a psychiatrist in January 2004 with complaints of difficulty sleeping, indifference towards school, anxiety and depressed mood. At the time of that presentation, he was taking escitalopram, quetiapine, and lamotrigene. He was diagnosed with Bipolar disorder and ADHD and the plan was to begin a trial of atomoxetine and taper and stop the lamotrigene. He was also placed on zolpidem, 10 mg each evening. Several days later, he attempted suicide with the zolpidem after relationship problems. He had not shown any suicidal ideations prior to that. His atomoxetine dose was increased from 40 mg to 80 mg three weeks from the initial visit and he was instructed to stop the lamotrigene. Three weeks later, the depression was reportedly improved, his aggression reduced and overall affect seemed "more flexible." At the time of his death, his medications consisted of atomoxetine, paroxetine, quetiapine, lamotrigene, and zolpidem. He was found face down in a wooded area near his home, approximately 22 hours after last being seen alive.

Autopsy findings reveal a well-developed male with pulmonary edema and no evidence of natural disease. There were a few abrasions on the face that were consistent with the terminal fall and body position. Toxicologic examination of postmortem blood from the inferior vena cava, just above the iliac bifurcation, revealed an atomoxetine level of 16 mg/L and a small amount of paroxetine (less than 0.10 mg/L). The liver level of atomoxetine was 240 mg/kg and paroxetine of <5 mg/kg. These levels of atomoxetine are markedly higher than any levels published to date.

The presence of both the atomoxetine and paroxetine complicates the toxicologic picture, as they are both metabolized by the cytochrome P450 2D6 enzyme. It has been documented that co-administration of other 2D6 inhibitors with atomoxetine can increase serum atomoxetine levels three- to fourfold. In one documented non-fatal overdose of atomoxetine alone, the patient developed seizures and a prolonged QTc, but was medically managed and survived. Because of the co-administration of these two medications and the lack of suicidal ideations or suicide notes, the manner of death is undetermined. The cause of death is atomoxetine and paroxetine poisoning.

Atomoxetine, Attention Deficit Hyperactivity Disorder, Paroxetine

G92 Methadone Deaths are on the Increase in Maryland (1998-2004)

Mary G. Ripple, MD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD 21201; Cheryl Rinehart*, Margaret Hsu, Erin Artigiani, and Eric Wish, PhD, Center for Drug Abuse Research, 4321 Hartwick Road, Suite 501, College Park, MD 20740; and David R. Fowler, MD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD 21201*

After attending this presentation, attendees will learn the details about the increase in methadone related deaths in Maryland and they will realize the importance of cooperation between state drug research groups and the medical examiner's office.

This presentation will impact the forensic community and/or humanity by assisting the forensic community in recognizing local and national trends in methadone related deaths and the need to be diligent in checking the information that is given to research groups that share data with medical examiner's offices. They will also realize that the cooperative effort between these groups can result in the elucidation of causes for drug trends that can be of public benefit.

This presentation will review the increase in Methadone deaths in the State of Maryland from 1998-2004 and discuss the cooperative efforts of the Office of the Chief Medical Examiner (OCME) and the Maryland Drug Early Warning System (DEWS) at University of Maryland's Center for Substance Abuse Research (CESAR).

Methadone is a narcotic used in the treatment of addictive disorders and chronic pain. Nationally, methadone associated deaths increased rapidly in 2001 and 2002. A national report in 2004 showed that the recent increases in methadone use and associated mortality were related to its use as an analgesic and not to its use in opioid treatment programs. Maryland also showed a significant increase in methadone related deaths from 1998 to 2004.

The computerized files of the OCME were searched for all cases positive for methadone by toxicology. These cases were then individually reviewed to determine the number of cases in which methadone intoxication was the only cause of death and those in which methadone contributed to the cause of death in multiple drug intoxications. The concentration of methadone, cause and manner of death, and demographics were reviewed for those cases.

There was over an eight-fold increase in the number of methadone intoxication deaths from 1998 to 2004 with a peak 11-fold increase in 2003. There was over a five-fold increase in the total number of drug deaths

involving methadone, including methadone only and multiple drug deaths involving methadone. During this time the commercial distribution of methadone increased at a much faster rate than the admissions to methadone treatment programs. Most decedents were white males in their late 30s and early 40s. Over the years, the residents of Baltimore City made up a decreasing proportion of the deaths. Medical conditions contributing to death made up a small percentage of cases. In all cases, the most commonly found drugs were antidepressants. The most common other lethal drug was morphine in the multiple drug intoxication deaths. The most common manner of death was undetermined. There was no significant difference in the concentration of methadone in the methadone only vs. multiple drug intoxication deaths. The source of the methadone was unknown in over 50% of the cases and this spurned a pilot study in which OCME pathologists collected additional information from September 2004 to May 2005 about each decedent's source of methadone using a specially prepared CESAR form. Even using the form, information about the source of methadone was still unknown for over 50% of the cases.

Our review has findings similar to the national review, in that decedents most likely obtained methadone through means other than treatment programs. The increase in methadone deaths appears to be due to the procurement of legally prescribed drug for chronic pain or illegal diversion and street sales and does not appear to be from its use in treatment programs. Investigators were not asking specific enough questions about the source of methadone. If additional information was requested on the CESAR form and that information was not needed for the determination of cause and manner of death, then additional calls were not made and the information was listed as unknown. In the future, OCME investigators will be paid by funds from CESAR to collect the desired information for these forms. Thus, in the near future, an answer to this question should be available. Also, as a result of this review, the OCME adopted a new protocol in which each separate drug is now listed in the cause of death and this will facilitate statistical research.

Methadone, Research, Maryland

G93 Methadone-Related Deaths: A Review of Medical Examiner Cases in a Large Metropolitan Area

Lisa B. Shields, MD*, Donna M. Hunsaker, MD, and Tracey S. Corey, MD, Office of the Chief Medical Examiner, Urban Government Center, 810 Barret Avenue, Louisville, KY 40204; John C Hunsaker III, MD, JD, Office of the Associate Chief Medical Examiner, University of Kentucky Department of Pathology and Laboratory Medicine, 100 Sower Boulevard, Suite 202, Frankfort, KY 40601-8272; and Michael K Ward, MS, Kentucky Medical Examiner's Program, Office of Forensic Toxicology, 100 Sower Blvd Suite 202, Frankfort, KY 40601

The goals of this presentation are to (1) to present a review of methadone-related fatalities encompassing comprehensive medicolegal death investigations conducted at the Office of the Chief Medical Examiner in Kentucky between 2000 and 2004; (2) to offer guidance in the interpretation of toxicological data involving methadone, specifically in the context (a) of the victim's use of methadone prior to death and (b) of combinations with other drugs, particularly benzodiazepines, antidepressants, and other opiates.

The documented rapid rise in methadone-related deaths in Kentucky and nationally requires a better understanding of its pathophysiology and the ways it contributes to significantly increased morbidity and mortality. A thorough investigation into the practices of procurement and use/abuse

of this drug is essential to arrive at the proper designation of the cause of death. The interpretation of blood methadone concentrations alone or in combination with other psychoactive drugs must include inquiry concerning the victim's potential chronic use and tolerance of the drug. Research shows that pharmacogenetics play an equally important role in an individual's metabolism of methadone and other opiates. This presentation will impact the forensic community and/or humanity by demonstrating why further forensic study should focus on the interplay of drug metabolism with potential genetic links in individuals who die from opiate drug intoxication.

Methadone, a synthetic opioid, received approval by the U.S. Food & Drug Administration (FDA) in 1947 for use as an analgesic. By 1950, physicians prescribed it for the treatment of withdrawal symptoms associated with heroin and other opioids. The majority of methadone-associated deaths in this study include at least one other drug, in most cases another opioid or central nervous system depressants such as benzodiazepines. The synergistic effects of methadone in combination with ethanol, benzodiazepines, or other opioids may be lethal. Methadone-associated deaths skyrocketed in the early 2000's: a greater number of these deaths were reported to MedWatch (FDA's Safety Information and Adverse Event Reporting Program) in 2001 alone than in the previous decade; the number doubled once again in 2002. The dramatic increase is likely due to a rise in consumption attributable to either (a) the rise in prescription of oral methadone to outpatients for chronic pain management, or (b) the greater availability of "street" methadone, which may account for overall increases in illicit drug diversion tactics and usage.

This study reviews 176 methadone-related deaths involving postmortem examination with toxicological analyses at the Office of the Chief Medical Examiner in Louisville, Kentucky between 2000 and 2004. Analysis by the Kentucky Office of Forensic Toxicology revealed that more than a ten-fold increase in methadone-related fatalities occurred, varying from 6 cases in 2000 to 68 cases in 2003. Sixty percent were males; all were Caucasian. Individuals ranged between 17 and 60 years (mean age: 38). The average body mass index (BMI) was 26.2. The Coroner's investigation reported methadone use in 95 (54.0%) cases. Of these, 46 (48.4%) involved prescription by private physician, 19 (20.0%) obtained the drug illegally, 9 (9.5%) received it through a methadone treatment clinic, and 21 (22.1%) acquired methadone by unknown means. Of the 46 individuals receiving physician-prescribed methadone, 23 (50.0%) either initiated or refilled their prescriptions < 10 days prior to death. One-third of these had been undergoing pain management, as supported by the Coroner's documented clinical history and, in some cases, in conjunction with a lumbar or other significant surgical scar.

In view of the broad overlap in blood methadone concentrations in cases of toxicity compared to tolerant individuals on maintenance, interpretation of the postmortem blood methadone concentration was uniquely individualized for each subject. Evaluation included consideration of the history of past exposure, including amount, frequency, and duration of consumption, in an effort to determine whether the subject developed tolerance to methadone. With application of this evaluative methodology, a total of 130 (73.9%) individuals had toxic or lethal blood concentrations of methadone. The blood alcohol concentration (BAC) was negative in 152 (86.4%) of cases, while 9.1% had a BAC $\geq 0.1\%$; 4.0% had a level between 0.1% - 0.2%; and one victim had a level between 0.2% - 0.3%. The following psychoactive medications were detected in the blood: benzodiazepines (33.0%), antidepressants (39.2%), and other opiates (27.8%). The P450 metabolizers, promethazine and diphenhydramine, were frequently observed in combination with methadone, at 14.2% and in 10.2%, respectively. Urine was collected in 88.1% of cases. In addition to blood concentrations of drugs noted above, the urine screen confirmed cannabinoids in 28.4% and cocaine or its metabolites in 21.9% of all cases.

Methadone, Opiates, Pain

G94 The Value of Expanded Postmortem Toxicology Testing Menu

Luis E. Remus III, PhD, MD, Ashraf Mozayani, PhD,
Terry Danielson, PhD, and Luis A. Sanchez, MD, Harris County
Medical Examiners Office, 1885 Old Spanish Trail, Houston, TX 77054*

After attending this presentation, attendees will understand the value of retaining alternative tissues for postmortem toxicological analyses.

This presentation will impact the forensic community and/or humanity by demonstrating the utility of alternative postmortem tissue analysis in determining defensible cause of death.

The objective of this presentation is to relate experiences from the Harris County Medical Examiner's Office regarding use of brain tissue, as a supplement to blood, for the postmortem identification of cocaine and its metabolites.

First reported by Spiehler and Reed in 1985 (1), and then further clarified by Karch in 1998 (2), the concentrations of cocaine (COC) and benzoylecognine (BE) in brain parenchymal tissue are vital components to a defensible cause of death due to cocaine intoxication.

Over a 16-month period, in Harris County, there were 58 cases initially designated as undetermined but were suspected of being cocaine-associated deaths. Brain tissue from each of these cases had been obtained as part of the routine autopsy protocol at the time of necropsy. Due either to insufficient quantity, the complete lack or poor quality, of blood specimens taken from these cases, the traditional blood analyses did not identify COC or its metabolites and did not contribute to the determination of cause or manner of death. Subsequently, the brain tissue was analyzed for the presence of COC, BE, and/or cocaethylene (CE). Of the 58 cases analyzed, 35 (60%) COC, BE, and/or CE was found in the brain tissue. As a result, 35 cases that would potentially have been classified as undetermined could be closed and signed out as cocaine-associated deaths.

While the analysis of brain tissue should not be considered as a routine procedure, the collection of parenchymal tissue (e.g., brain) should be incorporated as part of the autopsy procedure. Even if not actually analyzed, this tissue may prove to be invaluable when more routine analyses prove to be non-contributory to the cause of death determination. Other solid tissues or alternative specimens such as hair, nail clippings, maggots, and other solid organs are proving to be useful in postmortem toxicological analyses.

In conclusion, the Harris County Medical Examiner's Office has observed the utility of alternative specimens, such as brain, in the determination of cause in cocaine-related, or suspected, deaths.

Cocaine, Alternative Tissue Testing, Cause of Death

G95 Arteriovenous Malformation and its Implications in Forensic Pathology: A Case Report

Anny Sauvageau, MD, MSc, Laboratoire de Sciences Judiciaires et de Médecine Légale, 1701 Parthenais Street, 12th Floor, Montreal, Quebec H2K 3S7, Canada*

After attending this presentation, attendees will gain better knowledge and understanding of the four types of vascular malformations (morphology, usual location, outcome) and their implication in forensic pathology.

Sudden deaths from the rupture of an arteriovenous malformation (AVM) are rare in forensic pathology practice. This presentation will impact the forensic community and/or humanity by illustrating the importance of understanding this entity to avoid confusing an AVM with child abuse.

The goal of this presentation is first to differentiate the four major groups of vascular malformations of the brain, which are arteriovenous malformation (AVM), cavernous angioma, venous angioma and capillary telangiectasia, and secondly, to describe their implications in forensic pathology.

AVMs consist of tangled masses of tortuous arteries and veins devoid of intervening capillaries that frequently extend from brain parenchyma into the subarachnoid space. Cavernous angioma is a tightly packed collection of hyalinized vascular channels most commonly found in the cerebellum, pons and subcortical regions. Venous angioma is composed of varicose veins generally located in the cerebral white matter. Capillary telangiectasia appears as a collection of small-caliber, very-thin-walled channels most likely found in the pons. Cavernous hemangioma is the only malformation lacking intervening brain parenchyma. AVM and cavernous angioma often cause hemorrhages. On the other hand, venous angioma and capillary telangiectasia are typically asymptomatic.

AVM is a rare cause of sudden death. In forensic context, six cases of such deaths have been reported, in three different papers. In five of these reported cases, children aged 5 to 10 years old complained of headache and went to lay down, and later found dead from a ruptured AVM within the cerebellum. The other one is an 8-year-old boy found dead in a swimming pool after rupture of an unsuspected brain AVM.

Presented here is the case of a 14-year-old girl who died from a ruptured arteriovenous malformation of the brain. The girl was in good health except for asthma. The eldest of nine, she lived in a family that was part of a marginal community. Her parents were members of a group that allowed child beating and refused all vaccination and modern medicine.

The girl was found dead in the morning, lying on her bed, her legs hanging off the side. Child brutality was suspected at first sight because of a bluish coloration on the side of her face, which was later proven to be livor mortis. On the previous morning, she was feeling fine and went to school. At noon, she started to feel sick. She vomited twice and complained of headache and nausea. Her body temperature was normal. She went home and went to bed by 6 pm, and later found dead the next morning.

External examination of the 60-pound and 4-foot-5 girl revealed nothing worthy of note. At internal examination, the 1580-gram brain showed massive edema with intracerebral hemorrhage and secondary necrosis around the left lateral ventricle, extending to the ventricle with widening of the latter. Microscopically, the lesion was composed of different caliber thick-walled vascular channels surrounded by intervening reactive cerebral parenchyma, with gliosis and hemosiderin deposits. The abnormal vessels extended into the subarachnoid space in some areas. The rest of the autopsy was unremarkable except for mild lung congestion. Toxicological analysis reveals only a therapeutic dose of acetaminophen. The death was attributed to a rupture of a cerebral AVM and the manner of death was ruled natural.

The present case is a reminder that the forensic pathologist should be able to recognize an AVM and know how to differentiate it from the others types of cerebral vascular malformations. Although rare, it can be a cause of sudden death, and should be considered in the differential diagnosis of intracerebral hemorrhage, and not confused with trauma, especially in children.

Sudden Death, Arteriovenous Malformation, Forensic Pathology

G96 Sudden Death in the Young in Australia

Johan A. Duflou, MBChB, MMed *, Department of Forensic Medicine, PO Box 90, Glebe, NSW 2037, Australia; and Rajesh Puranik, MBBS, Clara K. Chow, MBBS, Michael J. Kilborn, DPhil and Mark A. McGuire, MBBS, PhD, Department of Cardiology, Royal Prince Alfred Hospital, Missenden Road, Camperdown, NSW 2050, Australia

After attending this presentation, attendees will have a good understanding of the range of causes of sudden death in young persons, and be able to implement recommendations made from this analysis.

This presentation will impact the forensic community and/or humanity by providing a greater understanding of the range of diseases causing sudden death in the age range 5 to 35 years.

Objective: To determine the causes of sudden natural death in persons aged 5-35 years.

Method: A review of all autopsies conducted at a forensic medicine facility for the years 1995-2004 (inclusive). This facility serves over 2.5 million people in the eastern part of Sydney, Australia. Data collected included the subjects' age, height, weight, gender, circumstances of death and pathologic findings at autopsy. Deaths caused by trauma, accidental causes, drowning and drug toxicity were excluded from the analysis.

Results: There were 427 non-traumatic, sudden deaths in the 10-year period (70.7% male). Cardiac causes accounted for 56.4%, non-cardiac causes for 39.3% and the cause was not determined in 4.3%. The most common cardiac cause for sudden death was presumed arrhythmia in those with no or minimal structural heart disease (29.0%). Other causes were acute myocardial infarction (24.5%), myocarditis (11.6%), hypertrophic cardiomyopathy (5.8%), aortic dissection and dilated cardiomyopathy (5.4% each). Over two-thirds of deaths caused by acute myocardial infarction occurred in the 30-35 year age group. Sudden cardiac death occurred during physical activity in 10.8% of cases. Sudden cardiac death had been reported in a first-degree relative in 4.5% of decedents. The most common non-cardiac causes for sudden death were epilepsy (23.8%), intracerebral hemorrhage (23.8%), asthma (16.1%), and pulmonary embolism (12.5%).

Conclusion: Presumed cardiac arrhythmia is the most common cause of sudden natural death in the young. There was no reported history of sudden death among the relatives of most decedents.

Sudden Death, Arrhythmia, Autopsy

G97 Suicide Among 10 to 20 Year Olds in Cook County, Illinois: A Retrospective Review

Adrienne E. Segovia, MD, Clare H. Cunliffe, MD*, Mitra B. Kalelkar, MD, and Michelle Jorden, MD, Office of the Medical Examiner, County of Cook, 2121 West Harrison Street, Chicago, IL 60612

After attending this presentation, attendees will learn the risk factors and most common methods of suicide in this age group.

This presentation will impact the forensic community and/or humanity by identifying the following: the methods used to commit suicide among 10- to 20-year-olds in a large urban population, the frequency of drugs and alcohol in the study group, and the relationship of suicide to other factors studied. This information will further assist in the formation and implementation of prevention strategies.

The goal of this presentation is to present a review of the findings of a retrospective study of suicide deaths among 10- to 20-year-olds in Cook County, Illinois between 1994 and 2004. After attending this presentation the attendee will be able to recognize the risk factors and most common methods of suicide in this age group.

This presentation will impact the forensic community and/or humanity by identifying the following: the methods used to commit suicide

among 10- to 20-year-olds in a large urban population, the frequency of drugs and alcohol in the study group, and the relationship of suicide to other factors studied. This information will further assist in the formation and implementation of prevention strategies.

After steadily increasing during the late 1970s through the early 1990s, the Centers for Disease Control and Prevention reported that between 1992 and 2001 the overall suicide rate for 10 to 19-year-olds in the United States decreased from 6.2 to 4.6 per 100,000 population. In 2001, suicide was the third leading manner of death behind accidents and homicides among 10 to 19-year-olds. In the United States, approximately 2000 adolescents commit suicide annually. Nationwide, 8.5% of students in grades nine through twelve report that they have attempted suicide. Of those attempts, 2.9% required medical attention for their injury or overdose. Several major risk factors for adolescent suicide have been identified. Although a history of a previous suicide attempt is a known risk factor, according to the American Psychiatric Association, many teen suicide completers have never made a prior attempt. Other identified risk factors include a history of a psychiatric disorder (most commonly a mood disorder either alone or in combination with a conduct disorder or substance abuse), a history of sexual abuse, and a history of parental psychiatric disorder. A family history of psychiatric disorder probably increases the risk of suicide in two ways: by bestowing genetic vulnerability and creating home and living conditions with decreased social support, which increases stress at home. Girls are three times more likely to attempt suicide when a psychiatric condition is present in association with alcohol use or a conduct disorder. Peer related violence also appears to increase the level of suicide risk for boys and girls. A recent study found that several of the known risk factors for completed suicide are constant across cultures and countries. The precipitating event, according to one study, occurred from within 24 hours of death up to one year prior to death. The most frequent precipitants within the week prior to death were difficulties in, or the end of, a relationship, and arguments with relatives and friends.

The most common method, identified in numerous studies, is firearms. This is followed by asphyxial deaths - most commonly caused by hanging. Beginning in 1997, however, among 10 to 14-year-olds, asphyxia became the most common method, exceeding deaths caused by firearms. The explanation for this change is unclear. It may in part be due to youth focused firearm laws which are intended to keep firearms away from teenagers - such as gun safe storage laws known as child access prevention laws. Many states have adopted laws, which establish a minimum age for legal possession and purchase of a firearm in response to studies that have consistently found that the presence of firearms in the home increases the risk of adolescent suicide. In 1994, a federal law established 18 years as the minimum legal age for purchasing and possessing handguns. Illinois has a minimum age of 21 years for the purchase and possession of a firearm. Interestingly, a study examining the association of these laws and suicides found that among 14 to 17-year-olds there was no statistically significant association between suicide rates and laws setting minimum ages for firearm purchase or possession. This study did find a modest reduction in suicide rates among the same age group associated with child access prevention laws. Their model estimates that in the absence of the law the expected suicide rate in this age group would be 6.51 per 100,000 rather than the observed 5.97 per 100,000.

This study examines suicides in children and adolescents who live in Cook County, Illinois, a large culturally and racially diverse, primarily urban setting. Cook County, which includes the city of Chicago, has a population of 5,376,741 according to the 2000 census. Caucasians comprise 56.3% of the population, including 19.9% that are of Hispanic ethnicity, African-Americans comprise 26.1 %, Asians 4.8%, and other racial backgrounds 12.8 %. The same census indicates that the city of Chicago has a population of 2,896,016, and a slightly higher African American population — 36.7% — than the county. In the city, Caucasians comprise 42% of the population, Asians 4.3% and other racial backgrounds 17%.

This study explores the demographics, seasons, methods, situational factors, presence of drugs, presence of notes, history of previous suicide

attempts and the identification of known risk factors/stressors when possible. With cases involving gunshot wounds, the location of the injury, the caliber, and ownership of the weapon, (when available), was noted.

In the time period examined there were 254 cases of suicides: 205 male (81%) and 49 females (19%). The majority involved Caucasians, 120 (47%), followed by African-Americans, 87 (34%). Hispanics accounted for 42 (17%) of the cases. Among Asians, there were 5 (2%) suicide deaths.

The majority of the cases occurred in the 16- to 19-year-old age range, accounting for 74%. Overall, the leading cause of death was from a firearm injury, 48%, followed by hanging, 38%. Among 10- to 14-year-olds, however, the leading cause of death was asphyxia (hanging), which accounted for 65.8%. This is similar to a national trend in this age group, reported by the Centers for Disease Control and Prevention in June 2004, in which asphyxial deaths surpassed firearm deaths. Three methods tied for third, each accounting for 3%. The three were pedestrians who stepped in front of vehicles, carbon monoxide deaths, and falls from heights. Drug overdoses accounted for 2%. Self-immolation, drowning, and incised/stab wounds, each accounted for 1%.

The number of suicides was fairly uniform throughout the year. There were slightly more deaths during the spring (29%), compared to autumn (27%), summer (24%), or winter (20%). A history of previous suicide attempts was identified in 11%. Depression and/or another psychiatric disorder were found in 23%. Suicide notes were left by 28%.

Toxicology studies revealed the presence of alcohol, and/or drugs (cocaine, benzoylconine, opiates, methadone and phencyclidine) in 19.3%. Blood alcohol levels ranged from 12 mg/dl to 350 mg/dl (mean: 109.6 mg/dl).

Although the data from retrospective studies cannot predict who will commit suicide, by identifying risk factors, strategies and intervention, and assistance programs can be implemented for those who may be at risk. Families, friends, school personnel and healthcare providers need to continue their vigilance because the complexity of childhood and adolescent suicide requires multiple strategies to identify and assist those at risk. Childhood and adolescent depression is more common than many adults believe. In this study, 23% had a psychiatric history, and/or a history of depression. It is estimated that for every completed suicide there are between 100 to 200 suicide attempts.

Depression in children and adolescents can be misinterpreted as anger or sullen behavior. The years between ages 10 to 20 can be a difficult time. Warning signs or behaviors can be subtle and may be mistaken as typical growing pains. Some signs of depression include: unhappiness, isolated behavior, drop in school performance, loss of interest in activities that were formerly sources of enjoyment, increase in physical complaints, fatigue, lack of energy or motivation, changes in sleeping and eating habits, increase in drug and alcohol use, outbursts of temper, irritability, restlessness and reckless or dangerous behavior. It is important to remember that the traumatic events, which are the triggers or catalysts for suicide in this age group, may seem minor from an adult's perspective (such as failing a test/class, getting into an accident, breaking up or being rejected). There is no single theory, which explains why children and teenagers take their lives in great numbers. Strategies in the home may include restricting access to medications and firearms. Child firearm access prevention laws can only go so far because, ultimately, laws cannot protect those intent on harming themselves.

Suicide, Methods, Children & Adolescents

G98 Immunohistochemical Examination of α -Lactalbumin in SIDS (Sudden Infant Death Syndrome)

Annalisa Addante, MD, PhD*, Fiorenza Zotti, PhD, Andrea Marzullo, MD, Alessandro Dell'Erba, MD, PhD, and Massimo Collonna, MD, Section of Legal Medicine, University of Bari, Piazza Giulio Cesare, Bari, 70124, Italy

After attending this presentation, attendees will understand the usefulness of semiquantitative comparison of α -lactalbumin immunohistochemical staining in evaluating cases of suspected SIDS (Sudden Infant Death Syndrome).

This presentation will impact the forensic community and/or humanity by demonstrating the use of alpha-lactalbumin in the diagnosis of SIDS. The aim of this study is to evaluate the presence or absence of milk's particles within pulmonary histologic sections of 10 infants whose cause of death was suspected to be asphyxia due to human breast milk aspiration.

α -Lactalbumin is a whey protein. Previous immunohistochemical research with this antibody in SIDS deaths has been useful in some cases where aspiration was suspected as a cause of death (Iwadate K. et al., 2001).

The authors selected 10 cases of SIDS from the archives of the Section of Legal Medicine and Pathological Anatomy of the University of Bari. All tissues were embedded in paraffin. In order to demonstrate aspirated milk within the lungs, histological sections stained with Hematoxylin-Eosin (H&E) were initially evaluated. In each case, and when the staining was positive or suspected by H&E, immunohistochemical staining using commercially available anti-human α -lactalbumin antibodies was performed.

The authors compared the results of the 10 infants with pulmonary sections from a control group of five infants in which the cause of death was due to a cardiac malformation. In the control group of five deaths, none were positive for the antibody, while in the studied group there were two kinds of results. In the experimental group, one pattern showed small quantity of protein suggestive for a gastroesophageal reflux or cardiopulmonary resuscitation, with both of these factors a cause of terminal inhalation. In the second pattern, there was clear positivity of immunohistochemical staining. This result was clearly interpreted to mean that aspiration was the cause of death.

This method allows the pathologist to evaluate in a semiquantitative manner for the possibility of milk aspiration (Iwadate K. et. al., 2001). Using this technique, the authors are able to evaluate in detail cases in which the circumstances, the autopsy, and the classical histological techniques alone do not allow for a definitive diagnosis. It is possible that a re-examination of cases of SIDS using this technique could be useful in evaluating for the possibility of breast milk aspiration.

Lactalbumin, Breast Milk Aspiration, Immunohistochemistry

G99 Forensic Approach in a Case of Simultaneous Sudden Infant Death Syndrome

Francesco M. Morreale, MD, Irene Riezzo, MD, Stefano D'Errico, MD, and Raffaella Bisceglia, MD, Institute of Forensic Pathology Foggia University, V.le Luigi Pinto 1, Foggia, 71100, Italy*

Simultaneous Sudden Infant Death Syndrome (SSIDS) has received limited attention in the medical forensic literature with only a few articles directly addressing this topic. The goal of this presentation is to present a rare case of simultaneous sudden infant deaths (SSIDS) in twin infants. The complete multidisciplinary approach from scene investigation, autopsy examinations, and performance of toxicological testing, satisfies the SIDS criteria and explains this simultaneous lethal event.

This presentation will impact the forensic community and/or humanity by reporting the simultaneous death of a pair of twins. The rarity of the event makes it peculiar and the described complete pathologic investigation (death scene investigation, autopsy examination, and toxicological screening) is strongly recommended in SIDS and is warranted in SSIDS cases.

The case of a simultaneous death in premature, identical male monozygotic, 138 days old twins who were found lifeless in their crib three or four hours after feeding is presented. In the history given by the mother, she stated that early in the morning she fed her sons and then put them at one end of their crib. A few hours later she found the babies in prone position, cyanotic and breathless. She immediately took each of them out of the crib, wet their faces, and alerted medical rescue, meanwhile trying to unsuccessfully resuscitate them. It was also noted that the babies suffered from a cough and respiratory difficulties with mucus production for the last few days, and were seen by a general practitioner who prescribed a cough syrup. The mother also stated that both babies refused feeding before their deaths. The extended family had no history of prior SIDS deaths. After death notification, the authority immediately alerted a forensic pathologist and a detailed scene investigation was performed. Upon the death scene investigation, the babies were found lying on the sofa in the restroom of a small and poorly furnished apartment situated on the ground floor. A domestic gas stove was connected to its fuel cylinder and was found cold to the touch in the same room. A technical assessment performed by fire fighters revealed that the gas supply system was functioning perfectly. The mother, except for cigarette abuse, denied risk factors for SIDS, such as maternal alcohol consumption and legal or illegal drug use during the pregnancy. Internal temperature of the infants measured by means of a bulbous thermometer was 29°C each, and external temperature was 10°C. Rigor mortis was present and livor mortis was represented by fixed reddish-purple coloration localized on anterior part of the body. External examination was unremarkable, showing no sign of traumatic injuries and/or signs of compression of the nose or mouth or upper airway obstruction. Only an intense cyanosis on lips and nails was observed. Complete autopsies two days later were performed. In both cases, cardiac sections showed a septum secundum atrial septal defect, the lungs were hypoexpanded and heavy with diffuse, firm, red boggy parenchyma, with the presence of white fluid in the upper respiratory tracts. Examination of other organs showed cerebral edema, epicardial petechiae, and intense vascular congestion. Histological examination of the hearts revealed the presence of multiple foci of myocardial contraction band necrosis, and myofiber break-up. Examination of the sinoatrial (SA) node and the bundle of His revealed no abnormalities. The lungs showed subpleural haemorrhages, alveolar septa mildly thickened by edema, capillary congestion, alveolar edema, and interstitial infiltrates with leukocytes. No other findings were found except for brain edema and generalized intraparenchymal acute hemostasis. A complete toxicological screening was performed to test for concentrations of bromexine in blood and urine, and for determination of HbCO in the blood. Results of the analysis excluded toxic values for drugs, including carbon monoxide. Data provided from the death scene investigation,

medical history of the children before death, macroscopic and microscopic autopsy findings and the results of toxicological examination, exclude any traumatic injury, carbon monoxide or drug intoxication, and led us to conclude that acute respiratory failure from interstitial pneumonia was the cause of the deaths. The presence of environmental risk factors such as the ambient air temperature in the infants' room, number and position of covers, type of bed, prone sleeping position, cosleeping, mother's cigarettes abuse, and recent signs and symptoms of illness, acting at the same prolonged time on each baby, had to be considered relevant in justifying the simultaneity of the lethal event.

Simultaneous Sudden Infant Death Syndrome, Acute Respiratory Failure, Interstitial Pneumonia

G100 Infant Position and the Assessment of Risk Factors for Asphyxia: A Review of 209 Sudden Unexpected Infant Deaths

Melissa A. Pasquale-Styles, MD, Wayne County Medical Examiner Office, 1300 East Warren Avenue, Detroit, MI 48207; Patricia L. Tackitt, RN, MS, Michigan Public Health Institute, 2438 Woodlake Circle, Suite 240, Okemos, MI 48864; and Carl J. Schmidt, MD, Wayne County Medical Examiner Office, 1300 East Warren Avenue, Detroit, MI 48207*

After attending this presentation, attendees will understand the importance of a scene investigation, preferably with reenactment using a doll, in identifying the risk factors for asphyxia in a sudden, unexpected infant death.

This presentation will impact the forensic community and/or humanity by demonstrating how historically, the investigation of an infant death has focused predominately on autopsy and microscopic findings with little understanding or consideration of the risk factors for asphyxia at the scene. Since most infant autopsies are negative for significant disease or injury, many of these have traditionally been called sudden infant death syndrome (SIDS). Even in some cases where asphyxia was strongly suspected at the scene, such findings have been ignored in favor of a SIDS diagnosis or cause of death based on some evidence of natural disease at autopsy such as a respiratory tract infection. By ignoring risk factors for asphyxia in many cases, pathologists have missed emphasizing a major cause of sudden infant death through the years.

At the Wayne County Medical Examiner Office in Detroit, Michigan, from 2001 to 2004, scene investigations were performed on 209 sudden and unexpected infant deaths, ages 1 day to 12 months. This included a follow-up visit, usually performed by a public health nurse. A reenactment of the position of the infant's body when found using a doll took place in all except 7 scenes where parents refused or a doll was unavailable. The 209 cases were reviewed to assess the position of the infant at the time of discovery and identify the common risk factors for asphyxia including bed sharing, overlay, wedging, strangulation, and prone position, demonstrated obstruction of the nose and mouth and coverage of the head by bedding. Sixty (28.7%) of these infants died in their cribs, 110 (52.6%) died after being placed to sleep in adult beds, 25 (12.0%) died after being placed to sleep on couches, 5 (2.4%) died in car seats and 9 (4.3%) died in miscellaneous other locations. Conclusive evidence of asphyxiation including witnessed overlay, wedging, or strangulation was established in 27 cases (12.9%). Bed sharing occurred in 114 deaths (54.5%). An infant position with demonstrated complete obstruction of the nose and mouth upon discovery was shown in 64 cases (30.6%). Prone positions on soft bedding +/- partial obstruction of the airway, general prone position, and/or coverage of the head by bedding were documented in 30 cases (14.4%). Overall, one or more risk factors for asphyxia were identified in 178 out of 209 cases (85.2%). Nonspecific criteria which may complicate breathing in an infant with airway compromise were identified in 59 out of 178 infants with asphyxia risk factors (33.1%) and included symptoms of the flu or upper

respiratory infection, medication with sedating decongestants, known respiratory complications of prematurity and/or a previously diagnosed medical condition for which they were not exhibiting acute symptoms. Thirty-one of 209 infants (14.8%) had no discernible risk factors for asphyxia. The information gathered at the scene investigation regarding the infant's position at death was completely different from the initial death report in 26 of 209 cases (12.4%) and revealed additional information regarding asphyxia risk factors in 92 cases (44%). Of the 209 infants, the cause of death of 49 (23.4%) was determined to be position-related asphyxia, 35 (16.7%) were natural causes (with pneumonia/airway inflammation and congenital heart disease predominating), 67 (32.1%) were designated sudden infant death syndrome (SIDS), 57 (27.3%) died of indeterminate causes and 1 case was ruled accidental aspiration of food. The increasing awareness in risk factors for asphyxia at the scene has led to a reduction in the diagnosis of SIDS at the Wayne County Medical Examiner Office from 38 in 2000 to 2 in 2004 (94.7% decrease). In this same time period, the diagnosis of position-related accidental asphyxias in the 1-day to 12-month age group increased by 283% from 6 to 17 and indeterminate causes of death increased by 900% from 3 to 27. This study suggests that asphyxia plays a greater role in many sudden infant deaths than has been historically recognized, and a thorough scene investigation with doll re-enactment is an effective way to identify the risk factors. A better understanding of the significance of these risk factors is needed so that the causes of many sudden infant deaths can be determined and appropriate preventive measures reinforced.

Sudden Infant Death, Infant Position, Asphyxia

G101 Hyperglycemic Hyperosmolar Nonketotic Syndrome in a Sixteen-Month Old Child With Rotaviral Diarrhea

Mary E. Carr, MD*, and Andrew M. Baker, MD, Hennepin County Medical Examiner's Office, 530 Chicago Avenue, Minneapolis, MN 55415

The goal of this case study is to present a child death due to severe dehydration from hyperglycemic, hyperosmolar, nonketotic syndrome (HHNS), with concomitant rotavirus diarrhea.

This presentation will impact the forensic community and/or humanity by reviewing the rare entity of HHNS in children; and discussing the differentiation between stress-induced hyperglycemia, diabetic ketoacidosis (DKA) and HHNS.

A sixteen-month-old male child, born at twenty- five weeks and five days gestation, had several congenital anomalies including serious mental and neurological deficiencies.

The initial five months of his life were spent in the hospital during which time he never demonstrated hyperglycemia or showed signs of being diabetic.

Three days prior to his death he developed episodic, profuse watery diarrhea. He was fed a banana, rice, applesauce, toast, (BRAT) diet, without toast. He was also treated with acetaminophen and bismuth subsalicylate. There were no visits to a physician.

On the third day of his illness, he was fussing at 0430. His mother tried to give him cough medicine but he refused. She changed his diaper, laid him prone, and rubbed his back. He was notably limp. When she checked on him approximately two hours later, he was unresponsive. Paramedics were called, but death was obvious and no resuscitation was attempted.

Postmortem examination revealed a slightly dysmorphic male, weighing 18 pounds and having a crown-heel length of 29.5 inches. The occipital frontal circumference was 16.8 inches. The eyes appeared sunken. The organs had dull surfaces and were tacky to touch. There was no physical or historical evidence of previous or recent abuse.

The stomach contained 300cc of light pink fluid without any food fragments. The intestinal contents were of a similar consistency to that of the stomach and light tan in color. The brain had markedly small cerebellar hemispheres and atrophic optic nerves. The hippocampi were atrophic and the lateral and fourth ventricles were mildly dilated. Microscopic sections from the pancreas, heart, lungs, liver, kidney, adrenals, thymus, and trachea were normal. Vitreous electrolytes included a glucose of 598mg/dL, vitreous osmolality 430mOsm (285-305mOsm), sodium-158mEq/L, chloride-140 mEq/L, urea nitrogen-37mg/dL, and creatinine-1.0 mg/dL. Acetone was negative. Stool culture was positive for rotavirus. Toxicology was positive for liver acetaminophen with 25mcg/gm, and liver salicylate of 3.5mg/100gm.

Diarrhea illness, world wide, represents a leading or second cause of death for children less than five years old. In the United States only about 300 child deaths per year are due to diarrhea.

HHNS is almost always a disorder of Type II diabetes mellitus in elderly, neglected, or debilitated adults. In HHNS, glucose levels are elevated, often as high as 1000 mg/dL or more. Ketones are negative because lipolysis is inhibited. Serum osmolarity is high, with the measured level being higher than the calculated level. Acidosis may occur, and is usually due to lactate from hypoperfusion.

Fewer than 30 cases of HHNS have been reported in children since 1960. In most of these, the children are less than two years old and/or neurologically impaired. Mortality is as high as seventy five percent, and occurs from dehydration or from cerebral edema if rehydration occurs too rapidly.

HHNS in children represents either the initial presentation of diabetes mellitus, or it is associated with gastroenteritis, usually rotavirus, as was the case with this child. When HHNS is associated with gastroenteritis it is a transient condition and, if the child survives, they have no greater risk of developing diabetes mellitus than the rest of the population. The mean glucose level (634 mg/dL) is lower, and the sodium is higher (mean 135 mEq/L), when gastroenteritis is the cause of HHNS.

Suggested laboratory studies needed to make the diagnosis of HHNS, and to exclude diabetes mellitus, include glucose, osmolarity, HgA1C, plasma insulin levels, and islet cell antibodies.

Although samples to exclude diabetes mellitus did not remain in this case, this child, who had a severe neurologic disorder and no prior history of a hyperglycemic event, and who was hyperosmolar with rotavirus diarrhea, represents a rare case of HHNS.

Hyperglycemic, Hyperosmolar, Nonketotic

G102 Starvation – Interpretation of Morphological Findings and Pitfalls

Véronique Henn*, and Manfred Kleiber, PhD, Institute of Forensic Medicine Martin-Luther-University, Franzosenweg 1, Halle, 06112, Germany; and Eberhard Lignitz, PhD, Institute of Forensic Medicine Ernst-Moritz-Arndt-University, Kuhstr. 30, Greifswald, 17489, Germany

After attending this presentation, attendees will learn how to interpret the morphological findings in cases of starvation.

This presentation will impact the forensic community and/or humanity by helping to avoid the misinterpretation of the morphological findings in cases of starvation by demonstrating the classifications of malnutrition and potential pitfalls in its diagnosis.

Starvation is still a worldwide and every day problem. A high infant mortality exists in many Asian, African and some Central and South American states, which is directly explainable by hunger and its after-effects. In European and North American countries cases of death from starvation are rare, but nonetheless, are not unknown in the forensic pathology literature. Actually, illness resulting from wealth and overfeeding are much more prevalent.

Nowadays, cases of death due to starvation originate, in general, from physical or psychical diseases, from food refusal or food deprivation. The latter cause of intentional food depravation of a child being in most cases a sign of child neglect punishable by the law.

Starvation due to consumptive illness resulting from serious natural disease, such as cancer, is always related to the original natural disease. Deaths caused by malnutrition are cases of unnatural death.

Under-nutrition can be classified in certain stages. According to the Gomez-Classification the body weight of a malnourished individual is compared to the expected weight of an individual of the same age. The categories mild, moderate and severe malnutrition is based on a body weight of 75 to 89%, 60 to 74% and <60%, respectively, of the expected body weight. With this classification it is difficult to interpret the correct body-weight of children. Because of the different growth rates of children, in these cases of suspected starvation, the Waterlow classification (Table 1) should be used. The chronic growth retardation of a child can be assessed by comparing the measured height of the body with the expected height. Then the weight of the individual is compared with the expected weight of the body corresponding to the actual height to assess the actual state of under or malnutrition.

Growth Retardation (Chronic)	0 normal Height (% of the expected height at a defined age)	1 mild > 95	2 moderate 95 - 87	3 severe 87 - 80	
Protein-Energy-Malnutrition (Acute)	Weight (% of the expected weight at a defined age dependent on the actual height)	0 normal > 90	1 mild 90 - 80	2 moderate 80 - 70	3 severe < 70

In this study, cases of starvation were evaluated to point out the difficulties in interpretation of body weight and weight of internal organs and to demonstrate potential pitfalls in this analysis.

The following conclusions can be drawn from this analysis:

- The suspicion of death through starvation becomes evident at first sight.
- The real cause of starvation has to be confirmed by numerous examinations (autopsy and histology and toxicology).
- The autopsy of the body includes the determination of all measurable parameters (height, body weight, organ weight), as well as photo documentation.
- Verification of the development of the child at an early age and from birth on is necessary.
- Investigation by the police of the responsible caretakers for the child, and their responsibility in the starvation, must be carried out.
- Under certain circumstances, such as suspicion of a rare chronic disease, a pediatrician can be consulted for their expert opinion.

Starvation, Waterlow Classification, Malnutrition

G103 Perimacular Circular Folds in the Eyes of Injured Children

*M.G.F. Gilliland, MD**, Brody SOM at East Carolina University,
Department of Pathology & Laboratory Medicine, Brody 7 South 10,
Greenville, NC 27834

After attending this presentation, attendees will gain an understanding of how to recognize perimacular folds, will know when to look for them, and know in what kinds of cases perimacular circular folds have been reported to be present.

This presentation will impact the forensic community and/or humanity by demonstrating an increasing ability of forensic pathologists to recognize perimacular circular folds and stimulate interest in looking for such folds in a wider variety of death investigations, although most perimacular circular folds have been seen in abusive head injury deaths.

Hypothesis: Examination of the retinas of a group of children would allow the identification of perimacular circular folds if present. Review of the clinical history, investigative information, and autopsy findings would help establish the significance of such circular folds.

Circular folds have been identified in the eyes of injured children. The initial reports described these findings in children described as battered babies and in children with head injuries attributed to shaking. Cases were selected to report the presence of circular folds. Another report described them in three of ten consecutive cases of child abuse. In all of these reports vitreous traction was the proposed mechanism in the development of circular folds. In the consecutive series report it was proposed that direct head trauma was sufficient to produce the acceleration deceleration traction. More recently, a report described circular folds in a child with crush head injuries occurring when a television fell from a stand, which was an accidental event.

Ocular examinations were a part of a prospective study of child deaths investigated at the Southwestern Institute of Forensic Sciences. Adequate material was available for a retrospective evaluation of 33 of the children's retinas for the presence of circular folds. This group consisted of 25 children with abusive injuries, 5 children with accidental head injuries, and one each of lethal trunk injuries, brain tumor and drowning. Perimacular circular folds were identified in 11 cases. Review of the clinical histories, investigations, and autopsy findings revealed that the circular folds were only found in children with abusive head injuries.

The mechanism of the head injury has previously been reported for a subgroup of head injured children from the entire series from the Southwestern Institute of Forensic Sciences. The mechanism of injury for the 30 head injured children in this group was established independent of information about the presence or absence of perimacular circular folds. Circular folds were seen in 3 of 15 deaths attributed to blunt force mechanisms, 7 of 12 deaths with combined shake and blunt force mechanisms, and 1 of 3 with the mechanism of injury attributed to shaking.

Conclusion: These observations confirm the association of perimacular circular folds with abusive head injuries in a larger group of child deaths than previously reported. The cases were not selected on the basis of circular folds or abusive head injury. The number of accidental head injuries and other causes is too small to clarify whether the perimacular circular folds could be found in other conditions. The mechanism of injury in 8 of the 11 children with circular folds included shaking which supports the proposed vitreous traction mechanism for the formation of perimacular circular folds. However, the presence of circular folds in 3 abusive head injury deaths attributed to blunt force injuries suggests more observations are needed to clarify this issue.

Perimacular Circular Folds, Abusive Head Injury, Vitreous Traction

G104 Postmortem Detection and Evaluation of Retinal Hemorrhages

Patrick E. Lantz, MD*, and Constance A. Stanton, MD, Department of Pathology, Wake Forest University Health Sciences, Medical Center Boulevard, Winston-Salem, NC 27157-1072

After attending this presentation, attendees will gain a better understanding of the variety of disease processes associated with retinal hemorrhages in neonates, infants, children, and adults.

This presentation will impact the forensic community and/or humanity by demonstrating how postmortem monocular indirect ophthalmoscopy permits visualization of the fundus after death and can identify retinal hemorrhages associated with a variety of conditions in children and adults.

Although occurring in about 25% of adults with subarachnoid hemorrhage, Terson syndrome has been considered rare in children and any retinal hemorrhages (RHs) not associated with inflicted childhood neurotrauma have been described as few in number and restricted to the posterior pole. A number of ophthalmologists, pediatricians, and forensic pathologists have asserted that RHs in conjunction with intracranial hemorrhages in children can be considered virtually pathognomonic for inflicted childhood neurotrauma or shaken baby syndrome based on the number, character, location, and distribution of RHs. Unfortunately but characteristically, most studies to date concerning hemorrhagic retinopathy in non-accidental head injury have lacked specific criteria for case definition, exhibited observational and selection bias or cases were selected by the presence or absence of RHs - the clinical or autopsy finding that was being sought as diagnostically valid.

Since June of 2004 the authors have used postmortem monocular indirect ophthalmoscopy to prospectively examine the eyes of 425 deceased individuals at the institution (medical examiner and non-medical examiner cases) ranging in age from birth to 96 years. The postmortem interval ranged from 1 hour to 3 days with 65.9% of examinations occurring less than 24 hours after death. Slightly over 17% exhibited retinal hemorrhages associated with a variety of diseases and conditions. The number of decedents with retinal hemorrhages by age group is listed in the accompanying Table.

Age Range of Decedents and Presence/Absence of Retinal Hemorrhages

	< 1 yr	1-4 yrs	5-9 yrs	10-14 yrs	> 15 yrs	Total
Cases in which fundi not visualized	6	0	2	1	5	14
Cases with no RHs	43	14	7	4	270	338
Cases with RHs	11	3	3	2	54	73
Total	60	17	12	7	329	425

Conditions or causes of death associated with the presence of RHs by age group and number of cases (noted in parenthesis) were:

< 1 yr: Birth-related (2), asphyxia/suffocation (2), Sudden Infant Death Syndrome (SIDS)/resuscitation (2), apnea/gastroesophageal reflux (1), intrauterine intracranial hemorrhage (1), blunt trauma of head (1), prematurity/congenital heart disease (1), meningitis (1)

1-4 yrs: Blunt trauma of head (3)

5-9 yrs: Blunt trauma of head (3)

10-14 yrs: Intra-cranial hemorrhage/metastatic cancer (1), blunt trauma of head (1)

> 15 yrs: Blunt trauma of head (17), coagulopathy (10), gunshot wound of head (7), ruptured saccular aneurysm (7), intra-cerebral hemorrhage/hypertension (6), subarachnoid hemorrhage/vascular malformation (1), hypoxic-ischemic brain injury/drug toxicity (1), meningo-encephalitis/leukemia (1),

intra-cerebral hemorrhage/amyloid angiopathy (1), hypertension (1), diabetes mellitus (1), pulmonary fibrosis/extracorporeal membrane oxygenation (1).

The manner of death in children under the age of 14 years with RHs (by age group and number of cases) was:

< 1 yr: Natural (7), Accident (2), Homicide (1), Undetermined (1)

1-4 yrs: Homicide (2), Accident (1)

5-9 yrs: Accident (3)

10-14 yrs: Natural (1), Homicide (1)

Histological ocular examination of 28 neonates, infants, children and adults with retinal hemorrhages from this study demonstrated a variable pattern as to the number, character, location and distribution of retinal and optic nerve sheath hemorrhages. Of the 73 individuals with retinal hemorrhages, 75.3% died in the hospital; however, only four children and one adult had documented clinical fundal examinations. The four children had child abuse consults while the adult experienced a vitreous hemorrhage from thrombocytopenia during treatment for leukemia. Postmortem monocular indirect ophthalmoscopy is a valuable technique for identifying retinal hemorrhages associated with a variety of conditions and diseases in children and adults.

Retinal Hemorrhages, Postmortem Monocular Indirect Ophthalmoscopy, Shaken Baby Syndrome

G105 Examination of Sexually Abused Child: What is the Impact on Judgment?

Nathalie S. Jousset, MD*, Department of Forensic Medicine, University Hospital, Angers, 49033, France; and Hubert C. Poirout, MD, Arnaud N. Gaudin, MD, Michel Penneau, MD, PhD, and Clotilde G. Rougé-Maillart, MD, Department of Forensic Medicine, 4 rue Larrey, Angers, 49033, France

After attending this presentation, attendees will know how the assumption of the possibility of sexual abuse leads almost systematically to a forensic examination. This fact has implications on the health of the victim and the course of the judicial action. However, it is an examination often poor in clinical elements that is used as material proof of abuse. The goal of this study was to try to better understand the contribution of this examination in the legal process.

This presentation will impact the forensic community and/or humanity by attempting to better understand the contribution of the forensic examination when sexual abuse is suspected, and the expected judicial follow-up in sexually abused child affairs.

Assumption of the possibility of sexual abuse leads almost systematically to a forensic examination. This fact has implications on the health of the victim and the course of the judicial action. However it is an examination often poor in clinical elements that is used as material proof. The goal of this study was to try to better understand the contribution of this examination in the legal process.

A retrospective study on a sample of forensic examinations was carried out on requisition. It concerned 74 children of less than 18 years old, examined between June 1998 and June 2000. With the authorisation of the court of Angers city, the judicial files were consulted on site.

It concerned 58 girls for 16 boys. The average age of the victims at the time of the medical examination was nine and a half years old. In 15 cases there was a history of ill-treatment. For nine percent of the victims, the father had been the subject of a penal judgement with prison sentence.

Nine cases related to acts of sexual improprieties, 58 cases of sexual transgressions and 25 cases of rapes or rapes attempts. In 61 percent of the cases, the victim revealed the facts. In 70 percent of cases, time between the facts and revelations was longer than one month.

The forensic examination did not find any disorder for the great majority of the children. In four cases, it highlighted hymenal damage of which two were assigned to sexual abuse. Forty-two victims underwent a

psychological or psychiatric consultation. For two children, their remarks were not recognised credible by the experts.

The total number authors blamed for abuse was 58. Nineteen had already been condemned for sexual abuse. In 26 cases, the father was the abuser. In 43 percent of the files, the authors acknowledged the facts. The courts pronounced the culpability of the authors for 42 victims. It was more frequently pronounced for the female victims (63 %) than for male sex (21 %).

Young girls are mainly the victims. In many cases they are abused by their father or by members of the close family. Forensic examinations did not often reveal cutaneous or genital disorders. The lesions can be fleeting and are often healed. Without bringing material proof, anatomical description makes it possible to come to a conclusion about the feasibility or not of some denounced sexual abuse. Conclusions of forensic examinations, when they partly contradict denounced facts do not call into question the reality of the sexual abuse. In many cases, the author is condemned despite everything. That highlights the importance of investigation and of the child's words.

Sexual Abuse, Child, Forensic Examination

G106 Sensitivity of Autopsy and Radiological Examination in Detecting Bone Fractures in an Animal Model: Implications for the Assessment of Fatal Child Physical Abuse

Cristina Cattaneo, PhD, MD, and Eloisa Marinelli, MD, Istituto di Medicina Legale, Università degli Studi, via Mangiagalli 37, Milano, 20133, Italy; Alessia Di Giancamillo, DVM, PhD, Dipartimento di Scienze e Tecnologie Veterinarie per la Sicurezza Alimentare, via Celoria 10, Milano, 20133, Italy; Mauro Di Giancamillo, DVM, and Olga Travetti, DVM, Dipartimento di Scienze Cliniche Veterinarie, via Celoria 10, Milano, 20133, Italy; and Laura Viganò, BSc, Pasquale Poppa, BSc, Davide Porta, BSc, Andrea Gentilomo, MD, PhD, and Marco Grandi, MD, Istituto di Medicina Legale, via Mangiagalli 37, Milano, 20133, Italy*

After attending this presentation, attendees will come to realize the limits of the radiological CT scan and autopsy assessment in the detection of antemortem bone fractures in cases of fatal child abuse, and that direct osteological assessment of certain anatomical areas (particularly the rib cage) is advisable.

This presentation will impact the forensic community and/or humanity by demonstrating how the osteological assessment of certain anatomic areas upon autopsy of infants is advisable, since radiology, autopsy, and CT scans may miss fractures.

Skeletal injuries are often strong indicators of child abuse and their detection is crucial. Regardless of whether one is referring to the living or the dead, bone fractures are perhaps the most important and problematic issue as far as detectability is concerned. According to some authors, skeletal injuries occur in 36-50% of abused children. Whereas external and internal soft tissue traumatic injuries will eventually show up at a thorough clinical examination or at the autopsy table, the presence of bone fractures whose distribution, number and age are crucial is not easy to detect, particularly if very recent or if inflicted in the circumstances of a lethal event and therefore just barely antemortem. In cases in which the child dies immediately after infliction of trauma, the signs may consist of very subtle soft tissue lesions and especially bone fractures – the latter being at times, particularly difficult to detect when healing processes (and therefore callus formation) have not taken place. Furthermore, hemorrhaging of soft tissues may be slight and barely visible upon autopsy, particularly in the paravertebral and posterior vertebral regions, or may be hidden by initial decomposition processes. Thus autopsy and radiological assessment are crucial.

However it is not really known how sensitive such procedures are. Although several studies have been performed, little research has been done on the actual sensitivity of radiology, CT scan, and autopsy on control cases. In order to do this in fact, it is necessary to verify, after radiological assessment and autopsy, all fractures, which are actually present on the bone by studying the cleaned skeleton.

The aim of this study was to compare the sensitivity of three diagnostic approaches of autopsy, traditional (conventional) radiology, and computed tomography on "battered" piglets, in order to verify the sensitivity of each method, with respect to the true number of bone fractures assessed once the piglet was skeletonized (osteological control).

Four newborn cadaver piglets that had died from natural causes were severely beaten postmortem in every district of the body. Traditional radiography, computed tomography (CT) and autopsy were performed. The piglet was then macerated until skeletonized and the number of all fractures present recorded (osteological control).

On the cranium, traditional radiology revealed only 35% circa of actual fractures, autopsy detected only 31 % ($P<0.01$ for both comparisons vs. osteological control), whereas CT imaging detected all fractures actually present. For ribs, radiology detected only 47% of all fractures present, and autopsy 65% circa ($P>0.05$ for both comparisons vs. osteological control), while CT scans detected 34% ($P<0.01$).

In suspected cases of fatal child abuse, the authors suggest that the bones of specific districts be directly analyzed either at autopsy or by collecting specific diagnostic sites, such as parts of the rib cage, and subjecting them to maceration. The removed areas could be replaced with artificial material for cosmetic purposes. These findings stress the importance of combined radiological, CT scan, autopsy, and osteological survey in the detection of perimortem bone fractures. This study confirms the possibly low sensitivity of autopsy and radiological analysis particularly in the detection of hairline fractures of head and thoracic osseous elements if fractures are perimortem and show no healing. According to the authors, in cases of suspected fatal child physical abuse, the bones of specific anatomic regions should be directly analyzed.

Child Physical Abuse, Bone Fractures, Radiology

G107 "Homicide by Heart Attack" - An Unusual Pediatric Death

Dwayne A. Wolf, MD, PhD, Harris County Medical Examiner Office, 1885 Old Spanish Trail, Houston, TX 77054*

The goals of this presentation are to illustrate and discuss applicability of previously published criteria for homicide by sudden cardiac death in pediatric cases. An unusual case of fatal child abuse will be presented as an example.

This presentation will impact the forensic community and/or humanity by demonstrating how the possibility of underlying potentially fatal natural disease must be considered in instances where multiple blunt trauma in a deceased child is unassociated with internal injuries of sufficient severity to explain the demise. Although the current example entails obvious natural disease, the presence of more subtle abnormalities should diligently sought in such cases. If a temporal correlation of abuse (with non-fatal injuries) with death can be documented by investigation, the manner of death may be properly classified as homicide.

This 17-month-old Hispanic female child had a history of various types of abuse, including blunt trauma as well as neglect. The mother was the reported perpetrator, and according to family members, this child was targeted because the mother had doubts as to her maternity (she speculated that the hospital had sent her home postpartum with somebody else's child).

On the date of death the mother phoned from home to her brother-in-law and initially indicated that this child had "fallen from the bed." Over the next several minutes she phoned her sister as well, made several other incriminating statements indicating that in fact she had "hit" the child, and even admitted to her sister "I killed the baby." The brother-in-law immediately rushed to her house, while simultaneously phoning emergency medical services. He arrived at the house at nearly the same time as ambulance personnel. Paramedics found the child unresponsive. Aggressive resuscitative efforts were unsuccessful and the child was pronounced dead upon arrival to the emergency room. As paramedics were entering the house the mother rushed out, drove to the local day care, retrieved her other children and fled to Mexico. The mother and siblings have not been returned to this country, despite multiple warrants.

The abusive nature of the child's injuries was undeniable. Contusions of various ages were distributed widely over all body surfaces, including the scalp, face, thorax, and extremities. Pressure type contusions were on the pinna. Multiple contusions were distributed across the mucosa of the lower lip, and a gaping laceration undermined the upper frenula separating the upper lip from the alveolar ridge. Internal findings were less impressive. In fact, no internal injuries were found. Furthermore, no natural disease was grossly evident. The microscopic appearance of the heart was strikingly abnormal; myocarditis was florid, with abundant lymphocytic inflammation, with intramyocyte edema and myocyte necrosis.

To paraphrase Davis's criteria for "homicide by heart attack," 1. the threat must be severe enough to be considered as a threat to the life of the victim; 2. the victim should perceive the incident as a threat to their life; 3. the threat must be an emotionally charged event; 4. death must occur within the emotional response period during or immediately following the threat; and 5. cardiac disease associated with predisposition to arrhythmia should be documented, although no acute cardiac change (ruptured plaque for example) need be found (J Forensic Sci 23:384; 1978). Although Davis's criteria have been applied primarily to instances of a threat without physical contact, more recent literature (J Forensic Sci 49:598; 2004) expands the criteria to include threats with actual physical contact, but the inflicted injuries are insufficient to explain death. Therefore, the investigative and autopsy findings in this case fit the published criteria for homicide by sudden cardiac death. Accordingly, the cause of death was classified as "sudden cardiac death (myocarditis) associated with multiple blunt force injuries." The manner of death was classified as homicide. Implications for similar types of pediatric cases will be described in the presentation.

Child Abuse, Myocarditis, Homicide by Heart Attack

Pathology/Biology

G1 Deaths From Accidental Steam Inhalation During African Traditional Therapy

Bhanwar Lal Bhootra, MD, Department of Health, PO Box 1944, Polokwane, Limpopo 0700, South Africa*

The goal of this presentation is to present to the forensic community the injurious effects of steam inhalation on the respiratory system, resulting in the deaths of two children. Death from steam inhalation is a quite rare occurrence. In many countries, steam inhalation is practiced to cure cold, cough, or respiratory ailments, etc.

This presentation will impact the forensic community and/or humanity by highlighting the hazards associated with steam inhalation, if done with the whole body covered with a blanket and if necessary precautions are not taken. Under these conditions, traditional therapy can be risky.

Case history: Two children (aged 17 and 6 years) and their mother were inhaling steam from boiling water in a pot, while covering their bodies (including the face) with a thick woolen blanket. After steam inhalation of about 5 minutes, the 17-year-old knocked down the pot and boiling water spilled on the hot plate, producing a considerable amount of steam. Boiling water also spilled on that child and mother, resulting in focal scalds. Within one to two minutes, both children experienced difficulty in breathing, collapsed, and died in the home.

At autopsy, there was oedema of the larynx with blanched white tracheal mucosa in the younger child and marked congestion in the older child. Grossly, the lungs, brain, and heart showed hypoxia signs. Microscopically, there was oedema and coagulative necrosis of the tracheal mucosa; the lungs showed congestion, oedema, and haemorrhages; and the brain showed congestion, oedema and focal intra-cerebral haemorrhages.

Cause of death was attributed to hypoxia from inhalation of steam.

It is common practice among the black Africans to use steam inhalation (traditional African therapy) known as ARAMELA in local Sotho African language) for respiratory problems or congestion or get rid of unspecified ailments, or for general well-being even when there is no evidence of any ailment (superstitious belief).

Moist air has more heat to give up than has an equal volume of dry air. Severe injuries tend to occur with steam inhalation in the form of oedema of the glottis, severe thermal tracheitis and destruction of bronchial mucosa, and haemorrhagic oedema of the centrally located alveoli which can lead to hypoxia and anoxia.

Steam Inhalation, Respiratory Tract, Hypoxia

G2 Firearm Injuries in Angers: 1990 - 2000

Arnaud Gaudin, MD, and Nathalie Jousset, MD, Service de Médecine Légale, Centre Hospitalier Universitaire - 4 Rue Larrey, Angers, 49100 Cedex 01, France; Gilles Tournel, MD, Service de Médecine Légale, Institut Médico-Légal - Place Deverdun, Lille, 59000, France; and Michel Penneau, MD, and Clotilde Rougé-Maillart, MD, Service de Médecine Légale, Centre Hospitalier Universitaire - 4 rue Larrey, Angers, 49100 Cedex 01, France*

After attending this presentation, attendees will be able to analyze a series of 168 cases of firearm injuries in a French city.

This presentation will impact the forensic community and/or humanity by analyzing the rate of firearm injuries and deaths in a French city and discussing the different governments' politics.

Firearms are a major cause of injuries and death in many countries, especially in the USA. In France, injuries caused by firearms account for only a small percentage of trauma admissions and deaths but are frequently the subject of media and public attention.

Materials: This study is a retrospective study. The authors examined the epidemiology of firearms injuries presenting to University Hospital of Angers from January 1990 to December 2000 (Institute for Legal Medicine and Unit of Intensive Care). Information was collected from forensic medical files, police reports, and judicial files.

Results: One hundred sixty-eight of firearm injuries were analyzed. The mean age was 42 years. Of the cases reviewed eighty percent were male and 74% died. Of the 90 weapons that could be positively identified, 20% were handguns. Most often, the shooters used a rifle—especially a shotgun. In many of the cases where a rifle was confirmed as the firearm used in the shooting, it was a 0.22 calibre low-velocity weapon. One hundred seventeen (70%) were classified as suicides: victims were often males, about 43 years old and the death rate was high (75%). The head and neck was the most favored site, accounting for 72% of the wounds; the presternal-precordial region of the chest accounted for 17% of the wounds. Twenty-five percent (25%) of cases were homicides: 57% male and 43% female. The presternal-precordial region of the chest was the most favored site (40%). Five cases (3%) were accidents: these injuries were sustained during handgun training, cleaning, or carriage of the weapon. Only four cases (2%) were undetermined.

Discussion: In France, the deaths from firearms represent 3,100 deaths / year (population: about 55 million). This rate is lower than other countries with flexible laws. Stricter gun control laws were enacted by the government, prohibiting the ownership of military-style, high-velocity, semi-automatic rifles. Indeed, no shooting in this series involved high-velocity weapons, and nationally these weapons account for only 1% of all firearm deaths. However, firearms are a frequent means of suicidal death, and the number of homicides committed with a firearm is not insignificant. Continued restricted access to firearms is necessary to maintain France's relatively low rate of fatal injuries.

Forensic Pathology, Wounds Ballistics, Firearms

G3 Evaluation of a Novel Tagging and Tissue Preservation System for Human Remains

Martin Grassberger, MD, PhD, and Christina Stein, PhD, Department for Forensic Medicine, Medical University of Vienna, Sensengasse 2, Vienna, A-1090, Austria; Stefan Hanslik, PhD, Identilab Forensic Services, Handelskai 94-96, Vienna, A-1200, Austria; and Manfred Hochmeister, MD, Department for Forensic Medicine, Medical University of Vienna, Sensengasse 2, Vienna, A-1090, Austria*

The goal of this presentation is to describe a new, easy-to-use, barcode-based tissue collection, preservation and body tracking system, which might prove instrumental in the containment of mass fatalities such as aircraft accidents, war-related accidents, environmental disasters (e.g., earthquakes, hurricanes, floods), terrorist bombings, or mass murders.

This presentation will impact the forensic community and/or humanity by simplifying the use of this tissue collection and body tagging system, as well as the convenience afforded by working in an ambient temperature environment without the requirement of a refrigerator/freezer or any other additional device, while maintaining DNA integrity for a long period of time, representing potential benefits for the forensic community.

Tissue preservation is a critical issue in forensic investigations where human remains are collected for DNA analysis. The maintenance of a forensically sound chain of custody is also a critical part of field as well as laboratory practice. Low ambient temperatures and rapid recovery of human remains are ideal conditions to ensure successful DNA analysis. However, such conditions are rarely met in disaster areas, which are often encountered in geographically remote regions of the world. The new ear-tag system TypiFix™ works simply by pushing a clamp-like applicator. By

operating the loaded applicator a tissue sample is punched out by a collection stud and automatically introduced into a self-sealing sample container. In the tightly sealed sample container, the tissue and its DNA are preserved through desiccation by molecular sieve beads consisting of sodium-aluminium-silicate. The ear-tag and sample container are preprinted with the same identification number as well as a barcode. They are attached to each other until the sample is introduced in the sample container. Through this simultaneous barcoding of the remains and the tissue sample at the point of recovery, sample switch is excluded.

A feasibility study was conducted to determine the usefulness and the limitations of this device in a forensic setting and to evaluate the effect of long term storage of tissues in the sealed TypiFix™ container on DNA analysis using short tandem repeat (STR) methodology. Ten bodies were selected for this study (time since death 3 - 25 days). Tissue sampling with simultaneous tagging was performed at the interdigital fold between the thumb and the index finger of either hand using the TypiFix™ applicator. Samples were stored at room temperature and processed at 2 weeks and 6 months after collection. Using a special extractor clamp provided by the manufacturer of TypiFix™, the bottom of each sealed sample container was removed and dry tissue samples were transferred to 1.5 ml eppendorf cups. The tissue samples were subjected to DNA extraction using the QIAamp DNA Mini Kit (tissue protocol, Qiagen Inc., Valencia, CA). Quantification of human genomic DNA was determined using real-time PCR (ABI PRISM® 7000 Sequence Detection System) and the Quantifiler™ Human DNA quantification kit (Applied Biosystems). Autosomal STR analysis was carried out with 1 ng of genomic DNA using the AmpFLSTR® SGM Plus® PCR amplification kit. All analyses were performed in accordance with the manufacturer's instructions.

On average 8 ± 5.7 µg DNA (mean \pm SD) were purified from each sample. The success rate of STR genotyping after 2 weeks and 6 month was 100%. DNA profiles after six months of storage were identical to those obtained after two weeks.

Currently, the most commonly used method of preserving tissues for subsequent DNA analysis is freezing. Very few alternative approaches have been developed to preserve soft-tissue samples at room temperature. Using the described system keeps the collection costs low, provides fast and reliable DNA samples from a large number of individuals in a short time, and ensures a forensically solid chain of custody from the point of recovery in the field to the DNA analysis in the forensic laboratory.

The collection of tissue-samples for DNA analyses can easily be achieved under field conditions. In case of mass fatalities it enables investigating authorities to collect numerous specimen for DNA analysis and simultaneously label the remains. Barcodes can be manufactured according to customers' needs. The system is fail-safe and fraud-proof. The specimen container is contamination-proof since only the single-use parts come in contact with biological materials. The tissue sampling for DNA analysis is possible without the need to refrigerate or freeze samples. According to the manufacturer, tissues stored over 4 years in the TypiFix™ system are still suitable for amplification of long fragments by PCR.

Therefore the TypiFix™ system provides a new, reliable and useful tool for the recovery and simultaneously labeling of human remains and tissue samples in mass fatalities.

DNA Analysis, Tissue Preservation, Disaster Identification

G4 Lesch-Nyhan Syndrome and Child Abuse

Andrea M. Berzlanovich, MD, Institute of Forensic Medicine, University of Vienna, Sensengasse 2, Vienna, 1090, Austria; Martin Kraupp, MD, Department of Medical Chemistry, Medical University of Vienna, Währinger Straße 10, Vienna, A - 1090, Austria; Johannes A. Hainfellner, MD, and Herbert Budka, MD, Institute of Neurology, Medical University of Vienna, Währinger Gürtel 18-20, Vienna, A - 1090, Austria; Wolfgang A. Keil, MD, Institute of Forensic Medicine, University of Munich, Frauenlobstraße 7a, Munich, D - 80337, Germany; and Barbara Fazeny-Dörner, MD, Department of Medicine I, Medical University Vienna, Währinger Gürtel 18-20, Vienna, A - 1090, Austria*

After attending this presentation, attendees will understand the importance of distinguishing child abuse from Lesch-Nyhan syndrome (LNS); understand the first description of postmortem verification; and understand the diagnostic significance of the absence of the HPRT-enzyme in the deceased.

This presentation will impact the forensic community and/or humanity by describing how LNS should be suspected chiefly when self-injurious behavior is associated with the typical motor dysfunction and excessive production of uric acid. This may clearly distinguish it from child abuse.

Postmortem analysis of HPRT-enzyme activity is a new and important tool for forensic work-up, enabling—especially in cases of doubt—a first and guiding diagnostic step before parents are confronted with suspicion of child abuse. A confirmation of the HPRT-enzyme deficiency may not completely exclude additional child abuse. However, careful forensic analysis, including enzyme-diagnostics, combined with the presence of injuries typical of self-mutilation, will help to clarify the facts.

LNS is characterized by neurologic dysfunction, cognitive and behavioral disturbances, and uric acid overproduction. It results in complete deficiency of the enzyme hypoxanthineguanine phosphoribosyltransferase (HPRT), which catalyzes the conversion of hypoxanthine to inosine monophosphate (IMP) and guanine to guanine monophosphate (GMP) in the presence of phosphoribosylpyrophosphate (PPP). Thus, the deficiency of HPRT activity leads to accumulation of PPP resulting in excessive uric acid production and hyperuricaemia.

The hallmark feature of the disease is persistent self-injurious behavior with biting the lips, buccal mucosa and/or fingers, often resulting in partial or total destruction of perioral tissues and amputation of tongue and fingers.

The deceased, a four-year-old boy, was born after uneventful gestation and delivery. At the age of six months, he developed marked spasticity, double hemiparesis and choreoathetosis. Because the neurologic deficits were progressive and the serum level of uric acid elevated, LNS was suspected. This suspicion was confirmed after evaluation of HPRT-enzyme activity, which was almost completely missing. Initial self-mutilation occurred around the age of 18 months, following an accidental, pain-producing injury. Feeding was difficult and spasticity developed in upper and lower extremities; the boy could neither sit, nor stand nor walk without help, and he couldn't speak, only babble. He experienced several respiratory infections. One morning he had an elevated temperature of 101° F, without other signs of infection. After breakfast, he fell asleep, and a short time later, his mother found him lying in bed unconscious after vomiting. Paramedics performed resuscitation procedures without success. Although the boy's mother reported the diagnosis of LNS, suspicion of child abuse arose because of his injured fingers and his malnutrition. A forensic autopsy was performed.

Autopsy revealed an undernourished boy with developmental delay. His thumbs were scarred from repeated episodes of biting; his tongue, lips, and buccal mucosa showed abrasions. Both lungs showed pneumonia and discrete food aspiration; internal and microscopic examinations were otherwise unremarkable.

The formation of ¹⁴C-IMP was measured in a radioisotope assay in which ¹⁴C-labeled hypoxanthine was converted to the labeled nucleotide. Purine base and nucleotide were separated by thin layer chromatography, the radioactivity in the nucleotide and base fraction was determined by liquid scintillation counting, allowing the calculation of the amount of purine base converted to nucleotide. The erythrocytes were extracted. The assay was carried out by mixing assay buffer, PPP, and ¹⁴C-hypoxanthine with the sample. The reaction was stopped by cold perchloric acid. After centrifugation, the supernates were neutralized with equivalent amounts of KHCO₃ and KCLO₄ precipitated by centrifugation at 4°C. The supernates were spotted on aluminum backed silica-gel-thinlayer sheets containing a fluorescence indicator using unlabeled hypoxanthine, inosine and IMP as carriers. The spots containing hypoxanthine, inosine, and IMP were identified under UV-light, cut out and the radioactivity quantified by liquid scintillation counting. The controls of the series of postmortem enzyme assays demonstrated the HPRT-enzyme to be in the normal range at least up to five days after death. It was thus concluded that the HPRT-enzyme is relatively stable postmortem as compared to the boy's HPRT-enzyme activity of less than 1.5% one day after death, demonstrating the complete deficiency of the enzyme.

LNS should be suspected chiefly when self-injurious behavior is associated with the typical motor dysfunction and excessive production of uric acid. This may clearly distinguish it from child abuse. Postmortem analysis of HPRT-enzyme activity is a new and important tool for forensic work-up, enabling—especially in cases of doubt—a first and guiding diagnostic step before parents are confronted with suspicion of child abuse. A confirmation of the HPRT-enzyme deficiency may not completely exclude additional child abuse. However, careful forensic analysis, including enzyme-diagnostics, combined with the presence of injuries typical of self-mutilation, will help to clarify the facts.

Autopsy, Child Abuse, Postmortem HPRT-Enzyme Analysis

G5 Determining a Postmortem Submersion Interval (PMSI) Based on Algal/Diatom Diversity on Decomposing Mammalian Carcasses in Brackish Ponds in Delaware

John R. Wallace, PhD, Kathryn Zimmerman, and Erin High,
Department of Biology, Caputo Hall, Millersville University,
Millersville, PA 17551*

The goal of this presentation is to share a new technique to utilize a much-neglected biological evidence (aquatic plants) to determine a post-mortem submersion interval. The authors intend to demonstrate how algae and diatoms can be used in medicolegal investigations involving brackish or saline aquatic systems. The attendee will learn how to sample, photograph and identify algae and diatoms useful in forensic science.

Because very little is known on how bodies decompose in freshwater, brackish, and marine environments, and much less is known on how to determine a postmortem submersion interval (PMSI) (i.e., determine the time a body has been submerged in an aquatic environment until the point of discovery), this presentation will impact the forensic community and/or humanity by adding to a much neglected but growing database on decomposition in aquatic environments. The authors hope to provide the first analysis of mammalian decomposition in brackish ponds using botanical evidence to determine a PMSI. This approach has been used in freshwater systems but not in saline environments such as brackish ponds. It is hoped using this technique and type of plant evidence will shed new light in determining how long a body may have been submerged in these types of aquatic systems.

Algae and diatoms have been employed to estimate the location of drowning victims as well as link criminal suspects to specific aquatic crime scenes. However, little or no evidence exists on documenting algal

colonization and succession on mammalian carcasses in brackish or marine environments. The purpose of this presentation is to document how saline environments influence not only the rate that pig carcasses decompose, but also characterize the algal/diatom community at each stage of decomposition in order to use species diversity and composition indices to estimate a PMSI. The objectives of this study include: 1) characterize the physical changes and rate of pig decomposition in saline aquatic systems; 2) compare algal diversity on pigs to a natural substrate such as ceramic tiles and; 3) determine if species richness or diversity differs among stages of decomposition. This study was conducted in two slightly brackish water (brackish is defined as salinity levels between 5-18% parts per thousand-ppt) ponds near Smyrna, Delaware. The stages of decomposition were identified and characterized by physical changes. The duration of each stage was estimated in degree days. Water temperature was recorded for the duration of each trial. Salinity measurements were determined using a refractometer. To examine algal diversity on pig carcasses vs. a natural substrate, samples were collected every 3 days (trial one) and every 2 days (trial two) for approximately 20 days. Algal samples were preserved in Lugol solution and glacial acetic acid and stored in dark conditions until analysis. Algae and diatom species were identified using a light microscope and photographed with a Nikon Digital Camera. Species diversity and evenness among stages of decomposition were determined using Shannon and Simpson's diversity indices. The mean diversity indices for pig carcasses and ceramic tiles were compared using a t-test. Previous studies have revised or suggested that five (not six) stages of decomposition have been identified for mammalian carcasses in freshwater aquatic systems. Five stages are described in this study: Submerged Fresh, Early Floating, Advanced Floating Decay, Floating Remains, and Sunken Remains. Ponds in this study maintained a salinity value of 2-4 ppt. Accumulated degree days for trial one of this study was 893 degree days. Pigs began to float within three days, the duration of the Early Floating stage ranged from 3-9 days; Floating Decay stage ranged from 6-12 days; Advanced Floating Decay stage ranged from 9-21 days, and pigs sank within 15 – 24 days. The submerged fresh stage was characterized as the time the body initially entered the water until it floated to the water surface. Few physical changes were observed during this stage. The Early Floating stage was identified as when the pigs floated and began to bloat, forming indentations from the cage on their skin and with some algal growth. Little to significant disarticulation of limbs was observed on floating pig carcasses. The Advanced Floating Decay stage was characterized as much of the carcass having been removed, with the skull exposed and the loss of limb bones. The Sunken Remains stage was identified when the remains sank to the pond bottom with only bits of bones remaining. Algal diversity was significantly greater on pig carcasses than ceramic tiles. Diversity increased significantly as decomposition progressed until pig carcasses had reached the advanced floating decay stage. Mammalian carcasses will support algal/diatom communities and that these communities experience plant succession similar to terrestrial habitats. However, in terrestrial systems, plant succession/diversity increases over time; in aquatic systems, plant succession/diversity will increase and eventually decrease as the substrate (mammalian carcass) decomposes. This study shows how algal/diatom diversity and taxonomy can be used to determine the duration a submerged victim has been under water.

Brackish Ponds, Diatoms, Postmortem Submerged Interval

G6 Immunocompromised Female, Age 67, With an Angioinvasive Pulmonary Fungal Abscess

Darshan R. Phatak, MD, Beth Israel Deaconess Medical Center,
Pathology Department, 330 Brookline Avenue, Boston, MA 02215*

After attending this presentation, attendees will understand the vulnerability of the immunocompromised person to opportunistic organisms that may present unexpected autopsy findings and the necessity of a complete medical history.

This presentation will impact the forensic community and/or humanity by providing an added appreciation for a thorough medical history as an aid to correlate and make sense of unexpected autopsy findings in the immunocompromised.

This poster will present the autopsy of a 67-year-old Caucasian female with a longstanding history of hairy cell leukemia (HCL) refractory to chemotherapy in whom the pertinent autopsy findings included not only residual HCL, but also a large necrotic abscess within the right lung upper and lower lobes containing thrombus and angioinvasive fungal forms consistent with *Aspergillus* species.

The immunocompromised comprise a subset of the general population who are extremely susceptible to opportunistic organisms whether due to their primary disease process, medicines or therapies used to treat their underlying illness, or other medical conditions acting in concert with the above to render them extremely vulnerable to viruses, bacteria, fungi, and parasites.

This particular patient presented to the hospital after having low to moderate grade fever, nonproductive cough, and a sore throat for five days. After a workup revealed anemia, thrombocytopenia, leukopenia, and radiographic evidence of right lower lobe lung infiltrates, she was administered leukoreduced and irradiated packed red blood cells, a course of levofloxacin and erythropoietic drugs, and discharged.

She presented again eight days after her initial presentation complaining of persistent fevers, chills, an increase of coughing (now with pain), and pain on swallowing. She was admitted and made DNI/DNR. New imaging studies showed a mass lesion bridging the right upper lobe and superior segment of the right lower lobe suspicious clinically for acute infection vs. Leukemic infiltration. Despite administration of Zosyn and Ambisone during her inpatient course, there was no improvement in her condition. After a bronchoscopy with BAL, which was positive for *C. albicans*, the patient required oxygen via nasal canula to maintain oxygen saturation above 94%.

On the morning of her death, the patient had episodes of hemoptysis with dark blood, then bright red blood. She emergently underwent repeat bronchoscopy, where it was noted that there was a right tracheal obstruction thought to be clot and tissue. Attempts to remove the obstruction were unsuccessful and the patient entered asystole.

Even though this particular case occurred in the setting of a tertiary care teaching hospital, people having conditions analogous to that of the decedent are often maintained on therapeutic drug regimens in outpatient settings and can present as cases of sudden unexpected death to medical examiner offices. It is not only important, therefore, for primary care givers to be sensitive to changes in the baseline health of their patients as these may be the heralds of opportunistic infection, but also crucial for those performing the postmortem to obtain a complete medical history including medicines used (and if applicable, chemotherapy and radiotherapy) and to keep opportunistic infections in their differential as to the mechanism of death.

Hairy Cell Leukemia, Aspergillus, Autopsy

G7 Teen Fatality by Train: A Multidisciplinary Approach to Determination of Manner of Death

Mary H. Dudley, MD, Sedgwick County Regional Forensic Science Center, 1109 North Minneapolis, Wichita, KS 67214*

The goal of this case study is to illustrate a multidisciplinary approach to the death investigation, and highlight unique elements of staging in an attempt to disguise a suicide.

This presentation will impact the forensic community and/or humanity by demonstrating the value of a forensic team approach to the investigation of the circumstances of death for determination of the manner in complicated or staged death scenes.

Attempts by the victim to disguise suicides as homicides are not commonly encountered, and the following case study illustrates the requirement for a multidisciplinary approach to the investigation. Professionals from the disciplines of documents examination, fingerprint comparison, odontology, toxicology, forensic pathology, and law enforcement all provided information essential in the determination of manner of death.

The decedent was a 19-year-old male who resided in a small community in the Midwest. He recently graduated from high school, as class valedictorian, where he had excelled in sports as well as academics. During the early morning hours on a day in July, 2004, the engineer of a train traveling 60 miles per hour, approximately four miles from the decedent's residence, reported that he had struck "something" on the tracks. Upon searching the area, the decedent's unclothed body was discovered. The train traffic in the region where the body was discovered was reportedly fairly busy with trains passing through approximately every 30 minutes. The identity of the subject remained unknown until later that morning when family members reported the subject missing. Law enforcement investigators examined the decedent's bedroom, and discovered a handwritten note, in block letters, which indicated that the decedent had been abducted. The note, signed "The Eliminators," further made mention that the "train took care of him" and that investigators "might find a few pieces of him left at the train crossing" at a specific site. Pillows had been placed beneath the bedding to imitate a body, and the note had been placed on the pillows. There was no evidence of a struggle, and a sibling had been sleeping nearby. An exterior door in the residence near the bedroom had been discovered ajar. Further evidence recovered from the residence was a journal written by the decedent. Additional information provided by family revealed that the decedent was last seen the previous evening following a confrontation with his parents concerning his purchase of alcohol for a minor.

At autopsy, there were extensive blunt force injuries with multiple facial, basilar and calvarial skull fractures; avulsion of the brain and eyes; multiple fractures to the ribs, spine, and extremities; and multiple lacerations to internal organs. Also noted at autopsy were strands of baling wire wrapped loosely around the right wrist, waist and both ankles. Law enforcement investigators indicated that baling wire had been noted at the residence, and later discovered beneath the tracks where the impact occurred. Positive identification of the subject was obtained through dental comparison by an odontologist. A documents examiner analyzed the handwriting on the note, and it was compared with the subject's handwriting obtained from documents produced as schoolwork. The documents examiner determined that the handwriting on the note, though efforts had been made to disguise it, was consistent with the decedents' previously produced documents. A latent print was also obtained from the note, and was identified as the subject's. The content of the journal was also reviewed, and revealed the decedent's increasing despondence and self-doubt.

Despite the decedent's attempts to lead investigators to believe he had been a victim of homicide, the manner of death was determined to be suicide. Staging a homicide may be an effort to gain notoriety, install guilt or protect family members. Following this investigation, the decedent's motive for disguising the suicidal act remains unclear.

Staging, Multidisciplinary, Train Fatality

G8 A Fatal Case Due to Abdominal Compartment Syndrome (ACS)

Margherita Neri, MD, Marianna Di Padua, MD, and Emanuela Turillazzi, MD, PhD, Department of Forensic Pathology, University of Foggia, Viale Pinto 1, Foggia, 71100, Italy*

The goal of this presentation is to present to the forensic community a case of death due to a rare systemic syndrome: abdominal compartment syndrome (ACS).

This presentation will impact the forensic community and/or humanity by presenting a case worthy of reporting for the rareness of the syndrome and its great surgical and forensic interest.

This case has been studied by means of autopsy and histological examinations.

Abdominal compartment syndrome (ACS) is broadly defined as organ dysfunction derived from increase in intra-abdominal pressure. Prolonged, unrelieved increased intra-abdominal pressure at more than 20 mm Hg can produce pulmonary compromise, renal impairment, cardiac failure, shock, and death. This presentation discusses the clinical-pathologic features, the postmortem findings and microscopic features of a fatal case due to ACS.

Case Report: A 35-year-old Caucasian female went to the emergency room with increasing abdominal pain. The woman, admitted to the surgery unit, underwent a physical examination. It showed a sharply distended and painful abdomen, no peristalsis, and rebound tenderness. At abdominal ultrasonography, stomach and bowel loops appeared distended with copuscolated liquid material. Abdominal x-ray showed small bowel distended with air-fluid levels. Three years before, the woman had undergone an appendectomy. She was taken into the operating room for intestinal occlusion due to adhesions. On the first postoperative day, the patient had shock with numbness, cutaneous pallor, sweating, cutaneous marbling on upper and lower limbs, tachycardia, tachypnea, peripheral pulselessness, oliguria, and severe metabolic acidosis. After another day of continuous deterioration of her clinical condition, she was moved to the Intensive Care Unit. Her abdomen seemed distended, with no peristalsis; CT-scan confirmed bowel distention due to fluid and gas, with perihepatic and perisplenic fluid collections. Laboratory tests demonstrated leukopenia, neutropenia, and metabolic acidosis. Gynecologic examination revealed a rectocele. On the second day in the Intensive Care Unit the woman continued to get worse. She had anuria and hypotension; her intra-abdominal pressure, measured inside the urinary bladder by means of an ordinary Foley catheter, was 35 cm H₂O. Taken into the operating room for surgical abdominal decompression, the woman died. A complete autopsy was performed 48 h after death.

At autopsy the body was that of a well-developed adult with pale and dehydrated skin, ostia, and oral and scleral mucosae. The brain was congested and edematous. The left pleural cavity contained 200 ml of red liquid; the right pleural cavity contained 400 ml of the same liquid. The lungs were hypoexpanded and atelectatic. The peritoneal cavity contained 1000 ml of red liquid. The intestines appeared distended, with brown liquid material and pseudomenbranes in the large bowel. Examination of other organs was unremarkable.

The histological findings of the liver revealed necrosis in acinar zone 3. The kidney showed characteristics of shock: collapse, swellings of endothelial and surface cells, broadening of the basal membrane, and impairment of the loops in the glomeruli. The epithelia of tubules were flattened, and their nuclei were enlarged. The bowel wall showed areas of epithelial necrosis, fibrinous stratification, and inflammatory infiltration spread up to the muscularis mucosae.

It was concluded that the cause of death was fatal shock due to Abdominal Compartment Syndrome (ACS).

ACS is a clinical syndrome that occurs as a consequence of intra-abdominal hypertension. ACS is characterized by a tensely distended abdomen, elevated peak airway pressure, and impairment of cardiac and renal functions, leading to oliguria or anuria. Any insult that causes an acute increase in intra-abdominal volume can trigger ACS, including trauma to the abdomen as well as to distant sites, pancreatitis, hemorrhage, intestinal occlusion, ruptured abdominal aortic aneurysm, massive fluid resuscitation, and burns. The syndrome usually occurs in critically sick patients after major abdominal trauma or operations. Several cases were described where the syndrome developed without direct abdominal insult. These cases, however, were associated with severe hemorrhagic shock, burns, massive ascites, ileus, ovarian mass, or the use of anti-shock trousers.

According to clinical symptoms and measuring of intra-abdominal pressure, it is possible to make a timely diagnosis of ACS and operate for a prompt abdominal decompression. Clinical studies show a significant difference in mortality between ACS patients undergoing abdominal decompression and untreated patients (59% vs 100%). Further studies point out that a timely abdominal decompression and early treatment reduce both the incidence of ACS (64% vs 43%) and mortality of ACS (44% vs 28%) in patients at risk.

Abdominal Compartment Syndrome, Histological Findings, Postmortem Diagnosis

G9 Cane Corsos Attack: Two Fatal Cases

Sabina Di Donato, MD, and Emanuela Turillazzi, MD, PhD, Institute of Forensic Medicine, University of Foggia, Viale Luigi Pinto, 1, Foggia, 71100, Italy; Fernando Panarese, MD, Department of Experimental and Clinical Medicine, University of Magna Grecia, Policlinico Universitario Catanzaro, Via Tommaso Campanella 115, Catanzaro, 88100, Italy; Pietrantonio Ricci, MD, Department of Experimental and Clinical Medicine University of Magna Grecia, Policlinico Universitario Catanzaro, Via Tommaso Campanella 115, Catanzaro, 88100, Italy*

The goal of this presentation is to present the case of two spouses who were slaughtered by their three pet Cane Corsos. Investigations of the death scene and autopsy findings are described.

Although dog bite related fatalities on humans appear to be a breed-specific problem (Rottweiler and Pit Bull), other breeds may bite and cause fatalities at higher rates. Here the authors present the cases of spouses slaughtered by their own three Cane Corsos, an Italian Molossoid dog breed. This presentation will impact the forensic community and/or humanity by confirming the inadequacy of breed-specific ordinances.

The most common animal bite injuries in the United States are inflicted by dogs, accounting for 80-90% of all bites. It is estimated that between 1 and 4 million Americans are annually bitten by "man's best friend;" approximately 1 in 20 dogs will bite a human being during the dog's lifetime. The vast majority of these dog bite wounds produce minor injuries, and the victims never seek medical attention, but serious sequelae, and even death, may occur. In 2001, the U.S. Centers for Disease Control and Prevention (CDC) estimated that 368,245 persons were treated in U.S. hospital emergency departments (EDs) for dog bite-related injuries (rate: 129.3 per 100,000 population). Bite wounds, in fact, account for approximately 1% of all emergency department visits and more than \$30 million in annual health care costs.

Annual mortality rates from dog attacks are reported at 7.2 cases for 100 million inhabitants. Many victims of these fatalities, unfortunately, are young children (often <1-year-old), and old people (mainly women); in fact, these two groups are made up of weak and defenseless individuals, generally unable to protect themselves properly.

There is a strict relationship between the victim's age, severity of injuries, and injury site. The majority of dog bites to adults are directed to the extremities; conversely, the most frequent targets of dog attacks towards children are head and neck. This explains why the highest mortality is seen among children.

About 50% of fatal attacks towards human beings involve two or more dogs; on the contrary, non fatal bites almost always involve only one dog. In fact, belonging to a pack usually makes dogs behave more aggressive, and increases the probability of causing the victim's death.

The most commonly reported breeds are Pit Bull, Rottweiler, German Shepherd, Golden Retrievers, Husky, and Akita. Presented the case of a couple slaughtered by their three Cane Corsos, in the garden adjacent to their own house. The husband, a 76-year-old man, was found lifeless, lying face down in the bloodstained ground, completely covered with blood. He wore trousers and a pair of shoes, but his legs were hidden by leaves. His trunk was completely naked, but numerous shards of clothes were scattered

all around the area of aggression, abundantly blood stained. Injuries were localized to head, neck, trunk, and upper limbs, while the genitalia and lower limbs remained intact. The scalp was almost totally absent, so that the frontal, part of the temporal, parietal and occipital bones lay bare. The left lower eyelid and the left zygomatic region showed a stretch laceration of 4.5 x 3.2 cm, with exposure of the underlying bones; the left external ear presented a grossly semicircular recession of 3 x 2.5 cm. On the left supracleavicular region there was a deep oval shaped laceration of 5.4 x 4.7 cm, with the exposure of the clavicle, muscles, nerves, and resected vessels. There were numerous lacerations on the right side of the neck, the main one was a deep oval shaped gaping wound of 9.2 x 8 cm, which exposed part of the mandible, lacerated musculature and vessels. The left upper arm showed numerous gaping wounds, in particular the deepest were localised on the upper and lower part of the arm, on the elbow, and on the radial face of the forearm exposing, respectively, the humerus and the radius, lacerated muscles, tendons, nerves and vessels. Similar injuries were on the right upper arm, and in particular in the axillary cavity and on the elbow, where underlying tissues appeared completely destroyed. All these torn wounds presented ragged and irregular margins with adjacent puncture wounds, the so called a-hole-and-a-tear combination. In the vicinity of the bites described, but in particular on the back, were found the typical claw-marks: narrow, superficial, linear abrasions, parallel to each other, four or five in number. The wife, a 70-year-old woman, presented similar wounds over the upper extremities, neck and trunk. The internal examination of both deceased revealed mainly multiple transmural vessels tears. Deaths were attributed to exsanguination by external bleeding.

These represent unique cases, because, there appears to be no previous reports of fatal attacks with the involvement of the Cane Corso, an Italian breed of Molossoid dog. This confirms that all types of dogs may inflict injuries—even fatal—to people, and reveals the inadequacy of breed-specific ordinances.

Dog Bite, Fatal Dog Attack, Cane Corso

G10 Fatal Dog Maulings Associated With Infant Swings

Albert Y. Chu, MD, MHS, Carol Allan, MD, Mary G. Ripple, MD, Tasha Z. Greenberg, MD, and David R. Fowler, MD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD 21201*

After attending this presentation, attendees will become familiar with the phenomenon of dog bite-related fatalities involving children left unattended in infant swings. In addition, attendees will become familiar with the epidemiological, medical, and forensic aspects of fatal dog maulings in children.

This presentation will impact the forensic community and/or humanity by suggesting an as yet undescribed association between infant swing use and dog attacks, which may have significant child safety implications. It will also impact the forensic community by increasing its awareness of the general features of dog-bite-related-fatalities.

Two cases of fatal dog maulings of children left unattended in wind-up infant swings are presented, an event not previously described in the literature. In addition, a review of dog bite fatalities in children autopsied in Baltimore over the last ten years and a review of the existing literature on this topic will be presented.

Case 1: A two-and-a-half-week old male infant was left in a wind-up swing by his parents, who went outside to smoke cigarettes. The family dog, a one year-old pit bull named “Jigga,” remained in the room with the infant. Upon their return, the parents discovered that the swing was overturned and the infant was on the floor, unresponsive, with bite marks to the body and face. Postmortem examination revealed multiple injuries, including contusions, abrasions, lacerations, and puncture wounds of the

head and torso, fracture of the parietal skull, subarachnoid hemorrhage, multiple anterior and posterior rib fractures bilaterally, contusions of the lungs and heart, and lacerations of the liver.

Case 2: A three-month-old male infant was asleep in a wind-up swing when his parents went to bed in a separate bedroom. Three hours later, the mother awoke and, upon checking the infant, found him on the floor unresponsive with the swing tipped over. The family dogs that were present, an eight year-old Chow Chow named “Sandy” and a nine year-old Dachshund named “CoCo,” were removed by Animal Control. Postmortem examination revealed multiple injuries consistent with attack by a medium to large sized dog, including numerous contusions, abrasions, lacerations, and puncture wounds of the skin; damage to the atlanto-occipital joint; fractures of the skull, mandible, clavicle, and ribs; rupture of the spleen and left kidney; laceration of the liver; and contusions of the lung.

Dog bite-related fatalities are uncommon events. Children are at particularly high risk, because the majority of dog bites occur in children and children are more susceptible to severe injury from dog bites. Other known risk factors for fatal dog attacks include male gender of the victim and dog breed; a majority of attacks occur on the dog-owner’s property and often without any known provocation.

Canine aggression is a well-described behavioral phenomenon and has been subdivided into various types; of these, predatory aggression refers to the hard-wired instinctual drive to chase, catch, and kill prey. A distinguishing feature of predatory aggression is that it is usually triggered by movement, often with little change in the dog’s mood. In each of the above cases, infants were left unattended in mobile wind-up swings in the presence of trusted household pets. These cases not only underscore the importance of not leaving young children unattended in the presence of pet dogs, but also raise the possibility that mobile swings may trigger a predatory response in dogs and thus may represent an additional risk factor for dog attack.

Dog, Infant, Swing

G11 Contribution of Burn Injury in a Blunt Trauma Case With Incineration

John B. Davis, BS, Eastern Virginia Medical School, 700 West Olney Road, Norfolk, VA 23507-1607; and Leah L. Bush, BS, and Wendy M. Gunther, MD, Office of the Chief Medical Examiner, Tidewater District, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510-1046*

The goal of this presentation is to discuss a complex case in which incineration, not the primary cause of death, may have occurred just prior to death from blunt head trauma, in a homicide. In addition, the authors review recent literature on significance of carbon monoxide, traces of tracheal soot, and other findings, in determining whether incineration occurred antemortem or postmortem.

This presentation will impact the forensic community and/or humanity by discussing the issues involved in determining whether incineration of a body, on which lethal blunt head trauma had been inflicted, occurred before or after death.

Assailants in homicide have often made use of incineration in an attempt to conceal the evidence of the crime. Incineration usually occurs postmortem. Accelerants are sometimes used. This case illustrates the questions that arise when autopsy findings suggest that burn injury may have begun before death.

The Virginia Beach Fire Department responded to a rubbish fire in a field. On extinguishing the blaze, they discovered the unburned shoes and lower legs of an unidentifiable, partially incinerated decedent, extending from the burned rubbish. Local law enforcement was called to the scene, and the body was transported to the Medical Examiner’s Office.

The body proved to be that of an adult male, with charring present over most of the body surface area, but with sparing of both lower legs and

portions of the upper arms. There was exposed muscle, partial skeletonization of the face, and a postmortem epidural hematoma. In addition to the charred body, a distinct odor of accelerant was noted on the debris and clothing transported with the body. Autopsy revealed blunt impact trauma to the right side of the victim's head, traces of soot in the trachea, and cherry red discoloration of the muscles.

Investigation suggested that an assailant had attempted to destroy evidence of homicide by pouring an accelerant over the victim's body and igniting it after inflicting blunt trauma to the head. The literature states that traces of soot in the trachea may occur postmortem. The contribution that burning may have made to this blunt trauma homicide, the role of carbon monoxide determination in flashover burns, and evidence in general for antemortem vs. postmortem incineration, will be discussed.

Incineration, Antemortem Burn Injury, Blunt Trauma Homicide

G12 A Field Study of the Foraging Behavior of Blowfly Maggots

David L. Gibo, PhD, and Deana Hathout, BSc, University of Toronto at Mississauga, 3359 Mississauga Road North, Mississauga, Ontario L5L 1C6, Canada; Brent Walker, BA, Conestoga College, Law and Security/Police Foundations, School of Health Sciences and Community Services, 299 Doon Valley Drive, Kitchener, Ontario N2G 4M4, Canada; and Brian Dixon, PhD, 1645 Howat Crescent, Mississauga, Ontario L5J 4G6, Canada*

After attending this presentation, attendees will understand the possibility that the largest blowfly maggots found on a body may be relatively recent arrivals, having crawled over to the fresh remains when their initial food source (e.g., a dead mouse) became depleted, resulting in the risk of significant errors by investigators attempting to calculate postmortem interval.

This presentation will impact the forensic community and/or humanity by alerting the forensic community to the possibility that if foraging behavior by food-deprived blowfly maggots is a reasonably common phenomenon, larger (older) blowfly maggots that have managed to find their way to a fresh body can be a source of large errors when investigators attempt to calculate postmortem intervals based on published rates of maggot development times. On the other hand, foraging by food-deprived blowfly maggots could also provide a possible explanation for the presence on bodies of anomalous maggots that are larger than expected according to other independent evidence.

It is generally assumed that the largest, and presumably the oldest, blowfly maggots (i.e., larvae of Calliphoridae) found on a body initially arrived as eggs deposited by flies attracted to the remains. There is the possibility, however, that at least some of the large maggots crawled over to the body from some other piece of carrion in the immediate environment. For example, if a body is dumped in a field near the remains of a dead mouse, and if the mouse remains had been nearly consumed by blowfly maggots, at least some of the maggots may abandon the depleted mouse remains and crawl over to the fresh food source, greatly complicating the situation for forensic entomologists. During the late summer of 2003 and the late spring of 2004, field studies were conducted of the foraging response of blowfly maggots feeding on a depleted, or nearly depleted, food source. The field studies were conducted in cages that excluded vertebrate scavengers but not blowflies and other invertebrates. The experimental situation was manipulated such that the maggots were presented with three choices: (1) remaining on a low quality and rapidly deteriorating food source, (2) abandoning the deteriorating food source and crawling approximately 45 cm across bare soil to a shelter containing a moist cloth and a fresh food source, or (3) abandoning the deteriorating food source and crawling approximately 45 cm across bare soil in the opposite direction to a shelter containing a moist cloth but no food.

In every cage at least some maggots remained on the deteriorating food source until it had either been consumed, dried out, or the experiment was terminated. However, during the late summer experiment of 2003, in 6 of 12 test cages, early third instar maggots of *Lucilia* sp. abandoned a deteriorating food source (i.e., a nearly consumed and/or rapidly desiccating piece of liver), and crawled across the bare soil to reach the shelter containing the fresh food source (approx. 40 gm of fresh beef liver) and began feeding. Similarly, during the late spring experiment of 2004, in 6 of 12 cages, early third instar maggots of *Phaenicia* sp. exhibited the same foraging behavior. The number of foraging maggots that crawled into the food shelters varied greatly, ranging from 1 – 2 individuals (4 cages) to more than 100 (3 cages). In one cage at least 387 maggots, as confirmed by rearing the adult flies (*Lucilia* sp.), had crawled into the food shelter. Although there were 7 cases where maggots crawled into shelters that contained only a moist cloth, the numbers were much lower. In 5 cages where maggots had crawled into the food shelters, one maggot in each cage moved in the opposite direction and crawled into the non-food shelter. In two cages where no maggots had crawled into the food shelters, a single maggot in one cage, and two maggots in the second cage, crawled into the non-food shelters. Finally, in 10 cages no maggots crawled into either shelter.

Blowflies, Maggots, Foraging

G13 Cavotricuspid Isthmus Rupture and Hemopericardium: A Delayed Complication of Cardiac Radiofrequency Catheter Ablation

Ezra Ellis, MD, and Patrick E. Lantz, MD, Department of Pathology, Wake Forest University Health Sciences, Medical Center Boulevard, Winston-Salem, NC 27157*

After attending this presentation, attendees will become aware of delayed fatal complications of cardiac radiofrequency ablation.

This presentation will impact the forensic community and/or humanity by providing heightened awareness of potential complications of cardiac radiofrequency ablation that may occur weeks or months following the procedure.

Radiofrequency ablation (RFA) has been used in humans since 1981 for the treatment of cardiac dysrhythmias. Numerous studies have shown that it has a high success rate with infrequent complications. The indications for RFA include atrioventricular (AV) nodal re-entrant tachyarrhythmias, accessory pathway dysrhythmias, focal atrial tachycardia, atrial flutter and idiopathic ventricular tachycardia. Reported complications include AV block, post-pericardiectomy syndrome, atrio-esophageal fistula, coronary artery stenosis, acute hemopericardium, and delayed right ventricular aneurysm.

A 47-year-old woman had a history of atrial flutter and underwent radiofrequency ablation with an 8-mm catheter. The initial ablation line consisted of 17 radiofrequency applications (maximum power 70 watts and maximum temperature 70 degrees), most for 60 seconds. The line of block extended down from the cavotricuspid region to the inferior vena cava (IVC). A procedural follow-up study showed unidirectional block with a questionable area near the IVC. An additional 20 RFA applications were applied superior to the previous line but the applications were also extended into the IVC. A repeat follow-up study showed successful RFA of her atrial flutter and bidirectional block across the cavotricuspid isthmus at baseline and following an isoproterenol challenge.

Six weeks following her cardiac RFA she presented to another hospital complaining of chest pain. Troponin levels, a cardiac stress test and an echocardiogram were described as normal and she was discharged. Five days later she had a witnessed collapse at home. Emergency medical services responded and found her asystolic. Further resuscitative efforts

were unsuccessful and she was pronounced dead in the emergency department.

At autopsy, she had a cavotricuspid isthmus disruption with a 450 mL hemopericardium. Microscopically, the site of disruption had homogenization, necrosis, fibrosis and extravasated blood. Associated with the fibrosis and necrosis were chronic inflammatory cells and granulation tissue. Elastic fibers were disrupted near the site of rupture and hemosiderin laden macrophages were present.

The authors were unable to find a previous report of delayed cavotricuspid rupture and hemopericardium following cardiac radiofrequency ablation; however, in experimental animal studies damage to the tricuspid valve and IVC occurred most frequently with high energy pulses and 8-mm catheters.

Radiofrequency Ablation, Cardiac Dysrhythmias, Complications

G14 Sudden Death of a Fourteen-Year-Old Female With Hb S-C Disease

Victor V. Frolov, MD, Jeffrey M. Jentzen, MD, and John R. Teggatz, MD, Milwaukee County Medical Examiner Office, 933 West Highland Avenue, Milwaukee, WI 53233*

The goal of this presentation is to review the sudden death of a child with sickle cell anemia – Hb S-C type. The attendees will learn the different genetic forms of sickle cell disease, their complications, and the potential mechanisms of death with sickle cell anemia.

This will impact the forensic community and/or humanity by demonstrating an unusual sudden death in an adolescent with an element of past physical abuse.

According to her caretakers (mother and a grandmother), this 14-year-old black female child had been complaining of vague headache and back pains for several days. At the morning of her death she had complained of her “eyes turning color,” increased headache “behind her eyes,” and difficulty in “straightening out the fingers of her left hand.” Her mother interpreted her daughter’s complaints as predominantly an attempt to avoid school that day, and dismissed them from having any serious medical implications. At 1:00 p.m. that day, she was found lethargic and unresponsive. The mother and grandmother attempted to help her stand up, but failed. Of note, despite the grandmother’s wish to immediately call for help, the mother rejected such initially, and the 911 call was not placed until some time later when the mother “could not feel a pulse.” Paramedics arrived at 3:30 p.m., and she was pronounced dead after resuscitative efforts.

On initial external examination at the Medical Examiner’s Office healed, patterned loop-type scars were noted on the deceased’s torso, buttocks, and extremities. No acute injuries were present. Autopsy examination revealed a well-developed, well-nourished young adolescent female with scleral icterus and an overall slight jaundice appearance. Internal examination was remarkable for bilateral pulmonary edema, massive splenomegaly (spleen weight of 1,190 grams), and evidence of extreme anemia. No internal injuries were present. Microscopic examination was remarkable for extensive sequestering of sickled red blood cells within the spleen and a hypercellular bone marrow with areas of scarring. Postmortem toxicology was negative for alcohol or drug/medication substances other than a small quantity of acetaminophen. Vitreous electrolytes were unremarkable. Postmortem viral and bacterial cultures were negative, although a blood sample was positive on immunoassay for parvovirus B 19 antibodies IgM and IgG.

Sickle cell anemia is an autosomal recessive disease caused by a point mutation in beta hemoglobin gene chromosome 11p 15.4 (Hb S; 6 Glu leads to Val and Hb C; 6 Glu leads to Lys.). Approximately 8% of black Americans are heterozygous HbS. The carrier rate for HbC is about 2%

to 3%. HbC has a greater tendency to aggregate with HbS that does HbA, and hence those with HbS and HbC (designated HbSC) have a more severe disease than do those with HbS and HbA. On deoxygenation, abnormal hemoglobins undergo aggregation and polymerization. This converts the hemoglobin from freely flowing liquid to viscous gel and results in distortion of the red cells, which acquire a sickle shape. Patients have to deal with problems ranging from severe anemia, vaso-occlusive complication, and chronic hyperbilirubinemia to severe infection. In children painful vaso-occlusive crises are extremely common, as well as hand-foot syndrome. An aplastic crisis represents a temporary cessation of bone marrow activity usually induced by parvovirus infection of erythroid cells. Sequestration crisis may occur in children with splenomegaly. With modern treatment approximately 90% of patients survive to the age of 20 years, and close to 50% survive beyond the fifth decade. No reported case of rapid death from Hg S-C type sickle cell anemia was found in the literature.

In this case the child had an acute infection with parvovirus B19, which was confirmed by blood serology. It is believed the cause of death was acute sequestration of blood with an aplastic crisis induced by the parvovirus, and thus ruled the death as natural. The mother of the deceased did not promptly call for medical help. She acted such in fearing the discovery of previous child abuse – which does suggest possible medical neglect and, thereby, a potential for other interpretations as to manner of death.

Sickle Cell Anemia, Hb SC Type, Parvovirus B19

G15 Interpreting Lesions to the Conduction System of the Heart in Case of Death Pursuant to Cocaine Ingestion

Katarzyna Michaud, MD, Thomas Krompecher, MD, Béat Horisberger, MD, Marc Augsburger, PhD, Frank Sporkert, PhD, and Patrice Mangin, MD, PhD, Institut Universitaire de Médecine Légale, Bugnon 21, Lausanne, 1005, Switzerland*

The goal of this presentation is to evaluate the potential role of the pathological lesions of the conduction system in the pathomechanism of death in cocaine users and to demonstrate the difficulties of forensic investigations when death is preceded by cocaine ingestion.

This presentation will impact the forensic community and/or humanity by presenting several cases in which it was concluded that pathological lesions in the conduction tissue may play a role in the occurrence of death attributed to intoxication following cocaine ingestion.

Since 2000, there has been a considerable increase in cocaine use and cocaine traffic in Switzerland. This trend is matched by an increasing number of deaths attributed to intoxication in the presence of cocaine and of its metabolites. However, it is not always clear whether intoxication is the sole cause of death.

Any forensic scientist will agree that death can be attributed to intoxication only after a complete autopsy, which includes histological analyses. Potentially lethal levels of a drug must be found and any other cause of death must be excluded. A rigorous approach is especially important in the case of drug users, which may occasionally present very high levels of certain substances without any sign of severe intoxication.

In the case of death after cocaine ingestion, the interpretation of the results of toxicological analyses carries an additional difficulty. Some victims present pathological lesions, such as cardiovascular lesions, that may or may not be linked to repetitive cocaine ingestion. The long-term and short-term cardiovascular toxicity of cocaine is well established. Some pathologies, caused by cocaine ingestion and which may in fact explain the observed death, can be identified through a macroscopic examination. Such is the case for a cerebral hemorrhage or the rupture of an atherosomatous plaque in the coronary artery.

Cocaine use is also known to cause cardiac rhythm disorders, some of which have morphological substrates that can be detected through a microscopic examination. A survey of the literature shows that there have been few investigations of the conduction system of the heart in cocaine users and that no studies have ever examined conduction tissue in chronic users whose drug ingestion was confirmed by hair analysis. It thus appeared of interest to identify pathological lesions in the conduction system of the heart in chronic cocaine users that may explain cardiac rhythm disorders and even some deaths.

This presentation focuses on the different lesions found in the conduction system of the heart in cocaine addicts. Many authors believe that such lesions may be the cause of sudden death. The most frequently observed lesions consist of severe thickening of the atrioventricular node artery, intranodal and perinodal fibrosis, and microscopic foci of myocarditis.

Several cases with observable pathological lesions will be presented. The victims were young subjects: all were known to the police as long-term drug users, and some were undergoing a methadone treatment. In each case, a forensic autopsy and toxicological analyses were performed, including hair analysis to establish chronic drug use in general, and cocaine use in particular. This study included only cases in which toxicological analyses revealed the presence of cocaine in the blood, in the urine and in the hair.

It was concluded that pathological lesions in the conduction tissue may play a role in the occurrence of death attributed to intoxication pursuant to cocaine ingestion.

Cocaine, Conduction System, Hair Analyses

G16 Defibrillator/Pacemaker Evaluation in the Los Angeles County Medical Examiner Office

Lakshmanan Sathyavagiswaran, MD, Daniel Rieders, MD, and Joseph Muto, Department of Coroner, Los Angeles County, 1104 North Mission Road, Los Angeles, CA 90033*

After attending this presentation, attendees will be updated on the usefulness of soliciting cardiology consultations on deaths involving Implantable Cardioverter Defibrillator (ICD)/Implantable Pulse Generator (IPG) (pacemaker) as they relate to determination of cause/manner of death; and will be provided guidelines on disposition of equipment.

This presentation will impact the forensic community and/or humanity by providing examples of quality evaluation on implanted ICD and pacemakers. Mortuaries/medical examiners/coroners are provided with vital information related to their safety in handling decedents with implantable ICD/pacemakers, and disposition of same.

LA County Coroner's Office uses the services of a cardiologist/electrophysiologist to conduct forensic evaluations of implanted defibrillators/pacemakers. In some cases the device is explanted by the medical examiner and the cardiologist conducts interrogation with the programmer testing of the pulse generator. This provides information of device function, events, and whether the battery is depleted.

In other cases the device and lead system is intact in the decedent, in which case the integrity of the lead system can be verified by the cardiologist with similar interrogation techniques. The cardiologist also reviews the clinical records and pacemaker tracings, and provides opinions on the pacing system.

Implantable cardioverter defibrillators have to be turned off using a programmer to prevent morticians getting a shock. Pacemaker and ICDs should be removed prior to cremation because of sealing techniques, they will rupture during cremation due to pressure buildup.

In California, the IPG/ICD is the property of the family. If removed for evidentiary and cause of death reasons they have to be returned to the

family or, after testing is completed, disposition by the coroner needs family consent. They cannot be reused or refurbished, as U.S. Federal law prohibits it. Nuclear pacemaker must be removed to satisfy nuclear regulatory agency requirements for 100% removal of all radioactive modules. Pacemakers have been used for identifying decedents. Several case examples from the LA County Coroner will be discussed. A newly developed pacemaker policy will be shared.

Pacemaker Evaluation, Cardiology Consultation, Defibrillator Disposition

G17 Traumatic Cardiovascular Complications of Catheter-Based Procedures: Relevance to Medicolegal Death Investigation

Edward J. Tweedie, MD, London Health Sciences Centre, 339 Windermere Road, London, Ontario N6A 5A5, Canada*

After attending this presentation, attendees will be aware of potential traumatic cardiovascular complications of catheter-based procedures and will be able to recognize them at autopsy and determine their significance in the context of a medicolegal death investigation.

This presentation will impact the forensic community and/or humanity by underscoring the scope and utilization of catheter-based procedures. The forensic community must be aware of these uncommon but well-recognized adverse events because many of these deaths become medicolegal death investigations due to their often unexpected nature related to a medical procedure.

Using several case examples, the audience will become aware of potentially life-threatening traumatic cardiovascular complications that can result directly from a wide variety of catheter-based procedures.

There are a wide variety of procedures, both diagnostic and therapeutic, which involve catheterization of the heart and great vessels. These include standard, well-established procedures such as central venous catheterization for fluid, nutrition or medication administration, and pulmonary artery catheterization for pulmonary pressure monitoring. Specific cardiac interventions include endomyocardial biopsy, radiofrequency endocardial ablation for arrhythmia control, cardiac pacemaker and implanted defibrillator placement, diagnostic coronary angiography, and angioplasty procedures. These all carry with them a low but well-recognized risk of traumatic perforation. In addition, more novel procedures, including intravascular ultrasound, and laser and rotational atherectomy, continue to be developed.

The following autopsy case examples will be presented: brachiocephalic vein perforation by a central venous catheter in a dialysis patient resulting in fatal hemothorax, right ventricular perforation by a pacemaker electrode in an elderly woman with heart failure, coronary artery dissection caused by diagnostic coronary angiography, and pulmonary artery perforation by a pulmonary artery catheter after open heart surgery.

When perforation occurs, the outcome may be fatal and—due to the nature of such deaths—many are investigated in a medicolegal context. The pathological findings at autopsy must be properly recognized and then interpreted. Factors impairing pathological recognition may include a delay from the time of intervention to the time of death, no prior clinical awareness of the adverse event, prior removal of the catheters, inadequate availability of clinical history, and medical examiner or pathologist unfamiliarity with the nature of the procedure. When such events are identified, it may be difficult to determine the relative contribution of the resultant hemorrhage or damage to the cause of death in the presence of other major co-morbid conditions. Furthermore, it may be difficult to decide upon the manner of death, whether accidental or natural, when other significant disease is present. Proper investigation requires careful review of the medical record and a complete autopsy. Care must be taken to leave catheters and lines in place so that they can be properly inspected in-situ.

Associated hemorrhage should be quantified, and photographs should be taken. Microscopy may aid in dating lesions if healing reaction has developed at the site of injury.

Medical examiners and pathologists who perform autopsies in a hospital-based setting should familiarize themselves with the ever-expanding array of catheter-based endovascular procedures so that when adverse complications occur, they will be properly recognized. It is noted that potential complications are not limited to vascular perforations. As new procedures and equipment are introduced, vigilance for adverse events may assist in assessing their overall safety.

Cardiovascular, Catheter, Complications

G18 Increasing Heart Valve Donation by Utilization of a Cardiovascular Registry

Susan J. Roe, MD, Regina Medical Center, 1175 Nininger Road, Hastings, MN 55033; Shannon Mackey-Bojack, MD, and Rachel M. Meuleners, Jesse E. Edwards Cardiovascular Registry, 333 North Smith Avenue, Suite 4625, St. Paul, MN 55102; Lindsey C. Thomas, MD, Regina Medical Center, 1175 Nininger Road, Hastings, MN 55033; and Jack L. Titus, MD, PhD, Jesse E. Edwards Cardiovascular Registry, 333 North Smith Avenue, Suite 4625, St. Paul, MN 55102*

After attending this presentation, attendees will understand the benefits of utilizing established cardiovascular registries to increase the number of heart valve donations by medical examiners/coroners.

This presentation will impact the forensic community and/or humanity by providing the forensic community details of how an office in a large metropolitan area was able to allow a significant number of heart valve donations by requiring that the remnant myocardium be examined by a cardiovascular pathologist. There were no significant delays in time to sign the death certificate nor in determination of the cause of death by requiring this specialized review.

The Minnesota Regional Coroner's Office (MRCO) is the smallest of four offices covering the greater Minneapolis/St. Paul area, serving a population of 642,000 persons, the second smallest in the area. The other three offices have a combined jurisdictional population of 2,489,600. Two of these offices also have large numbers of referral cases from rural Minnesota.

MRCO made the decision to allow heart valve donations whenever possible and to require the tissue services organization to document cardiac findings and to send the remnant myocardium to the Jesse E. Edwards Cardiovascular Registry for examination by a cardiac pathologist.

This study examines the result of this change in practice. The number of heart valve donations was 15 in 2002 and 23 in 2003. The total number of heart valve donations from other offices combined was 11 in 2002 and 6 in 2003.

There was no significant increase in the average number of days until death certificate completion (14 vs. 21 days).

Heart valves were donated in 21 accidental death cases. The age range was 15 to 54 years. Significant cardiac findings included: atherosclerotic coronary artery disease (4), cardiomegaly (3), myocarditis (2), moderate myxomatous change of mitral and/or tricuspid valves (3), focal subendocardial fibrosis (1), and 80-90% stenosis of a large intramyocardial artery (1). Six of the hearts were normal.

Heart valves were donated in 10 suicidal death cases. The age range was 16 to 54 years. Significant cardiac findings included atherosclerotic coronary artery disease (4), cardiomegaly (2), probable arrhythmogenic right ventricular cardiomyopathy (1), biventricular hypertrophy (1), and focal subendocardial fibrosis (1). Two of the hearts were normal.

Heart valves were donated in seven natural death cases. The age range was 23 months to 58 years. Significant cardiac findings included atherosclerotic heart disease (2) and one case each of possible arrhythmogenic right ventricular cardiomyopathy, healing myocarditis, and myocardial small vessel disease. One heart was normal.

Four of the seven natural deaths were cardiac related and three were non-cardiac related. The structurally normal heart was found in a 23-month-old child with severe developmental delay and microcephaly. In one case, the cause of death was due to a pulmonary thromboembolus. In the third case, the only cardiac finding was medial hypertrophy of intramyocardial arteries. This particular case involved a witnessed arrest 30 minutes after ingestion of sildenafil citrate (Viagara). The cause of death in this case was certified as "sudden cardiac death."

The practice of utilizing cardiovascular pathologists at a cardiovascular registry for examination of post valve recovery hearts has lead to significant numbers of heart valve donations at the authors' institution. This process has not resulted in a delay in death certification and has not compromised the determination of the cause or manner of death. In fact, it has been beneficial in several areas. There are some inheritable cardiac conditions that are well known to cause sudden death. Recognition of these conditions is sometimes subtle, but the diagnosis may have enormous implications for family members. Examination of the remnant heart by cardiovascular pathologists who are accustomed to studying cases of sudden death and working with families also provides the pathologist with additional physician resources. Furthermore, as seen by review of these cases, many cases of non-natural deaths have a significant cardiac abnormality. These conditions may not have been evaluated completely without donation, if a complete autopsy had not been required. Some of these conditions also may have genetic implications for family members.

Tissue Donation, Cardiovascular Pathology, Cause of Death

G19 A Review of Pathologic Findings in Specimens Following Heart Valve Donation

Shannon M. Mackey-Bojack, MD, Jesse E. Edward's Registry of Cardiovascular Disease, John Nasseff Heart Hospital, 333 North Smith Avenue, Suite 4625, St. Paul, MN 55102; Susan J. Roe, MD, Rachel M. Meuleners, and Lindsey C. Thomas, MD, Regina Medical Center, 1175 Nininger Road, Hastings, MN 55033; and Jack L. Titus, MD, PhD, Jesse E. Edwards Registry of Cardiovascular Disease, John Nasseff Heart Hospital, 333 North Smith Avenue, Suite 4625, St. Paul, MN 55102*

After attending this presentation, attendees will understand cardiopathologic examination of hearts following heart valve donation is beneficial and may yield important information in determining cause of death.

This presentation will impact the forensic community and/or humanity by increasing awareness of the forensic community in the nationwide shortage of cardiac tissue grafts and the role of the Medical Examiner in tissue donation.

The Cardiovascular Registry was founded in 1960 by Dr. Jesse E. Edwards in St. Paul, MN, for the purpose of studying, classifying, and categorizing heart disease. The Registry, under the direction of Dr. Edwards, was very involved in describing congenital and acquired heart disease. Since its formation, the Cardiovascular Registry has examined over 27,000 cardiac specimens and cardiovascular surgical specimens.

In 2001 the Cardiovascular Registry was approached by one of the nation's largest tissue donation procurement agencies for the purpose of performing cardiovascular pathologic examinations of post valve recovery hearts. This collaboration began in 2001.

The current study was undertaken to review the type of remnant hearts received and to tabulate the abnormalities identified. All remnant hearts received over the period of 33 months were included in the study, for a total of 492 cases.

The information received for each case includes the body height, weight and suspected cause of death. Comprising the 492 cases were 206 accidents, 75 suicides, 91 natural deaths, 5 homicides, and 116 cases in which the cause of death was undetermined at the time of heart valve procurement.

Of the suspected natural deaths, 13 were classified as non-cardiac related. The remaining 78 were suspected cardiac deaths. Seventy-seven of the 78 cases had significant cardiac findings; some had more than one major abnormality for a total of 83 significant cardiac findings. Only one heart was structurally normal.

Significant atherosclerotic coronary artery disease with a >75% stenotic lesion was identified in 59 cases. One decedent was less than 25 years of age. Thirty-six of the 59 did not have infarction; 22 had myocardial infarction. Other significant cardiac abnormalities in the natural group included: myocarditis (6), cardiomegaly (4), bicuspid aortic valve with stenosis (3), arrhythmogenic right ventricular cardiomyopathy (2), acute aortic dissection (2), anomalous origin of a coronary artery (1), aneurysmal coronary artery (1), hypertrophic cardiomyopathy (1), dysplastic intramyocardial arteries (1), mitral valve prolapse (1), coronary artery thrombo-emboli (1), and prior valvular disease with mechanical valve replacement (1). In the natural death group, 33 incidental cardiac findings were identified including: moderate atherosclerotic coronary artery disease, myocardial bridge, acute angle of origin of the coronary artery, cardiomegaly, myxomatous change of a valve, patent foramen ovale, and post inflammatory mitral valve disease.

Accidental death constituted the largest group, with 205 cases (42%). Fifty-one had significant cardiac abnormalities and 107 had incidental cardiac findings, including 9 congenital abnormalities. Twenty-three had traumatic injuries, which were either contusions or lacerations. Injuries were found only in this accidental group of cases. One hundred and three of the remnant hearts were normal.

Of the 75 suicides, 22 had significant cardiac abnormalities including two cases of arrhythmogenic right ventricular cardiomyopathy, an inheritable condition. A third case of possible arrhythmogenic right ventricular cardiomyopathy and one case with focal areas of myocyte disarray were present in this group. Twenty-three incidental cardiac abnormalities, including congenital abnormalities, were also identified.

Five remnant hearts were from homicides. Three cases had severe atherosclerotic coronary artery disease or cardiomegaly. One case had mitral valve prolapse. Only one heart was structurally normal.

The second largest group of cases, 116, were those in which the manner of death was undetermined at the time of heart valve procurement. Included in this group were cases in which only the mechanism of death was reported. In 93 of the cases the cause of death was listed as "pending." In this group were 63 with significant cardiac abnormalities including severe atherosclerotic coronary artery disease (33), myocarditis (12), cardiomegaly (11), and one case each of hypertrophic cardiomyopathy, bicuspid aortic valve with stenosis, non-infective endocarditis, severe coarctation of the aorta, acute angle of origin of a coronary artery, thrombo-embolus, and dysplastic intramyocardial arteries. Thirty-eight cases had normal hearts. In 58 cases, incidental cardiac findings were identified including 5 congenital abnormalities.

The study demonstrates that significant and/or incidental cardiac abnormalities may be identified following heart valve donation.

The study also demonstrates that potentially inheritable conditions such as hypertrophic cardiomyopathy and arrhythmogenic right ventricular cardiomyopathy may be present when death was due to other causes. The diagnosis of these conditions is critical, with significant implications for surviving family members.

In summary, due to the nation wide shortage of bioprosthetic materials, tissue donation is critically needed. A thorough cardiopathologic examination remains possible in remnant hearts and may be beneficial in determining the cause of death.

Tissue Donation, Heart Disease, Sudden Death

G20 Sudden Death in a Calipatria State Prison Inmate With a Single Coronary Artery

Darryl J. Garber, MD*, Imperial County, California, Los Angeles County Coroner's Office/Department of Medical Examiner, 1104 North Mission Road, Los Angeles, CA 90033; and Henry Proo, Imperial County, California, 328 Applestill Road, El Centro, CA 92243

After attending this presentation, attendees will understand how to determine the presence of a "true" single coronary artery and to utilize this cardiac malformation as the cause of sudden and unexpected death in the absence of other pathophysiology.

This presentation will impact the forensic community and/or humanity by demonstrating the pathophysiology with a single right coronary artery, and by classifying the finding of a "true" single coronary artery as a pathological entity of functional significance potentially leading to sudden death in the absence of other cardiac malformations.

This presentation is the case of a 31-year-old black man who had been incarcerated for approximately six years prior to his death. The decedent was an inmate at the Calipatria State Prison located in Southern California. He was in the midst of doing exercises in the exercise yard when he suddenly collapsed. He was subsequently taken to the prison infirmary and transferred to a local hospital for treatment, however, was pronounced dead despite resuscitative efforts. The decedent had no significant past medical history and no history of any drug usage. Postmortem examination revealed a slightly enlarged heart with a single right coronary artery and complete absence of the left coronary artery and corresponding circulation. Gross and microscopic evaluation of the heart revealed subendocardial fibrosis of the anterior and anteroseptal left ventricle characteristic of chronic myocardial ischemia. Also grossly and microscopically evident was superimposed acute myocardial infarction in the same region of the heart. Changes consistent with poor vascularization, lack of blood flow and oxygenation of the myocardium of the heart in the distribution of the absent left anterior descending coronary artery were identified.

A brief review of congenital malformations of the coronary artery circulation will be presented, including criteria for a true single coronary artery. A single coronary artery without other cardiac malformations should be considered as a pathological entity potentially leading to sudden death. Training and experience have demonstrated that this entity is usually of no functional significance unless the single artery becomes occluded. This is usually reported as an "incidental" finding, not contributing to death. This rare pathological entity may in itself lead to acute and chronic myocardial ischemia, myocardial infarction and sudden death. In this particular case, the decedent had a six-year history of incarceration during which time he had a history of chronic exercise, which apparently exacerbated the cardiac ischemia and ultimately resulted in acute myocardial infarction with sudden death.

Single Coronary Artery, Sudden Death, Myocardial Ischemia and Infarction

G21 An Accident Waiting to Happen: The Chicago Porch Collapse of 2003

Aldo J. Fusaro, DO*, J. Scott Denton, MD, Adrienne E. Segovia, MD, Edmund R. Donoghue, MD, and Eupil Choi, MD, Cook County Medical Examiner's Office, 2121 West Harrison Street, Chicago, IL 60612; J. Lawrence Cogan, MD, LA County Medical Examiner's Office, 1104 North Mission Road, Los Angeles, CA 90033; Mitra B. Kalelkar, MD, Cook County Medical Examiner's Office, 2121 West Harrison Street, Chicago, IL 60612

After attending this presentation, attendees will understand the various injuries, both traumatic and asphyxial, associated with a structural porch collapse.

Disasters with multiple fatalities are common, and this presentation will impact the forensic community and/or humanity by assisting medical examiners and forensic pathologists to understand injuries that are sustained in a porch collapse, the mechanism of the injuries, and how best to certify the cause of deaths based on autopsy and death scene investigation findings.

The authors present a mass casualty during a party in the upscale Lincoln Park neighborhood of Chicago. On the warm summer evening of June 29, 2003, a party was underway within the upper two floors of a 3-story building that spilled out onto the two attached wooden porches. At approximately 12:30 a.m., the 3rd floor porch began to shake. Some partygoers exited the porch into the adjacent apartment. Others remained on the porch and began to jump up and down. The porch floor separated from the building and the side vertical supports and "pancaked" down onto the second floor porch. The second floor porch floor likewise separated and collapsed onto the first floor porch, which then collapsed to the ground and into a basement stairwell. Approximately 50 people were on the 2nd and 3rd floor porches at the time of the collapse; no one was on the first floor porch or in the basement stairwell.

Emergency medical services responded quickly and extricated victims from the debris. Fifty-seven people were injured at the time of the collapse, and of these, 12 were pronounced dead at the scene. One person died after surviving approximately 19 hours in the hospital. The body positions of the victims on the two decks when they collapsed are not known.

Five of the victims were female and eight were male. They ranged in age from 19 to 30 years. At autopsy, all subjects had extensive cutaneous injuries consisting of abrasions, lacerations and contusions. All subjects also had identifiable petechiae on or over more than one body surfaces, including face (12/13), conjunctiva (10/13), oral mucosa (2/13), laryngeal/epiglottic mucosa (3/13), visceral pleura (3/13) and epicardium (1/13). High cervical spine fracture/dislocation were found in 5/13. Bony fractures were identified in four subjects. Visceral injury was identified in one. The cause of death in 5/13 cases was compressional asphyxia due to porch collapse, with a significant contributing factor of cervical spine fracture/dislocation. The cause of death in 6/13 was compressional asphyxia due to porch collapse. One of 13 had extensive skull fractures with brain injury and the cause of death was multiple injuries due to porch collapse. The one delayed fatality died from anoxic encephalopathy due to compressional asphyxia due to porch collapse. The wooden porch remnants were torn down and quickly replaced with a steel porch. Structural engineering analysis of the porch was performed, with the results to be summarized during the oral presentation.

Traumatic asphyxia, originally described by Ollivier and later refined by Perthes, is currently defined as asphyxia caused by external pressure to the thorax, inhibiting respiration. The main anatomic finding is cutaneous, mucosal and serosal petechiae of the head, chest and upper extremities. The term compressional asphyxia is a more descriptive term, better understood by the lay public as a relatively gradual compression as opposed to a sudden crushing mechanism.

Following the accident, the city of Chicago revised its inspection criteria for building porches, and in a 2-month sweep, inspected 4,000

porches. Approximately 1,200 building owners were cited for construction faults. There are an estimated 300,000 porches within the city of Chicago. At the one-year anniversary of the collapse friends and family held a candlelight vigil for the victims at the collapse site. Nineteen days after the one-year anniversary of this deadly porch collapse, another smaller, similar wooden porch in the same neighborhood collapsed, causing seven people to fall 8 – 10 feet. Fortunately, no one was injured or killed.

Traumatic Asphyxia, Porch Collapse, Compressional Asphyxia

G22 Forensic Medicine in France

Eric Baccino, MD*, Laurent Martille, MD, and Anne Dorandeu, MD, Service de Medecine Legale Chu de Montpellier, Hospital Lapeyronie 371 av du Doyen G. Giraud, Montpellier, 34295, France

After attending this presentation, attendees will understand the organization of forensic medicine in France and the interest in clinical forensic medicine.

This presentation will impact the forensic community and/or humanity by highlighting new fields for forensic doctors.

Medicolegal activity: Few teams perform the whole scope of medicolegal activity: "classical" forensic pathology, but also "clinical forensic medicine." These teams are based in CHUs (Centre Hospitalier Universitaire, or university hospitals, of which there are 25 in France) where usually forensic toxicology from biological samples, DNA, physical anthropology, and forensic histology are also available. Entomology and diatom identification are only done in one center for each. Several of these teams are also in charge of medical care to detainees.

Around 7,000 forensic autopsies are performed yearly for a population of more than 60 million people. This low level of autopsy performance is not only due to a low crime rate, but also to French judicial particularities. Only in four cities is more than one autopsy is performed every working day.

When possible, a forensic doctor will be called to the death scene; 14,000 to 25,000 scene examinations per year in France seems a reasonable hypothesis.

Clinical Forensic Medicine includes the examination of people in custody (around 250,000 per year nationally) and also of living victims: child abuse, battered women, assaults, and rapes cases. It is estimated that 45,000 living victims are examined each year by forensic physicians.

Forensic Doctors: Two hundred fifty physicians are employed full time in forensic medicine throughout the country. As a result of this limited number, only in some university hospitals will it be possible to have a forensic doctor on duty around the clock every day of the year, for all the types of clinical forensic activities mentioned above. In smaller cities and rural areas, forensic doctors will focus on serious penal case such as rape, homicide, and child abuse, the rest being done by general practitioners.

A majority of forensic doctors are now trained through a national diploma called "**Capacité des Pratiques Medico-Judiciaires**." The diploma requires that during 2 years, the students will have 30 days practical instruction per year in an accredited hospital unit. The other possibility is **D.E.S.C.** (Complementary Specialized Study Diploma) reserved to the medical interns; after 4 years of internship in any speciality, the candidate becoming a forensic medicine specialist will need 2 more years of practical and full time training in a medical forensic unit plus 200 hours of lectures. The graduate will be able to perform all types of forensic medicine activities (including autopsies).

A recent survey showed that around 750 forensic doctors were needed to provide the appropriate and basic emergency forensic medicine services (clinical and crime scene examination) to each local judicial court.

Teaching and Research: INSERM (National Institute of Medical Research) has no forensic medicine section (nor a forensic science section) and there is no PhD program in forensic medicine.

State funded research programs in forensic medicine are limited to scattered projects (fewer than 10 so far). During the medical curriculum of general practitioners, between 20 to 40 hours of lectures will be dedicated to forensic medicine (medical certificates about living victims and death certificates, principles of medical liability, and medical confidentiality).

Conclusion: The role of forensic medicine in France is increasing as the forensic doctors are turning to “Violence Medicine” specialists. The relative importance of autopsies is decreasing, a rather positive point with regard to the (worldwide) difficulties for funding this activity, but has an adverse effect on the experience of practitioners. Concentrating forensic autopsies in regional hospital-based centers seems to be the only solution, for the sake of quality.

Forensic Medicine, France, Organization

G23 Near Miss Incidents: Feasibility Studies Assessing Forensic Physicians' Perceptions of Near Misses in Police Custody Suites in London, United Kingdom

David Best, PhD, Institute of Psychiatry, King's College, De Crespigny Park, London, SE5 8AF, United Kingdom; Siobhan Havis, MSc, Police Complaints Authority, 10 Great George Street, London, SW1P 3AE, United Kingdom; and Jason Payne-James, LLM, MB, FRCS, DFM, Forensic Healthcare Services, Ltd, 19 Speldhurst Road, Victoria Park, London, E9 7EH, United Kingdom*

After attending this presentation, attendees will gain an understanding of the causes of near miss incidents and how they may be applied to the care of prisoners in custodial settings.

This presentation will impact the forensic community and/or humanity by raising awareness of the need for further research into the care of prisoners in custody, in order to try and prevent harm or death occurring.

Background: Deaths of prisoners in police custody are tragedies for all those involved. Potentially preventable deaths in police custody include those which involve illicit drugs, alcohol and deliberate self-harm. Near miss incidents (NMI) that did not result in death have a crucial role in understanding risk factors in custody. A program of research has been developed to study near miss incidents. For the purposes of this research NMI, have been defined as ‘an unplanned and unforeseeable or unforeseen event that could have resulted, but did not result, in human death or may have resulted in injury or other adverse outcomes.’

Aims & Methods: An initial study was undertaken with pilot interviews of 3 forensic physicians (FP) practising in London, U.K., to create a structured questionnaire for all forensic physicians working in London. The questionnaire was the basis of a retrospective recall survey of all FPs working in London as Forensic Medical Examiners (FME) designed to assess numbers of NMIs, patterns in occurrence and relevant learning points within the previous 6 months. A cover letter, background questionnaire (exploring the background of the medical practitioner), copies of NMI survey, and reply paid envelopes were sent to each FME ($n = 134$) in London, working for the Metropolitan Police Service. Data about all incidents were anonymised.

Results: There was an overall response rate of 73% ($n=96$). Of FME respondents, 18% were Principal grade, Senior (24%), Standard (35%) and Assistant (23%). 20% of FMEs had specific mental health training and qualification. 52% had forensic qualifications such as the Diploma of Medical Jurisprudence, and the Diploma of Forensic Medical Sciences. FMEs had been qualified in medicine for a mean of 27 years and had been FMEs for a mean of 11 years. Thirty-eight NMIs were reported by 27 FMEs (of all levels) although the retrospective method meant that some data are incomplete. The reason for police contact was recorded as alcohol ($n=8$), theft and robbery ($n=7$), warrants ($n=4$), violence ($n=3$), traffic violations ($n=2$) and single cases of drugs, murder and immigration offences.

Twenty-seven NMIs involved white Caucasians, 4 involved Asians, and 2 involved blacks (origin not known). Form 57M (a screening questionnaire used in police custody to identify medical and mental health problems) was positive in 12 cases, and the Police National Computer had warnings in 6 cases. Of the main perceived cause of each NMI, illicit drugs were involved in 12/38; alcohol in 17/38; deliberate self-harm in 11/38; problems with searches, checks or rousing in 8/38; failure of inter-agency communications in 5/38; and insufficient resources in 4/38. In a number of cases more than one factor was involved. Examples of type of NMIs were: illicit drugs – overdose, drug swallowing, drug concealment, theft of drugs from FME; alcohol – self-harm, physical injuries (ruptured spleen, head injury), hypoglycemia; self-harm – concealed knife, self-hanging on paper suit, drug swallowing.

Summary and Conclusions: Using the figures generated by this study, the reported rate of NMIs is 0.4 NMI per FME which gives a total annual rate of 107 NMIs in this setting. These data reflect the incidence of NMI in one of 43 police forces in England and Wales. These data are broadly consistent with documented patterns of deaths in police custody that would appear to reinforce the validity of the data. The need for a prospective study is supported. The next stage is a prospective 6 month study in which NMIs will be recorded around the time of occurrence, with analysis of each incident subsequently conducted by a research team, in order to learn lessons which may be utilised to attempt to prevent potentially avoidable deaths in police custody.

Deaths in Custody, Forensic Physicians, Near Miss Incidents

G24 Fatal Pulmonary Thromboembolism and Hereditary Thrombophilias

James R. Gill, MD, and Susan F. Ely, MD, OCME, 520 First Avenue, New York, NY 10016*

The goal of this presentation is to present to the forensic community the role that hereditary thrombophilias may play in deaths due to venous thromboembolism (VTE). Forensic pathologists will understand the availability and usefulness of postmortem DNA testing for hereditary thrombophilias in deaths due to thromboembolic events.

This presentation will impact the forensic community and/or humanity by showing how any and all data generated by increased post-mortem testing could bring illuminating information to the medical literature, allowing forensic practice the ability to keep pace with this important and rapidly developing field, and potentially contribute to the reduction of morbidity and mortality and the enhancement of public health.

The autopsy dissection, personal and family medical histories, and ancillary studies pertaining to pulmonary embolism (PE) are important components in the investigation of these deaths. But, the detection of a PE at autopsy and even that of apparent underlying risk factors do not necessarily signify the end of the investigation. Molecular analysis for genetic risk in selected cases might further explain fatal outcomes in persons in whom causality is inadequately explained. Also, on occasion, no apparent predisposing conditions are identified. Hereditary thrombophilias may play a causal role in the development of PE in some of these deaths. With the availability of postmortem molecular testing, their significance in such deaths may be better understood. Most importantly, beyond more accurate death certification, these tests have the potential to reduce morbidity and mortality for surviving family members.

Pulmonary thromboembolism is commonly diagnosed in forensic pathology practice, as it often causes sudden death. It is attributed to a wide variety of predominantly acquired etiologies. Although likely etiologically multifactorial, some commonly diagnosed proximate causes include: surgery, pregnancy, injury or relative inactivity of any cause, cancer, obesity, or serum hyperviscosity. On occasion, no apparent predisposing conditions are identified. In these instances, occult hereditary thrombophilias may play a contributory causal role.

Currently, there are DNA techniques that allow for the postmortem diagnosis of some hereditary thrombophilias. These include Factor V Leiden (FVL), Prothrombin (PT), and Methylenetetrahydrofolate reductase (MTHFR) mutations. Less common abnormalities involving antithrombin III, protein C and S, plasminogen, dysfibrinogenemia, hyperhomocysteinemia, and antiphospholipid antibodies were not tested for, as functional and serologic diagnostic assays are ill-suited for postmortem blood.

Resistance to activated protein C, the most potent endogenous anticoagulant, is due to a mutation of the factor V gene (i.e., the Leiden mutation) which results in decreased control of thrombin generation. The G20210A autosomal dominant mutation in the prothrombin gene is associated with an increased amount of prothrombin, which promotes the formation of thrombin. Hyperhomocysteinemia (plasma homocysteine concentration >15 μmol/L) is a risk factor for venous (and arterial) thrombosis. Increased concentrations of homocysteine are partly determined by enzymes involved in its metabolism. Some mutations in methylenetetrahydrofolate reductase (MTHFR) and cystathione-B-reductase (CBS) are associated with elevated concentrations of homocysteine.

At the Office of Chief Medical Examiner of the City of New York, 124 deaths (of 15,280 undergoing autopsy) were caused by PE between December 2000 and September 2003. Of those, 34 postmortem blood samples from persons having one or more of the selection criteria were analyzed by a molecular fluorescence method (FRET) for FVL, PT, and MTHFR mutations. Characteristics of decedents who were candidates for these tests were based on widely used clinical criteria and included: age < 45 years, pregnancy-related deaths, history of recurrent or unexplained stillbirths, oral contraceptive pill use, hormone replacement therapy, treatment with chemotherapy, weak risk factors (long flights, car rides, or slight obesity), or deep venous thrombosis of undetermined etiology.

Heterozygous mutations involving FVL (1 case), PT (3 cases), and MTHFR (8 cases), as well as a single homozygous mutation for MTHFR, were detected, a total of 35% of those tested. Five deaths were clearly causally related to one or more of these mutations. The possibility of causal relationships in the remaining 29 deaths is discussed.

Venous Thromboembolism, Thrombophilia, Hereditary

G25 An Expert Witness Requests Re-evaluation of SOP in Autopsy Reporting, Supported With Case Examples

Anita K.Y. Wonder, MA*, Wonder Institute, PO Box 1051, Carmichael, CA 95609-1051

After attending this presentation, attendees will gain an appreciation for the importance of listing all breached arteries by name and injury on autopsy reports.

This presentation will impact the forensic community by suggesting a standard operating policy revision in autopsy reporting where arterial injury is ignored if absent from direct cause and/or manner of death.

Medical experts should name all breached arteries and include interpretation of injury to facilitate reconstruction of criminal events. This presentation will illustrate with case examples where knowledge of arterial injury, even if not listed in the autopsy report, could have saved time and concern for justice and assisted reconstruction of incidents from bloodstain pattern evidence.

Arterial injury is often encountered in casework, yet not all injuries are mortal. Breach may occur to the carotid, temporal, brachial, and deltoid arteries, which may project considerable arrays of blood drops without resulting in death. On the other hand, even minor arterial vessel injury may shift results from a survivable assault to death from homicide, suicide, or accident via hypovolemic shock. When reconstructing crime events, it is essential to know that arterial blood vessels were breached. The identification and interpretation of arterial injury requires medical expertise.

For example, a gunshot wound to the head which nicks the temporal artery may be reported as GSW to the head, without listing arterial injury. This omission may limit time and detail in reporting, but can create inconvenience and embarrassment later when investigators attempt to place the origin of an assault. Without specific information regarding arterial damage, reconstruction conclusions may err. Three less than satisfactory ways in which information regarding arterial damage may be obtained after the autopsy report:

1. Law enforcement representatives attending the autopsy may ask the pathologists technical questions.
2. The bloodstain pattern experts may interview the pathologist at a later date.
3. Attorneys may bring out the information during direct or cross examination at trial.

The least desirable consequence may be ignoring the distinct arterial damage bloodstain patterns because no arterial injury was mentioned in the autopsy. Arterial damage from even minor injury may contribute to rapid blood loss. In such cases the cause of death may be listed as exsanguination. Identifying where the artery was breached positions the victim where the crime emphasis of survival (assault) versus death (homicide) occurred.

Three case examples are shown to emphasize the essential information possible when arterial damage is recognized.

Case 1: A homicide occurred in a dormitory building. Bloodstain patterns were found at two locations: in the victim's room and along the hall outside the room. An expert was hired to answer the question of where the fatal assault began. The identification and position of the injured artery, and behavior of blood drops distributed best answered the question.

Case 2: Statements of an assailant placed a victim over a large pool of blood when the assailant left the scene. When photographed, the victim's body was in an entirely different position with evidence of considerable arterial rain between positions. Information obtained during the investigation suggested that a second assailant could have committed the murder after the first one left. Because no interpretation of the bloodstains was initially made, and the police took the confession without verification, it is possible that justice was not served in this case.

Case 3: An alleged drive-by shooting was shown to be a homicide within the vehicle when the tracking of the blood was aligned with arterial damage to the carotid artery. Death was by hypovolemic shock 24 hours later.

In conclusion, adding the name and injury of breached arterial blood vessels to autopsy reports will supply essential information and prevent later inconvenience and possible reverses of justice.

Arterial Injury, Autopsy Reporting, Bloodstain Patterns

G26 Sudden Death Following Brief Compression of the Neck

John W. Eisele, MD*, Forensic Consultants Medical Group, 2291 March Lane, Suite 179E, Stockton, CA 95207; Gerald J. Berry, MD, Stanford Pathology Consultants, 300 Pasteur Drive, Room H-2110, Stanford, CA 94305; and Michael J. Ackerman, MD, PhD, and David J. Tester, BS, Long QT Syndrome Clinic and Sudden Death Genomics Laboratory, Mayo Clinic College of Medicine, 200 First Street, SW, Hilton 11, Rochester, MN 55905

The goal of this presentation is to present a well-documented case of sudden death following brief compression of the neck, and to discuss the possible mechanisms for this phenomenon and methods to evaluate these mechanisms.

This presentation will impact the forensic community and/or humanity by providing a well-investigated case of a type of death which has been poorly documented in the past, and has caused extensive debate

in the forensic pathology community and court system. The presentation will emphasize proper procedures in investigating this type of death.

Nearly all forensic pathology texts make reference to sudden death following brief compression of the neck; these deaths are attributed to a hypersensitive carotid sinus reflex. Review of the medical literature, however, reveals that reports of death by this mechanism refer to elderly individuals with significant cardiovascular disease or other factors that could explain their deaths independent of the neck compression. The vast majority of references to a hypersensitive carotid body discuss only fainting as opposed to sudden death. A case recently investigated in which the death of a 14-year-old youth following brief neck compression was witnessed and thoroughly investigated.

Three reliable witnesses reported that there was a brief tussle with another youth, during which the decedent attacked the other youth and held his neck with both hands. The other youth pushed the decedent against a wall and compressed his neck with one hand while he faced the decedent. The compression continued for 15 to 30 seconds, at which time the decedent collapsed. He was pulseless and apneic; cardiopulmonary resuscitation by a trained bystander as well as paramedics and emergency room personnel continued for nearly an hour before he was declared dead.

A thorough autopsy was performed. This included a complete gross examination with layered, *in situ* dissection of the neck structures, and complete histological and toxicological examination. Multiple microscopic sections of the heart and serial sections of the conduction system were examined during the initial autopsy and re-examined by a cardiac pathology consultant. In addition the carotid bodies and adjacent arteries were serially sectioned and examined by this consultant. None of these procedures revealed an anatomic cause of death or any significant disease or injury. Molecular autopsy for long Q-T syndrome is underway.

The presentation will include detailed history and autopsy results, a review of the pertinent literature, a discussion of possible mechanisms of death in this and similar cases, and a discussion of procedures to be followed in performing a complete investigation of these deaths.

Sudden Death, Neck Compression, Long Q-T Syndrome

G27 The Spontaneous Oesophagus Perforation: A Forensic Point of View

Renaud Clement*, and Olivier Rodat, PhD, Department of Forensic Medicine, University of Nantes, 1 Rue Gaston Viel, Cedex, 44 093, France

After attending this poster, attendees will understand a case report of forensic autopsy of an unusual cause of death.

This presentation will impact the forensic community and/or humanity by demonstrating the contribution of Boerhaave syndrome to sudden death.

An autopsy was performed on a young adult, who apparently died during his sleep. Mediastinitis was established and empyema was also found in the left pleural cavity. The esophagus examination showed a tear in left side. The lesion occurred in the distal esophagus and showed the leak communicating freely with the left pleural space. Esophageal perforation was the cause of empyema, and death resulted from barotrauma to the lower oesophagus during the effort of vomiting. The disease is Boerhaave syndrome, a serious and rapidly fatal spontaneous esophagus rupture. Forceful ejection of gastric contents in an unrelaxed esophagus against a closed glottis is the mechanism described. The tear thus produced is vertical, akin to the "Mallory-Weiss" tear. The poster discusses the historical, statistical, pathophysiological, diagnostic and therapeutic aspects of Boerhaave syndrome.

Spontaneous Oesophagus Rupture, Autopsy, Death

G28 Human Wicks: The Almost Complete Destruction of Major Portions of the Human Body by Fire Fueled at Least Partly by the Body Fat of the Victim

Phillip M. Burch, MD*, Office of the Medical Examiner, 1300 Clark Avenue, St. Louis, MO 63117

After attending this presentation, attendees will be able to assess a fire scene that involves a human body that provided its own fuel for the fire.

This presentation will impact the forensic community and/or humanity by assisting the attendee in the reconstruction of a fire scene to establish if a human body was a source of fuel for the fire.

The charred remains of an adult human female were discovered in an abandoned house in St. Louis, MO, in early January of 2004. The female was determined to be the victim of a blunt trauma homicide. Much of the torso and lower extremities were basically destroyed by the fire, in some places even down to the bones (not even the hot, prolonged fire of the kind applied at crematoriums totally destroys the bones). Although it is thought that the fire occurred where the body was discovered, nothing else at the scene was altered by the fire. How such a fire could occur and go undetected by passersby during the fire will be discussed. The remains of this case, and others like it, resemble those described in cases of so-called "spontaneous human combustion" and this phenomenon or myth will also be discussed.

Scene Reconstruction, Body Fat, Human Wick

G29 DNA Extraction and Anthropological Aspects From 6th to 7th Century A.D. Bone Remains

Nunzio Di Nunno, MD, PhD*, Sezione di Medicina Legale, Bari University, Piazza G. Cesare n. 11, Bari, 70125, Italy; Vito Scattarella, BSc, Sandro Sublimi Saponetti, BSc, and Patrizia Emanuel, BSc, Bari University, Piazza G. Cesare n. 11, Bari, 70125, Italy; and Stefania Lonero Baldassarra, BSc, and Cosimo Di Nunno MD, Sezione di Medicina Legale, Bari University, Piazza G. Cesare n. 11, Bari, 70125, Italy

After attending this presentation, attendees will be able to implement the knowledge of the DNA extraction.

This presentation will impact the forensic community and/or humanity by proposing a modified protocol for DNA extraction.

In the archeological site of the early Christian Episcopal complex of Saint Peter, in Canosa di Puglia (Bari, Italy), during the operations of archaeological excavations, tombs were discovered. They were dated between the 6th and 7th centuries A.D. with Carbon 14 methodology. Five skeletons were found in the five tombs:

28A: male individual, 43 years old. The height was 170 cm, the biomass was 65.7 kg. The analysis of the bones indicated several noteworthy pathologies, such as a number of hypoplasia lines of the enamel, the presence of Shmorl hernias on the first two lumbar vertebrae, the outcome of subacromial impingement syndrome.

28E: male individual, with a biological age of death between 44 and 60 years. The height was 177 cm. He had a post-traumatic fracture callus of the medial third of the clavicle with an oblique fracture rima.

29B: female individual, 44-49 years old. The height was 158.8 cm, the biomass was 64.8 kg. There was Wells' bursite on the ischial tuberosity, on both sides.

29E: male individual, 45-50 years old. The height was 169.47 cm, the biomass was 70.8 kg. The third and the fourth vertebrae showed the Bastrup syndrome (compression of the vertebral spine). There were radiological signs of deformity on the higher edge of the acetabula and results of frequent sprains of the ankles.

31A: male individual, 47-54 years old. The height was 178.65 cm, the biomass was 81 kg. The vertebral index showed a heavy overloading in the thoracic-lumbar region. There were bony formations under the periosteum on both on the higher and medium facets of the first metatarsus, and on the higher and lateral facets of the fifth metatarsus on both sides. As the topography indicates, these small ossifications coincided with the contact points between the back of the foot and parts of the upper of the shoes.

From the osseous remains, in particular from the teeth (central incisors), the DNA was extracted and typed in order to identify potential family ties among all the subjects. The extraction technique used came from the DNA Promega technique, partially modified by the authors. Stay times of the sample in the extraction buffer were increased and were increased the PCR cycles.

Ancient Bone Remains, DNA Extraction, DNA Fingerprint

G30 Risk Factor Analysis and Characteristics in Community Acquired MRSA

Julia M. Braza, MD*, Karoly Balogh, MD; and Anthony Martyniak, MD, Beth Israel Deaconess Medical Center at Harvard Medical School, 330 Brookline Avenue, Boston, MA 02215

The goal of this presentation is to increase awareness of community acquired methicillin resistant *Staphylococcus aureus* (MRSA) infections, and its shift in epidemiology. It is relevant to the medicolegal and public health fields to identify such cases, especially in younger individuals, as it is a reportable disease and a cause of sudden death.

This presentation will impact the forensic community and/or humanity by identifying the risk factors for community acquired MRSA infection in patients without underlying chronic illness, and discussing different and atypical presentations, so that the forensic community can better recognize MRSA in individuals who acquire the agent outside of a hospital setting.

The focus of this case report is patient J.V., a 28-year-old Puerto Rican man who presented to the Emergency Department with a two day history of increasing shortness of breath, chest pain, and bloody sputum. His past medical history was significant for previous herpes infection, and a right thigh abscess that was drained two weeks prior to admission. The patient's social history was significant for incarceration for 5 years (he was released one year prior to admission) and being a smoker. The patient denied intravenous drug use, and maintained a negative HIV status. J.V.'s hospital course initially manifested as a pulmonary process (consistent with necrotizing pneumonia), with an almost complete opacification of the left lung on chest x-ray. On the third day of admission, J.V. deteriorated with septicemia, shock, acidosis, anuric renal failure, disseminated intravascular coagulopathy, paralysis, and a purpuric rash involving his face, anterior chest, right arm, lower extremities, and back. Blood cultures revealed gram positive cocci in pairs and clusters, consistent with the organism *Staphylococcus aureus*. Histologic findings at autopsy revealed extensive bilateral acute pneumonia with multiple pulmonary infarctions, hemorrhage, and necrotizing vasculitis.

The patient had a rapidly progressive course (6 days) of methicillin resistant *Staphylococcus aureus* infection, with no known underlying chronic illness or health-care associated risks factors such as recent hospitalization, recent outpatient visit, recent antibiotic exposure, chronic illness, diabetes, or malignancy. Therefore, by exclusion, this is a case of community acquired MRSA. However, the severity and very rapid progression of the infection, which led to his death, raises the question of the possibility of other risk factors, such as intravenous drug use, underlying HIV infection, or contact with a person or persons with the above-stated risk factors. There is also an associated chance of increased MRSA transmission in certain community clusters such as in correctional facilities,

athletic teams, and nursing homes (JAMA, 2003). Such populations have a higher incidence of sharing common personal objects or facilities that would make transmission of MRSA (especially via cutaneous and respiratory inoculation) more common. The patient's history of five years of incarceration places him within this risk category.

MRSA was first acquired outside of a hospital setting in the 1980s when intravenous drug users in Detroit were reported to have a MRSA bacteremia, according to Collins *et al.* (*Medical Journal of Australia*, 2002). Currently, the Centers for Disease Control (CDC) is conducting an active population-based surveillance for community acquired MRSA (CA-MRSA) in selected regions of the U.S. to help characterize the incidence and risk factors for MRSA in the community (JAMA, 2003). Iyer *et al.* have studied local outbreaks of CA-MRSA, specifically related to cutaneous presentations, with the finding that cutaneous abscesses were the most common presentation, (*J Am Acad Dermatol*, 2004). This finding is pertinent to the patient presenting with a cutaneous abscess on his thigh 2 weeks prior to his pulmonary symptoms.

In conclusion, J.V.'s clinical picture and autopsy findings demonstrate a case of CA-MRSA. MRSA is now emerging as a community based agent, and with its varied presentations, such as cutaneous abscesses, shock, and pneumonia, clinicians and pathologists need to include MRSA in the differential diagnosis.

MRSA, Risk Factors, Community Acquired Disease

G31 Commotio Cordis: Sudden Death Among Young People During Sporting and Recreational Activities

Sunil K. Prashar, MD*, and Karoly Balogh, MD, Beth Israel Deaconess Medical Center, 330 Brookline Avenue, ES-112, Boston, MA 02115

After attending this presentation, attendees will have an improved understanding of sudden deaths due to commotio cordis including its definition, demographics, mechanisms, treatment, prevention, and potential medicolegal consequences.

This presentation will impact the forensic community and/or humanity by improving awareness among the forensic community of sudden deaths due to commotio cordis. Increased understanding of commotio cordis may lead to more accurate determination of cause of death by forensic professionals, improve preventive and safety measures in the community, and help avoid inappropriate charges and convictions in the criminal justice system.

A 21-year-old white man with no significant medical history was hiking and rock climbing with friends and sustained a 15-foot fall which led to immediate loss of consciousness. A policeman was the first rescuer to the scene. He found the young man to be apneic and pulseless. The policeman administered defibrillation and cardiopulmonary resuscitation. The man was airlifted to a local hospital where he was pronounced dead shortly after admission. The case was referred to the medical examiner's office. At autopsy, multiple horizontal abrasions were observed on the face, thorax, and legs. There was no intracranial or spinal pathology. There was no evidence of cardiomyopathy and the coronary arteries had normal anatomy. There was focal petechial hemorrhage on the posterior epicardium. Blood toxicology was positive for cannabinoids and ethanol (0.010 gram %). The cause and manner of death were determined to be commotio cordis and accident, respectively.

Commotio cordis is defined as cardiovascular collapse secondary to cardiac arrhythmia caused by low energy impact blunt trauma to the chest without structural injury to the sternum, ribs, or heart.

Maron *et al.* (JAMA, 2002) reviewed 128 cases entered into the U.S. Commotio Cordis Registry. The ages ranged from 3 months to 45 years with a median age of 14 years. Seventy-eight percent were under 18 years old and 95% were male. Eighty-one percent involved precordial blunt impact from a projectile, most commonly a baseball, softball, or

hockey puck. Twelve percent involved a fight, play fighting, or parental discipline. One case involved a fall on playground monkey bars. It is thought that the narrow, compressible chest of youth increases the risk for commotio cordis.

Link *et al.* (Prog Biophys Mol Biol, 2003) conducted a series of experiments on a swine model to improve understanding of the mechanisms of commotio cordis. Using projectiles fired at anesthetized juvenile swine, the researchers found that ventricular fibrillation could be consistently produced when impact occurred 10-30 milliseconds prior to the T-wave peak. Impacts led to premature ventricular depolarization. Ventricular fibrillation was most consistently produced by impacts at the center of the left ventricle. The authors found that early defibrillation was a critical factor in survival.

It has been suggested that soft core baseballs, improved chest protection, and the presence of defibrillators at organized sporting events may decrease commotio cordis events and deaths.

Of particular importance to the medicolegal community, Maron *et al.* (American Journal of Cardiology, 2002) described six cases of commotio cordis which entered the criminal justice system. The cases involved parental discipline, domestic dispute, and gang initiation. In all cases, there was no intent to cause death and none of the victims showed sufficient trauma to cause death. Convictions ranged from reckless homicide to first degree murder, with sentences from 8-20 years. The authors purport that criminally negligent homicide is not the appropriate charge in many cases of commotio cordis and that it is the responsibility of the physician community to educate the justice system regarding the nature of commotio cordis deaths.

Commotio cordis is an important cause of sudden death in young people during sporting and recreational events. It is caused by low energy impact blunt trauma to the chest which causes fatal cardiac arrhythmia. Rapid defibrillation is critical to survival. Protective measures may decrease commotio cordis events and deaths. It is of great importance to increase awareness of commotio cordis within the medicolegal community to prevent inappropriate criminal charges and convictions.

Commotio Cordis, Sudden Death, Cardiac

G32 Guidelines and Medical Malpractice in Minor Head Injury Management

Luigi Viola, MD, Nunzio Di Nunno, MD, PhD, Roberto Quaranta, MD, Alessandro Dell'Erba, MD, PhD, and Francesco Vimercati, MD, Bari University, Piazza Giulio Cesare, 11, Bari, 70124, Italy*

This presentation will impact the forensic community and/or humanity by showing the limitations of guidelines used in the management of minor head injuries.

The use of therapeutic-diagnostic protocols and guidelines is spreading more and more within healthcare systems. The guidelines are based upon the latest scientific discoveries of Evidence Based Medicine, and oriented to suggest the most appropriate procedures, optimal recovery time, and tools and resources for every patient in order to identify the best clinical practice and the best possible treatment for that patient.

According to some experts' opinions, the international standardization of the best possible treatment of the most widespread pathologies implies some negative aspects, such as the restriction in being free to make diagnostic and therapeutic decisions by doctors.

Regarding forensic medicine, these guidelines are gaining significant importance: from defensive medicine to medical malpractice. In the forensic medical field, protocols and guidelines are used as scientific references to confirm or contest the doctors' behavior in the cases in which there is the suspicion of professional error.

As minor head injuries (1.6 million victims per year in U.S.A.) may have grievous disabling consequences, the guidelines on this topic have great importance. They provide that patients without neurological signs

and symptoms and with a Glasgow Coma Score of 15 should not be hospitalized.

This study is aimed at verifying the effective reliability of these guidelines in order to make them more complete and to prevent potential malpractice events.

For this purpose, 1,035 case histories, representing all the hospitalizations occurring during the year 2002 in all seven hospitals in a province in Southern Italy, were examined. Two hundred fifty-eight hospitalized people (25%) were negative for loss of consciousness, vomiting, amnesia, cephalgia, and risk factors (clotting pathologies, use of anticoagulant drugs, alcoholism, use of narcotics, previous surgery of the cranium, disabled elderly people), and the physical examination at admission showed a Glasgow Coma Score of 15. All of these patients were admitted to the hospital contrary to guidelines. In fact, for this kind of patients the guidelines suggest discharge, with an instruction sheet in case of the onset of neurological symptoms. An observation period in the hospital and C.T. scanning by the first six hours would be for the patients with loss of consciousness only.

During hospitalization, these patients underwent plain film radiography and/or CT scanning of the head that documented cranial fractures in 7 cases and intracranial lesions in another 5.

Conclusions: the study shows that in the 5% of the patients with minor head injury, noamnesia, and normal neurological examinations—patients that should not be submitted to any medical treatment in accordance with the guidelines—performing additional diagnostic tests could reveal the presence of lesions more serious than initially suspected. The non-diagnosis of these lesions could produce forensic-medical problems resulting in potential malpractice allegations.

Guidelines, Medical Malpractice, Minor Head Injuries

G33 Sudden Death Due to Bilateral Spontaneous Pneumothoraces in a Marijuana User

Joseph A. Felo, DO, Cuyahoga County Coroner's Office, 11001 Cedar Avenue, Cleveland, OH 44106*

After attending this presentation, attendees will realize the rare, and potentially fatal, complications of chronic marijuana smoking.

To the author's knowledge, there have been no previous reports in the medical literature of sudden death due to bilateral spontaneous pneumothoraces in an individual known to use marijuana. This presentation will impact the forensic community and/or humanity by demonstrating the adverse pulmonary effects of marijuana smoking, and focusing on a rare complication that may result in sudden death.

Marijuana remains the most commonly smoked illicit substance in American society. There is a public perception that marijuana smoking has little adverse effect on physical health. However, habitual marijuana smoking may produce lesions in the conducting airways and lung parenchyma similar to those lesions caused by repeated inhalation of tobacco smoke. 9-tetrahydrocannabinol and combustion products of *Cannabis sativa* are respiratory irritants. Compared to tobacco smoke, marijuana smoke causes a fivefold greater increment of blood carboxyhemoglobin level, a threefold increase in the amount of tar inhaled, and retention of one-third more inhaled tar in the respiratory tract. The pulmonary effects of chronic marijuana smoking include epithelial remodelling of airways and barotrauma.

Inhalation of marijuana smoke involves deep, sustained inspiratory effort, often followed by frequent and prolonged Valsalva maneuvers. As a consequence of increased intraalveolar pressure, there may be rupture of alveoli with air leakage into the septal connective tissues. Peripheral dissection of air within the pulmonary interstitium may lead to the formation of visceral pleural blebs or bullae.

Rupture of the visceral pleural bullae may result in a pneumothorax, which is rarely fatal. The reported case documents the gross and micro-

scopic autopsy findings of a 23-year-old male who was a known habitual user of marijuana, whose sudden death was due to bilateral spontaneous pneumothoraces with bilateral apical bullous lung disease. Although giant bullae and nonfatal pneumothoraces have been documented by chest x-ray and CT scan in smokers of marijuana, there have been no known previous reports in the medical literature of sudden death due to bilateral spontaneous pneumothoraces in an individual known to use marijuana.

Marijuana, Pneumothorax, Bullous Lung Disease

G34 Venous Bullet Embolism of a Large Caliber Bullet From the Right External Iliac Vein to the Heart: Case Report and Review of the Literature

Mary G. Ripple, MD*, and David R. Fowler, MD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD 21201

After attending this presentation, attendees will understand the importance of pre-autopsy radiographs in the evaluation of gunshot wounds, become aware of the possibility of large caliber bullets embolizing through the venous system, and become familiar with the literature on venous bullet embolism.

This presentation will impact the forensic community and/or humanity by emphasizing the importance of pre-autopsy radiographs in the evaluation of gunshot wounds, providing the forensic community with a recent literature review on venous bullet embolism, and highlighting the possibility of a large caliber bullet embolizing through the venous system.

This poster will report a case of an unusual venous embolism of a large (.45) caliber bullet from the right external iliac vein to the right ventricle of the heart, and present a literature review of venous bullet embolism to better familiarize the forensic pathologist with this rare entity.

Arterial embolism of a bullet is rare; however, venous embolism is an even more rare occurrence. In both circumstances the bullet is usually a low velocity, small caliber bullet. The literature to date has not reported a case of a .45 caliber venous bullet embolus.

A 30-year-old African-American male was found lying on the floor in a storage room of a convenience store with a gunshot wound to the left lower quadrant of the abdomen. The victim had been standing in front of the store when an unknown suspect approached the victim and began shooting at the victim. The suspect chased the victim into the store and fired additional shots at the victim inside the store. The victim was taken to University of Maryland Shock Trauma and surgery was performed, which revealed a very large hemoperitoneum and retroperitoneal hematoma emanating from the pelvis. Complex vascular injury to the pelvis was repaired, as were the stomach and small bowel, including resection of two portions of the small bowel. The victim arrested on the operating table two hours into the surgery. A preoperative x-ray revealed a large bullet projecting over the right cardiophrenic angle. By report, the victim was supine from the time of the shooting until the autopsy was performed. Autopsy showed a typical gunshot entrance wound on the left side of the front of the abdomen with no soot or gunpowder stippling on the skin surrounding the wound. The bullet traveled front to back, left to right and downward, injuring the stomach, multiple loops of small bowel, the confluence of the left common and external iliac veins and arteries, the bifurcation of the aorta, and the right external iliac vein just proximal to its bifurcation. A minimally deformed, .45 caliber, copper-jacketed bullet was recovered from the right ventricle of the heart.

Bullet embolization should be suspected when there is an entrance wound and no exit wound and the bullet cannot be located in the suspected region after following its path either by visual or x-ray examination. The pattern of bullet embolization depends on body position during and subsequent to the injury; gravity; muscular and respiratory movements; the missile's size, weight and shape; the diameter of the vessel lumen; blood flow; and the blood volume status at the time of injury. Venous bullet

emboli usually end up in the right side of the heart or the pulmonary arteries, with the origin most commonly being the vena cavae or iliac veins. The literature has documented 76 cases of venous bullet embolism from 1834 to present. The vast majority of literature describing venous bullet emboli has been surgical, and therefore items of forensic importance, such as the caliber of the bullet, tend not to be reported. The largest review of 53 cases of venous bullet embolism did not report the calibers of any of the bullets. Of those cases reviewed, the largest caliber bullet found that resulted in a venous embolism was a .38 caliber.

This case emphasizes the importance of pre-autopsy radiographs in the evaluation of gunshot wounds, and points out that one cannot exclude the possibility of a venous bullet embolus simply because of the use of a large caliber bullet.

Venous, Bullet, Embolism

G35 Factors Affecting the Formation of Adipocere in Soils

Shari L. Forbes, BSc, PhD*, Centre for Forensic Science, University of Western Australia, M420, 35 Stirling Highway, Crawley, WA 6009, Australia; Barbara Stuart, PhD, Department of Chemistry, Materials and Forensic Science, University of Technology, Sydney, PO Box 123, Broadway, Australia, 2007; Boyd Dent, PhD, Department of Environmental Sciences, University of Technology, Sydney, PO Box 123, Broadway, Australia, 2007; and Ian R. Dadour, BSc, PhD, Centre for Forensic Science, University of Western Australia, M420, 35 Stirling Highway, Crawley, WA 6009, Australia

The goal of this presentation is to demonstrate to the forensic community the effect of particular burial factors on the formation of adipocere in a soil environment.

The presentation will impact the forensic community by promoting the significance of adipocere formation in burial environments and encouraging further studies in the field of forensic taphonomy.

This presentation will discuss particular factors that are regularly identified in a burial environment and their effect on the formation of adipocere. The research represents a major component of a three year study investigating adipocere formation in grave soils.

Adipocere refers to a soap-like substance that can form during the decomposition process. It is well known as a later postmortem change, particularly in burial environments. Adipocere formation occurs by the alteration of the soft, fatty tissue of a cadaver into a greyish-white substance which comprises mainly saturated fatty acids. The occurrence of adipocere in a burial environment leads to the inhibition of postmortem changes which subsequently preserves the human remains. The degree of decomposition and differential preservation observed depends on the surrounding environment.

Various conditions associated with the burial environment are believed to contribute to the formation of adipocere in soils. Conditions include temperature, moisture, soil type, soil pH, anaerobic environment and the presence of factors such as clothing, coffin, and lime. In the past there have been numerous observational studies commenting on these particular physical factors and methods of burial. However, the literature demonstrates a distinct lack of chemical studies confirming these observations. As a result, a three-year study was conducted to chemically investigate the effect of individual burial factors on adipocere formation in a soil environment.

In order to determine the effect of particular burial conditions on adipocere formation, experiments were conducted in a laboratory environment so that the individual variables could be adequately controlled. The experiments utilized porcine adipose tissue collected from the abdominal region of pigs (*Sus domesticus*) reared on identical diets for commercial use. The fatty tissue samples were buried in soil environments and allowed to decompose for a period of 12 months under individual burial factors. At the completion of this period the samples were analyzed to confirm the formation of adipocere and compared with control samples to determine the effect of the burial factors on its formation.

This presentation will discuss the results of the chemical study and identify those factors which accelerate and retard adipocere formation. Adipocere samples collected from grave exhumations and forensic cases were also analysed and the results will be compared with the controlled laboratory experiment. The research findings will highlight the effects of adipocere formation, particularly with regard to overcrowding in cemeteries due to its regular occurrence in grave sites, and its forensic implications when present in shallow burials or mass graves.

Adipocere, Burial Factors, Grave Soils

G36 Seasonal Distribution and Abundance of Forensically Important Flies in Santa Clara County

Adrienne Brundage, MS*, 1250 A Edgewood Road, Redwood, CA 94062

The goal of this presentation is to identify any seasonal or geographical patterns among forensically important flies within the county that may be important to future investigations using a simple and cost-effective method.

Entomologists working with local law enforcement often encounter gaps in the collective entomological knowledge due to local variation within and among important fly species. This presentation will impact the forensic community and/or humanity by attempting to help close such a gap within Santa Clara County, California.

Forensic entomology has become relatively common in criminal investigations. As insects become more common as indicators of post-mortem interval, gaps in information at the local level become apparent. While flies as forensic indicators are well studied, they exhibit great variation in both successional patterns and seasonal abundance due to microclimates. It is this variation that causes the forensic entomologist the most difficulty. The entomologist must adapt data from studies that have taken place miles away or create new, tailored studies to gather data specific to the current case. While the second option is ideal, time and monetary constraints can make it impossible, leaving the scientist to glean what general information is available in the literature. This does yield acceptable postmortem interval estimation, but accuracy suffers. These issues were brought to the forefront in the bay area by two cases in which general data had to be used due to a lack of local studies. The cases were completed successfully, but the entomologists on the cases identified several glaring gaps in the entomological data specific to Santa Clara County, California. The existence of these cases led to a two-year study of seasonal distribution and abundance of forensically important flies in Santa Clara County, designed to identify and quantify any patterns of fly succession that may be useful in future investigations.

Local homicide investigators were consulted, and three areas within the county were identified as the most common dump sites for human remains: urban areas (specifically within the city of San Jose, California), mountainous areas, and along rivers or streams. Four traps baited with beef liver were placed in each of these areas, one mile apart, and checked for flies once a week for two years beginning in 2001. The liver was changed as needed, and temperature data was collected for all corresponding days from the local airport. The insects collected were then pinned and stored for identification. The resulting collection consisted of over 16,000 flies and 3,000 beetles representing several families. In order to expedite the identification process, only flies belonging to the family *Calliphoridae* were identified, although any other insects were preserved in San Jose State's Entomology Museum for future reference and study. The identification process lasted one year, and the results were entered into a database where seasonal and geographical patterns were easily recognized. The results supported the findings in the two cases that prompted the study, while giving additional insight into current investigations within the county.

Entomology, Calliphoridae, Succession

G37 Establishing a Protocol Between Clinical and Forensic Institutions to Treat and Investigate Violence Against Women Cases

Miguel Lorente, MD, PhD, and A. Carrasco, Institute of Legal Medicine of Granada (Spain), Av.Sur; 5, Granada, 18071, Spain; José A. Lorente, MD, PhD, University of Granada, Department of Forensic Medicine, Granada, 18012, Spain; Enrique Villanueva, MD, PhD, Department of Legal Medicine, University of Granada, Avda. Madrid, sn/, Granada, 18071, Spain*

After attending this presentation, attendees will understand that most aggression against women are not treated correctly because they are unknown, although this does not mean that symptoms are not visible. Only 10% of cases are reported, but 100% of them go to medical institutions asking for assistance for symptoms direct or indirectly related to violence. This study highlights this situation, and underscores the need to coordinate and collaborate through a protocol between forensic and clinical institutions to solve medical and forensic issues and to avoid victimization.

The forensic and clinical medical community must consider violence against women as a global problem. This presentation will impact the forensic community and/or humanity by giving an integral answer that helps the forensic investigation and the recovery of victims.

Introduction: Violence against women is not only a crime, but a social behavior rooted in cultural values given by a patriarchal conception of society and couple relationships. This means that when a case occurs, any of these cultural values may arise to explain and justify the aggression. Only a small percentage of cases (no more than 10%) are reported, and only these cases can get social help. However, all these women go to clinical institutions with symptoms related direct or indirectly to domestic violence.

Material and Methods: The study was performed in medical institutions (Emergency Service and General Practitioner Service) using different questionnaires about domestic violence (physical and psychological) and recording social and demographic features of the patients. The sample was all the women that went to the institutions a period of time of two months, and the tests were reviewed by a physician during a regular consultation.

Results and Discussion: There is no significant difference among the social and demographic features. Of this group of women (patients), 17.9% complained of domestic violence, but paradoxically 51.8% considered their relationships as "good" or "very good." Asking all of women if they would like doctors to ask regularly about family and couple matters, they answered "yes" in 88.5% of cases. Asked if they would like doctors to ask if they suffer violence and aggression, they answered "yes" in 88.6% of cases. But at the same time, 35% of women would not confirm domestic violence if the doctor reported the case.

Legal regulations on this subject need to be reviewed to try to help women and solve the cases. In this sense, a global approach needs to be introduced that considers not only the legal and forensic implications, but also the clinical and the health issues behind this violence. A protocol under this global perspective would help women recover, avoid victimization, assist in answering forensic questions, and ensure appropriate legal action against the aggressors.

Violence Against Women, Domestic Violence, Protocol of Assistance

G38 Analytical Electron Microscopic Detection of Aluminum Received Intravenously

Sarah M. Colvin, MD*, Carol Allan, MD, Laron Locke, MD, Mary G. Ripple, MD, and David R. Fowler, MD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD 21201; and Victor Roggli, MD, Duke University Health Systems, Department of Pathology, Box 3712, DUMC, Durham, NC 27710

The goal of this presentation is for the attendees to realize the feasibility of detecting and identifying postmortem heavy metals in non-environmental exposure cases (i.e., mineral pneumoconioses).

This presentation will impact the forensic community and/or humanity by illustrating the utility of applying alternative methods, specifically scanning electron microscopy with electron dispersive spectrometry, for demonstrating the presence of aluminum intravascularly.

This presentation details the postmortem detection of aluminum inadvertently received intravenously. Careful consideration of investigative details can occasionally generate hypotheses that are difficult to conclusively prove using conventional forensic methods; however, focused collaboration with specialists from other fields can yield definitive causes of death as in this case of postmortem detection of aluminum as a result of a therapeutic misadventure.

A 77-year-old man with a past medical history of coronary artery disease and prior brachytherapy for localized prostate cancer was admitted to the hospital for continued urinary bleeding following direct visual internal urethrotomy for urethral stricture. At surgery, a persistent clot in the bladder and an inflamed prostate were discovered. The clot was removed and the prostate resected.

Alum bladder irrigation, containing aluminum ammonium sulfate, aluminum potassium sulfate, ammonium alum and potassium alum, was ordered, prior to and following the operation. The morning following the operation the man was discovered unresponsive. Both a nurse and doctor noted during resuscitative efforts that a bladder irrigation bag was connected to the man's intravenous catheter. In such cases, the involvement of hospital risk management is paramount; however, risk management from the hospital in this case could not conclude whether the Alum solution had infused intravenously, and if so, how much he had received.

The deceased underwent an autopsy. Gross autopsy findings were those of hypertensive and atherosclerotic coronary artery disease. Microscopic findings were most notable for thrombi in pulmonary arterioles and capillaries, which stained with periodic acid-Schiff stain.

Scanning electron microscopy (SEM) with back scattered electronic imaging (BEI) and energy dispersive spectrometry (EDS) was performed on the lung sections. The forensic community is more familiar with the role of analysis of gunpowder primer residues with SEM/EDS. These techniques are more often used on lung sections to determine composition of intrapulmonary materials that cause the different pneumoconioses. These same techniques were used in this case to determine if the aluminum-containing bladder irrigation material was present intravascularly. Smudgy material within some of the blood vessels demonstrated distinct peaks for aluminum with energy dispersive spectrometry.

Nitrogen and sulfur are commonly seen as endogenous tissue components; aluminum is not. It was concluded that the deceased had received intravenous Alum bladder irrigant solution and that this therapeutic misadventure was his underlying cause of death. This case demonstrates the benefit of selective use of non-conventional methods to solve a forensic case by the use of SEM with BEI and EDS in order to demonstrate intravascular aluminum.

Aluminum, Intravascular, SEM/EDS

G39 Evaluation of Clinical Diagnostic Accuracy in Post-Coronary Artery Bypass Graft Surgery Mortality

Marianne Hamel, MD, PhD*, Department of Pathology, Anatomy and Cell Biology, Thomas Jefferson University Hospital, 125 South 11th Street, Suite 204 Foerderer Pavilion, Philadelphia, PA 19107-4998; Johan A. Duflou, MMed, Department of Forensic Medicine, Central Sydney Laboratory Service, 42-50 Parramatta Road, Glebe, NSW 2037, Australia

The goal of this presentation is to demonstrate the medical and legal value of autopsy in non-forensic deaths, specifically those occurring after coronary artery bypass graft surgery.

This presentation will impact the forensic community and/or humanity by examining the value of performing autopsies in post-surgical deaths. The commonly held view amongst clinicians is that autopsies are of value for plaintiffs in medical malpractice suits. This paper shows that the autopsy can answer questions and provide valuable information on surgical technique, thereby decreasing the chances of litigation.

This presentation compares the accuracy of clinical diagnoses in post-coronary artery bypass grafts (CABG) mortalities to those made via postmortem diagnosis.

In accordance with relevant Australian legislation, all deaths within 24 hours of surgical anesthesia must be reported to the coroner. As part of this notification, detailed medical, surgical and anesthetic information is provided, medical charts are perused and a postmortem examination is conducted. Clinicians who treated the decedent are required to provide an opinion on the likely cause of death prior to being informed of the autopsy findings. The autopsy pathologist is therefore in an ideal position to ascertain the accuracy of clinical diagnoses after a comprehensive postmortem examination is performed.

A total of 140 deaths within 24 hours of CABG surgery were identified in the Department of Forensic Medicine in Central Sydney, Australia database spanning an 8 year period between 1996 and 2003. Of these, detailed information was available in 134 cases. Comprehensive autopsies, including histology, and—where relevant—toxicology and a range of other investigations, were conducted in all cases. Deaths were examined from seven hospitals, and all hospitals providing a cardiac surgery service in the Department's geographic coverage area were represented.

At autopsy, 23% of cases demonstrated clear discordance between clinical and pathological diagnoses. These deaths occurred despite intensive care monitoring, which presumably supplies exceptional vigilance in post-surgical care. Commonly misidentified conditions included pump failure, peri-surgical myocardial infarction, aortic dissection, and arrhythmia. Clinicians were more likely to diagnose acute myocardial infarction than autopsy pathologists. Errors in cause of death formulation were identified in the vast majority of cases on the basis of gross pathological findings, with histologic examination being of assistance in supporting the diagnosis rather than identifying a different or additional cause of death. Though there is a significant rate of diagnostic error in determining cause of death in post-CABG deaths, fewer than 1% of study deaths were a result of surgical error. The single error identified was a case of iatrogenic rupture of the iliac artery.

Hospital autopsy rates have fallen from a high of 30-40% in the 1960s to single digit rates today. This precipitous decline represents a myriad of lost opportunities to improve post-surgical outcomes. A reason frequently given for the decline in autopsy rates is a fear that the autopsy could be used as a tool to assist the plaintiff's attorney in malpractice litigation. Studies like this one suggest the opposite. Not only are autopsies an important clinical and post-surgical audit tool, but helpful in minimizing uncertainty in relation to possible errors in clinical management and surgical technique. The findings of this study suggest that the postmortem examination is far more likely to shield a clinician from liability than to expose technical mistakes.

Autopsy, CABG Surgery Deaths, Postmortem Diagnosis

G40 Adolescent Death: A 15-Year Retrospective Study

Nick I. Batalis, MD, and Kim A. Collins, MD, Medical University of South Carolina, 165 Ashley Avenue, Main Hospital, Room 281, Charleston, SC 29425*

After attending this presentation, attendees will know the most common causes and manners of death in the adolescent population; understand the typical victims, perpetrators, and trends in violent deaths; and be aware of the most common drugs of abuse in the adolescent age group.

This presentation will impact the forensic community and/or humanity by providing a thorough classification of adolescent deaths which could be useful in various ways to coroners, medical examiners, pathologists, and investigators when confronted with an adolescent death. Knowing common relationships of perpetrators to victims in violent deaths could help to find and convict the perpetrators. Also, understanding the typical victim and circumstances surrounding his or her death could help to prevent future violent adolescent deaths. A review of the toxicology in these cases could help delineate any trends in drugs of use and abuse in the adolescent age group, making it possible to prevent some accidental deaths through public health and safety measures. Finally, a review of natural deaths will demonstrate the most common natural disease processes, which could help in determining the causes of sudden, unexpected deaths in this population.

Adolescents, defined by the World Health Organization (WHO) as children ages 10-19, are a diverse group of people undergoing many changes in life as they develop, mature, and become adults. Still, pediatric forensic literature is dominated by reports, reviews, and studies of fetal, infant, and early childhood death. Previous studies have looked at specific aspects of adolescent death, but there remains a paucity of literature reporting the most common causes and manners of death along with other pertinent demographics of these victims.

The authors reviewed all cases of pediatric death referred to the Medical University of South Carolina Forensic Pathology section over the fifteen years between January 1989 and December 2003. In accordance with the WHO definition, only children 10-19 years of age were included. In all, 542 of 9540 total cases were studied. The authors examined the cause and manner of death along with the age, sex, and race of the victim. The toxicology results, perpetrator identification, death scenario and location, and victim traits were also analyzed. Homicides and suicides were due to gunshot wounds, blunt force trauma, sharp force injury, and asphyxia. Accidents were subdivided into environmental exposure, drug/inhalation toxicity, vehicle collision, and other. Natural deaths were classified by organ system. Adolescents comprise an eclectic mix of people vitally important to society, yet long-term comprehensive studies on the circumstances of their deaths are lacking in the literature. With a solid understanding of these circumstances it may be possible to predict, and hopefully prevent, future cases of adolescent death. The authors present their findings in this 15-year retrospective study to better aid forensic pathologists, death investigators, law enforcement, and epidemiologists.

Adolescent, Death, Forensic Medicine

G41 Heightened Awareness of Bioterrorism: Three Cases of Unusual Skin Lesions

John A. Stash, DO, Zabiullah Ali, MD, Carol Allan, MD, Ana Rubio, MD, Mary G Ripple, MD, and David R. Fowler, MD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD 21201*

Attendees will learn of the heightened awareness of bioterrorism since the terrorist attacks in 2001, and how this has raised the suspicion of law enforcement and medical personnel in evaluating skin lesions. The attendee will also learn the cutaneous manifestations of several bioterrorist agents.

This presentation will impact the forensic community and/or humanity by providing an increased understanding of how recent historical events involving terrorism and bioterrorism have affected the law enforcement and medical communities. They will gain an understanding through the case reports presented of how these events have increased the suspicion of bioterrorism when evaluating unusual skin lesions. They will increase their understanding of, and ability to recognize, the cutaneous manifestations of bioterrorist agents through the review of those agents.

The goal of this presentation is to discuss three cases of unusual skin lesions that presented in February of 2004, to the OCME in Baltimore, MD, and how the recent heightened awareness of bioterrorism affected the medical community and handling of these cases. In addition, skin lesions associated with bioterrorism will be reviewed.

Since the terrorist attacks on September 11, 2001, and the anthrax attacks that began two weeks later, there has been an increased awareness of possible terrorist and bioterrorist attacks throughout the United States. The media, in particular, has elevated this awareness not only with reports on the anthrax attack, but with reports of other possible agents that could be used in a bioterrorist attack, such as smallpox or plague. This increased awareness has lowered the threshold of the medical community in the suspicion of bioterrorist attack in the evaluation of skin lesions. The following three cases illustrate this heightened awareness and suspicion of bioterrorism, and also reinforce the role of the medical examiner in public health surveillance.

Case Report: A previously healthy 40-year-old Hispanic female had complained of rash and shortness of breath for one week. Her family found her on the floor and transported her to the Emergency Department. There she was noted to be asystolic, with fixed and dilated pupils and no respirations. Numerous crusted and scabbed lesions varying in size and stage of healing were noted on her face, torso, and extremities. The Emergency Department expressed concern about Varicella lesions other than Varicella-zoster (chicken pox), and the body was sent to the medical examiner's office to rule out smallpox.

Case Report: A previously healthy 46-year-old white male was found facedown in the hallway of the lower level of his home. The residence was secure and the family entered the dwelling after not being able to reach him for several days. According to a coworker, several days earlier, the decedent said that he would be out of the office for a week after being diagnosed with a viral infection at a local walk-in clinic. At autopsy, multiple crusted ulcers on his head, chest, left upper thigh, and anterior aspect of the right leg were noted. There was also a crusted eschar noted on his abdomen, and multiple non-crusted necrotic ulcers on his right buttock, right posterior medial thigh, left axilla, back of the neck, lower lumbar spine, and left upper chest. Law enforcement officials expressed concern about possible cutaneous anthrax because the deceased was employed by the National Security Agency.

Case Report: A previously healthy 61-year-old Chinese female that reportedly arrived from China 20 days earlier collapsed in her bathroom. Her family, who called 911, heard the fall. Upon EMS arrival she was found to be asystolic and ACLS was initiated. She was pronounced dead upon arrival to the Emergency Department. While in China she had contracted a pruritic skin disease of unknown cause, and since her arrival had also reportedly felt weak and experienced a gradual decline in appetite. The disease started on her right arm and spread to the rest of her body. For

the three days prior to her death she was bedridden. At the hospital multiple skin lesions in various stages of healing ranging from bullae to ruptured bullae, raw erosions, dried erosions, crusted lesions, and hypopigmented scars were noted. The local health department expressed concern about possible bioterrorism.

The heightened awareness of bioterrorism has stimulated an increased response to unusual and aggressive appearing skin lesions among the medical and law enforcement communities. These three cases illustrate that response, and also provide examples of possible mimickers of bioterrorism for comparison to the cutaneous bioterrorist agents reviewed.

Bioterrorism, Skin Lesions, Case Reports

G42 Amended Cause and Manner of Death Certification: A Six-Year Review of the New Mexico Experience

Philip R. Croft, MD, Sarah L. Lathrop, DVM, PhD, and Ross E. Zumwalt, MD, Office of the Medical Investigator, MSC11 6030, 1 University of New Mexico, Albuquerque, NM 87131-0001*

After attending this presentation, attendees will understand the state medical examiner office's experience with the amendment of cause and/or manner of death on death certificates, including frequency of amendment, time between original certification and amendment, reasons for amendment, and in what way death certification was changed. This presentation will impact the forensic community and/or humanity by providing information about how, why, when, and how often the cause and/or manner of death is/are amended on death certificates completed by forensic pathologists. While the answers to these questions are of value to the forensic community, little formal study has been undertaken in this area.

At the end of June 2003, the New Mexico Office of the Medical Investigator (OMI) computer database was searched for all amended death certificates signed by OMI pathologists from 1997 through 2002. Each case file was reviewed in order to identify only those death certificates (DCs) with amended cause and/or manner of death fields. Cases that were initially external examinations only and subsequently became autopsies, DCs originally signed out by someone other than an OMI pathologist, "brain only" research-oriented autopsies, and DCs originally signed out as "pending" were excluded. Cause of death (COD), amended cause of death (ACOD), manner of death (MOD), amended manner of death (AMOD), the time elapsed (TE) between the original and amended DCs, and the reasons for the changes were recorded for the remaining cases. The reasons for the changes were categorized as medical records review, histology, investigations, family concerns, microbiology, or error. "Family concerns" included any family member, as well as third parties such as friends, caretakers, or primary physicians. Statistical analyses were performed using SAS version 8.02 statistical analysis software for Windows and EpiInfo 2002.

The database search identified 108 cases that fit the above criteria, 0.86% of all cases handled at OMI over the study period. This total included 81 autopsies and 27 external examinations. One of the 108 cases was amended twice, increasing the total number of amended DCs to 109. Autopsy DCs from 1997 to 1999 were significantly more likely to be amended than those from 2000 to 2002 ($P=0.02$). COD was amended on 62 of these 109 DCs. Twenty-three different CODs were used in these 62 DCs, with arteriosclerotic cardiovascular disease (ASCVD) accounting for almost a quarter. Twenty-nine different ACODs were used on the resulting 62 amended DCs, with intoxicant(s) comprising nearly a third. MOD was amended on 72 of these 109 DCs. Natural deaths had the greatest percentage of amended DCs (1.39%), followed by suicides (1.22%). Overall, there was a significant association between manner of death and the number of DCs amended ($P<0.001$). For external examinations, natural and suicide DCs were significantly more likely to be amended than accidents ($P=0.0002$ and $P=0.019$, respectively). Natural-to-accident (N-A)

was the most common direction of change (28 DCs), followed by suicide-to-undetermined (S-U; 14 DCs). The mean TE between the original DC and amended DC was 3.83 months (SD 6.6 months). DCs amended secondary to investigations went the longest between signatures, with a mean of 8 months. The direction of change was significantly associated with TE ($P=0.04$). The directions most associated with an increasing TE were N-S, U-H, N-U, A-U, S-U and N-A. Toxicology was the most common reason for DC amendment (40 DCs) and MOD amendment (28 DCs), followed by family concerns (23 and 19 DCs, respectively) and investigations (13 and 12 DCs, respectively). Toxicology was also the most common reason for amending COD (26 DCs); histology was the second most common reason for COD amendment (11 DCs), followed by both family concerns and medical records review (8 DCs each). Of the fourteen DCs that changed from suicide-to-undetermined, eleven were triggered by family concerns. Of the twelve DCs in which MOD was amended secondary to investigations, nine moved to a MOD of undetermined. Twelve of the 109 DCs had "gunshot wound of head" as the COD, all but one of which had suicide as the MOD. Eight of these eleven suicides were subsequently amended to undetermined, and in ten the impetus was family concerns.

In conclusion, approximately 1% of death certificates signed by OMI pathologists had either cause or manner of death amended, with a slightly higher amendment percentage for external examinations than autopsies. ASCVD was the most commonly amended COD, and intoxicant(s) was the most common ACOD. There was a significant association between MOD and number of amended DCs. By percent, natural and suicide DCs were the most frequently amended. Natural-to-accident and suicide-to-undetermined were the most common directions in which MOD changed. Toxicology was the most common reason for amendment; family concerns were the impetus behind most suicide-to-undetermined amendments, with most of these cases involving gunshot wounds of the head. The average time to amendment was just under 4 months, and direction of change was significantly associated with the time elapsed. This information on how, why, when, and how often cause and/or manner of death certification is amended is both interesting and useful to the forensics community.

Death Certificate, Manner of Death, Autopsy

G43 The Relationship of Drug Abuse to Unexplained Sudden Death

Amy C. Gruszecki, DO, Jefferson County Coroner Medical Examiner Office, 1515 6th Avenue South, Suite 611, Birmingham, AL 35233; Gerald McGwin, Jr., PhD, Department of Epidemiology, School of Public Health, University of Alabama, Birmingham, AL 35233; C. Andrew Robinson, PhD, Department of Pathology, Forensic Division, University of Alabama, Birmingham, AL 35233; and Gregory G. Davis, MD, MSPH, Jefferson County Coroner Medical Examiner Office, 1515 6th Avenue South, Suite 611, Birmingham, AL 35233*

The goal of this presentation is to define the relationship between drug abuse and deaths where neither anatomical nor toxicological cause for death is found.

This presentation will impact the forensic community and/or humanity by recommending that decedents with a convincing history of drug abuse and no other anatomical or toxicological findings at autopsy have their cause of death certified as being due to chronic drug abuse.

Rationale: Cases of young adults with a history of drug abuse who have died suddenly and unexpectedly in whom neither anatomical nor toxicological cause for death is found at autopsy are received regularly. The common presence of a history of drug abuse, however, has led researchers to hypothesize that drug abuse not only induces some change that increases the risk of sudden death, but that this change persists after the drug is no longer detectable in the body. The first part of this study was presented at the 2004 Annual Meeting of the American Academy of Forensic Sciences in Dallas, Texas, where it was shown that deaths certified as undetermined

in cause and manner have an increased likelihood of having a history of drug abuse when compared to a control group of medical examiner cases. In this second part of this study was tested the null hypothesis, "There is no difference in the frequency of drug abuse in a study group dying of undetermined cause when compared to the frequency of drug abuse in a matched control group of patients admitted for cholecystectomy," with the intent of establishing whether a history of drug abuse increases the likelihood of sudden death.

Methods: A retrospective case-control study conducted of deaths investigated by the Jefferson County Coroner/Medical Examiner Office, Alabama between 1986 and 2003. The study group consisted of decedents between 10 and 70 years of age whose cause and manner of death remained undetermined following an autopsy and toxicological analysis for ethanol and drugs of abuse. The control group was chosen from living patients who underwent cholecystectomy at the indigent care hospital serving Jefferson County, Alabama, a population similar to that seen in the medical examiner office. Three controls were matched to each study group member to within 5 years of the age of the study decedent and within two calendar years of the date of death of the study decedent (to keep social trends and testing methods comparable). The charts of both the study group (decedents) and of the control group (patients) were reviewed for evidence of drug abuse. All toxicology results were noted in the decedents, including the presence of cocaine, any other drugs or medications, and ethanol. Decomposed remains were included in the study group. The charts of the living control group were reviewed for a history of drug abuse and hypertension in accordance with the hospital Institutional Review Board.

Results: The study group of undetermined deaths consisted of 62 decedents, 24 of whom had some evidence of drug abuse (history, physical signs, positive toxicology for cocaine or its metabolites in urine or bile, opiates, or methamphetamine). In the matched control group 9 of 186 patients had a known history of drug abuse. Cases in the study group were seven times (odds ratio 7.0; 95% confidence interval 3.5-14.1; p<0.0001) more likely to have a history of drug abuse than the controls. In other words, given the design of this study, an individual with an undetermined cause of death is seven times more likely to have a history of drug abuse than is a living patient chosen from a similar population. Given the small p-value, chance is an unlikely explanation for these results. Heart disease can cause sudden death by dysrhythmia, and should be considered as a cause of death in the decedents, but cases with heart disease sufficient to account for death were not considered undetermined as to cause of death and were thus excluded from the study group. This exclusion is reflected by statistical analysis that showed hypertension was less common in the study group than in the control group of cholecystectomy patients.

Conclusion: This is the second study to show that a history of drug abuse is far more common in decedents with an undetermined cause of death than it is in a control group chosen to represent a random sample of the population. Epidemiological theory indicates that for rare events, such as the death of an individual with a history of drug abuse, the measure of the association between the risk (here drug abuse) and the event (here death) is a valid and accurate predictor of the incidence of death due to a given risk factor. In other words, individuals who abuse drugs are at increased risk of dying suddenly because of their habit of abusing drugs, even if not acutely intoxicated at the time of death. Based on these findings, the authors recommend that decedents with a convincing history of drug abuse and no other anatomical or toxicological findings at autopsy have their cause of death certified as being due to chronic drug abuse.

Drug Abuse, Sudden Death, Pathology

G44 Natural Causes of Death Among a Federal Medical Center Prison Population

Peter T. Lin, MD, and Eric A. Pfeifer, MD, Mayo Clinic, 200 First Street, SW, Hilton 11, Rochester, MN 55905*

The goal of this presentation is to review the natural causes of death among federal prisoners treated at a Federal Medical Center during the period 1986-2004, in order to understand the spectrum of complicated natural disease present in the federal prisoner population and to use that knowledge towards a more accurate determination of manner and cause of deaths that occur while in custody.

This presentation will impact the forensic community and/or humanity by adding to the available knowledge base concerning natural causes of death in prisoner populations. Because of the referral medical center population studied, particular attention will be paid to complicated and severe natural diseases. An understanding of complex disease patterns present in prisoners will assist in accurately determining manner and causes of deaths in custody.

Outcome: To understand the spectrum of complicated natural disease present in the federal prisoner population and to use that knowledge towards a more accurate determination of manner and cause of deaths that occur while in custody.

Deaths that occur while in custody are routinely investigated, and often require an autopsy to determine the manner and cause of death. A thorough medicolegal investigation protects the interests of the prisoners, the custodians, and the general public by assisting in the prosecution of prison homicides, documenting natural causes of death when unnatural causes may be suspected, and identifying contagious diseases that may pose a public health risk to prisoners and facility personnel. As in non-incarcerated populations, the task of determining manner and cause of death in an apparently unnatural death is sometimes complicated by potentially lethal natural disease present in the deceased. Therefore, it is important for forensic pathologists and death investigators to understand the unique patterns of natural disease that occur in prisoner populations.

This paper will review natural causes of death among federal prisoners who were treated at the Rochester Federal Medical Center during the period 1986-2004. The Federal Medical Center system is a network of seven specialized medical centers located throughout the U.S. and operated by the Federal Bureau of Prisons. The Rochester Federal Medical Center is a major medical and mental health referral center for male prisoners. In some instances, consultations are provided through the Mayo Clinic.

Since 1986, the Mayo Clinic has performed 323 autopsies on deaths occurring at the Rochester Federal Medical Center. Of the 323 deaths, 320 were natural deaths and 3 were suicides, all by hanging. The vast majority of natural deaths could be attributed to one of 4 general categories, cancer-related (148), liver disease-related (63), AIDS-related (57), and cardiovascular disease-related (37). The average age at death for each category was: cancer-related, 54.2 years; liver disease-related, 49.6 years; AIDS-related, 39.9 years; and cardiovascular disease-related, 57.0 years. Less common natural causes of death included pulmonary embolism (3), stroke (3), sepsis (2), end stage renal disease (2), aspiration pneumonia (2), chronic obstructive pulmonary disease (1), warfarin toxicity (1) and sarcoidosis involving the heart (1). Among the cancer-related deaths, the five most common primary sites were lung (45), hematolymphoid (17), colon (16), pancreas (12) and head and neck (10). In addition, hepatocellular carcinoma was identified in 17 prisoners who died of liver disease. Some of the more unusual tumors included malignant fibrous histiocytoma (1), gallbladder carcinoma (1) and osteosarcoma (1). Among the 37 cardiovascular causes of death, 34 were due to ischemic heart disease and 3 were due to idiopathic dilated cardiomyopathy. Among the 63 liver-disease related deaths, 55 were associated with chronic hepatitis C infection, 3 with alcohol abuse without evidence of hepatitis C infection, 3 with no known cause, and 2 due to primary sclerosing cholangitis. The highest number of liver-related deaths occurred in 1999, accounting for 12 of 29 deaths that

year. AIDS-related deaths peaked in the year 1995, accounting for 11 of 23 deaths that year.

This study differs from previous studies of prison deaths because the study population consisted only of prisoner deaths occurring at a Federal Medical Center. Unnatural and sudden deaths are notably lacking due to the population studied, but the three suicides by hanging corroborate previous reports of an increased risk for suicide while incarcerated; the preferred modality being hanging. The over-representation of cancer-related deaths reflects the referral center population of this study. Previous studies have found cardiovascular disease to be the most common natural cause of death among prisoners. The distribution of cancer types suggests an increased number of deaths from hemato-lymphoid and head and neck cancers, and a decreased number of deaths from prostate cancer, compared to the general population.

Overall, the spectrum of disease present in federal prisoners appears to be as wide as would be expected in a prisoner population numbering over 2 million in 2003. With frequent allegations of prisoner maltreatment bringing increasing scrutiny into deaths occurring while in custody, further studies of natural disease in prisoners will assist in determining manner and cause of deaths in custody.

Natural, Deaths, Custody

G45 Distribution Pattern of Pulmonary Surfactant Protein A (SP-A) in Drowning and Opiate-Related Deaths

Carlo P. Campobasso, MD, PhD, Alessandro S. Dell'Erba, MD, PhD, Annalisa Addante, MD, PhD, Fiorenza Zotti, PhD, Sara Sblano, MD, and Massimo F. Colonna, MD, LLB, Section of Legal Medicine (Di.M.I.M.P.), University of Bari, Piazza Giulio Cesare, Policlinico di Bari, Bari, 70124, Italy*

After attending this presentation, attendees will understand the immunohistochemistry of pulmonary surfactant and the usefulness of SP-A staining as diagnostic marker of alveolar injury in drowning compared with agonal changes such as pulmonary edema in opiate-related deaths.

This presentation will impact the forensic community and/or humanity by demonstrating to the forensic pathology community a finding supporting the final diagnosis of drowning by routinely using SP-A staining.

Pulmonary surfactant covers the surface of the alveoli and prevents alveolar collapse by lowering surface tension. It is composed of phospholipids (90%) and proteins (10%). Four surfactant-associated proteins (SPs) have been identified: hydrophilic SP-A and -D, and hydrophobic SP-B and -C. SP-A is the most prevalent form, and is produced in the alveolar type II cells. Under normal conditions, SP-A is immunohistochemically detected in the alveolar type II cells, but also on the alveolar interior surface since a small quantity of SP-A is secreted into the alveoli. The immunohistochemical distribution pattern of SP-A in the intra-alveolar space has been previously reported as a useful tool to distinguish mechanical asphyxia from other hypoxic cases (Zhu *et al.*, 2000). It can also be considered a valuable marker of the pulmonary dysfunction in drowning, showing partial differences in pulmonary pathophysiology depending on the immersion medium (Zhu *et al.*, 2002). Many prominent, massive aggregates of granular SP-A staining observed in the intra-alveolar space have been considered the result of an enhanced secretion caused by strong forced breathing that often takes place in the mechanical asphyxia, or by over-excitement of the autonomic nervous system or, even more, by the Ca^{2+} ions in the edema fluid. The above-mentioned aggregated form may also indicate an early biochemical alteration of SP-A in asphyxial deaths.

To evaluate the role of plasma components exuded into the alveolar space and its relationship with the distribution pattern of SP-A, the authors

have retrospectively investigated a total of 48 forensic autopsy cases. They have been divided into three main groups: 18 cases of drowning (12 in salt water and 6 cases in fresh water), 20 cases of opiate-related deaths showing gross pulmonary edema and, as a control group, 10 cases of rapid deaths by gunshot injuries to the head without pulmonary edema. The study was carried out on paraffin tissue blocks from which serial sections (4 μm thick) were used for hematoxylin-eosin and immunostaining. For immunohistochemistry, anti-human SP-A mouse monoclonal antibody (Novo Castra Laboratories Ltd; U.K.) was used at 150-fold dilution, with a 1-hour incubation at room temperature, using the universal Avidin-Biotin Complex (ABC). The expression of the SP-A staining was scored semiquantitatively based on two staining patterns: membranous or linear staining on the interior surface of alveolar epithelia, and the interface of intra-alveolar effusion and granular staining showing many prominent massive aggregates of SP-A within the intra-alveolar space.

The results show that aggregated granular SP-A staining in the intra-alveolar space was frequently observed in drowning victims. A high intensity of this pattern was frequently found in these victims, suggesting a molecular alteration caused by a direct effect of aspirated water and/or subsequent metabolic disturbance in the alveolar type II cells. Granular deposits of SP-A in the intra-alveolar space were never observed in the control group of non-asphyxial deaths (10 cases of fatal gunshot injuries). The group of gross pulmonary edema observed in narcotic deaths showed a prevalent distribution of membranous or linear pattern staining and only scattered SP-A aggregates in the intra-alveolar space. The granular SP-A staining detected in pulmonary edema is consistent with previous findings of SP-A positive staining in lungs with secondary damage such as acute respiratory distress syndrome (ARDS) or a bronchial lavage causing both a biochemical alteration of pulmonary surfactant. These results suggest some molecular alterations of SP-A due to abnormal surfactant metabolism caused by edema fluid. Based on the comparison of SP-A distribution pattern between drowning, agonal changes such as pulmonary edema, and non-asphyxial deaths, the expression of intra-alveolar SP-A aggregates can significantly support the final diagnosis of drowning.

Pulmonary Surfactant, Drowning, Opiate-Related Deaths

G46 Drowning vs. Trauma and Other Causes of Asphyxia in Deaths in Water

Karen B. Looman, DO, Pathology Residency Program, Eastern Virginia Medical School, 700 West Olney Road, Norfolk, VA 23507-1607; Wendy M. Gunther, MD, Office of the Chief Medical Examiner, Tidewater District, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510-1046; and E.L. Kinnison, Office of the Chief Medical Examiner, Tidewater District, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510-1046*

The goal of this presentation is to review three cases which reveal the necessity of looking more closely at cases that involve water. They are ideal instances where the cause of death appeared obvious, but because a body of water was involved things were not what they seemed. These cases reinforce the need to perform autopsies on any case involved with submersion in water.

This presentation will impact the forensic community and/or humanity by reinforcing the need to closely evaluate violent deaths that involve water.

Drowning appears to be an easy cause of death to diagnose whenever a person is found not breathing in water. In reverse, drowning is not the first diagnosis that comes to mind when only a little amount of water is present at a scene. These three case histories illustrate some of the difficulties in evaluating the role of drowning in complicated cases, particularly when autopsy findings are found to be inconsistent with initial impressions gained from scene investigation. External examination of bodies in such cases may be misleading.

Case One: A 47-year-old male was standing on a dock pier performing martial arts exercises. He had a history of violence and substance abuse. A bystander witnessed this man finish warming up, tuck a necklace into his shirt, and dive off the pier head first. The man rose to the surface of the water, and floated as if unconscious. He was rescued within five minutes of the incident, but could not be resuscitated. External examination revealed a small abrasion along the vertex of his head. His face was congested, and he had some jugular venous distension. There were no other obvious external traumatic injuries. Death was initially attributed to drowning, with consideration of a cardiac event, possibly related to intoxication with cocaine.

Case Two: A 39-year-old male was driving alone in his sports car, without seat belt restraint, along a two-lane road. He lost control of the vehicle, which went off the roadway, flipped into the air, and landed on its roof in a ditch that contained four inches of water. It is not known how long the man was in the car prior to the arrival of the first bystanders who attempted to render aid, but the time interval was less than 10 minutes. The first bystanders attempted to pull the man from the passenger window of the car. When police arrived at 10 minutes from the time of the initial accident, the man was found face down outside the passenger window of his car. Emergency medical personnel failed to find a pulse, and he was pronounced dead. External examination of the body revealed adherent leaves and mud, with dicing injury to the forehead, left flank, and left thigh. Lacerations and bruising were apparent on the chin and lower extremities. Conjunctival and intraoral petechiae were identified. No other major trauma was obvious on external physical exam. Drowning was not considered among the causes of death at initial examination. Positional or traumatic asphyxia was considered.

Case Three: A 46-year-old male with a history of alcohol abuse was riding his bicycle at night along a street. He was struck by a motor vehicle, thrown into the air, and landed in a ditch, face down, in 6-7 inches of water. He remained in the water for several minutes, because the woman whose car had hit him was unable to pull him out unassisted. Ultimately, other bystanders pulled the man out of the water, but by that time emergency personnel could not revive him. External exam was remarkable for lack of injury, other than superficial abrasions on his hip and thigh. Cervical fracture was considered the likeliest possibility at initial examination.

These three cases underscore the difficulty in identifying what role drowning may play in death. Evaluation of the scene, the body, and the history may suggest a misleading cause of death. Autopsy may be required to make an ultimate diagnosis.

Drowning, Asphyxia, Violence

G47 Study of the Diagnostic Value of Iron in Freshwater Drowning

Geoffroy Lorin de la Grandmaison, MD*, M. Lettereux, PharmD, K. Lasseguette, MD, J.C. Alvarez, PharmD, Philippe de Mazancourt, MD, PhD, and Michel Durigon, MD, PhD, Department of Forensic Pathology, Raymond Poincaré Hospital, Garches, 92 380, France

After attending this presentation, attendees will be able to test the diagnostic value of iron (Ir) in freshwater drowning by investigating the postmortem levels of hemodilution in drowning cases compared to control cases.

This presentation will impact the forensic community and/or humanity by demonstrating the importance of postmortem biochemistry for the diagnosis of freshwater drowning.

Material and Methods: Twenty-six typical freshwater drowning cases were selected from all immersion cases autopsied in the Department of Forensic Pathology between 1998 and 2004 (n=128). The exclusion criteria were a long postmortem interval (more than one week) and causes of death other than drowning (acute intoxication or trauma). For all selected

cases, the diagnosis of drowning was based on the presence of autopsy findings (including overinflated lungs, pulmonary edema, frothy contents in the airways) and positive diatom test. The diatom test was performed after treatment of the samples with Soluen-350. The test was considered positive when a significant number of diatoms were detected in lungs and other internal organs (liver, kidney, bone marrow) and when concordance of diatom types recovered from organs and the putative drowning medium were found. A control population of 12 cases was also selected. For each case, age, sex, manner of death, postmortem interval, and resuscitation attempts were reported from the postmortem records. For each drowning and control case, blood iron levels were measured in the left ventricle (LV) and right ventricle (RV) of the heart. The mean difference of iron concentration (RVIr-LVIr) between the drowning group and the control group was compared. Furthermore, iron measurements were performed in 19 drowning cases showing advanced putrefaction.

Results and Discussion: The mean age of the drowning cases was 43.2 years. The mean age of the control population was 36.2 years. In the majority of the drowning cases, manner of death was suicide (n=14). The mean difference of iron concentration was significantly higher in the drowning cases compared with age and sex-matched controls ($p<0.001$). All drowning cases showed hemodilution. Four control cases showed hemoconcentration. No overlap was found in the RVIr-LVIr levels between the two groups. In the control group, the maximal RVIr-LVIr level was equal to 11 micromol/l. In the drowning group, the difference levels ranged from 12 to 387 micromol/l. Resuscitation seemed to have no effect on the results. In cases of drowning showing advanced putrefaction, the iron test was not reliable because biochemical iron measurement was often prevented by inability to obtain postmortem blood.

Conclusion: According to the results, iron seems to be a good biochemical marker for freshwater drowning with a short postmortem interval.

Drowning, Iron, Postmortem Biochemistry

G48 Elder Abuse and Neglect Death Review: Use of an Interagency Team

Christopher Swalwell, MD*, Medical Examiner's Office, San Diego County, 5555 Overland Avenue, Building 14, San Diego, CA 92123

After attending this presentation, attendees will understand the organization and implementation of an elder death review team, using the San Diego experience as an example.

This presentation will impact the forensic community and/or humanity by providing general awareness of efforts of local governments to address the issue of elder abuse and neglect deaths. The experience of San Diego County's elder death review team may be helpful to other jurisdictions in developing teams.

There is a growing national concern about abuse and neglect of the elderly. San Diego was one of the first counties in California to develop an Elder Death Review Team in response to legislation enacted in 2001. The California law provides for the development of an interagency review team "to assist local agencies in identifying and reviewing suspicious elder deaths and facilitating communication among persons who perform autopsies and the various persons and agencies involved in elder abuse or neglect cases." The law lists suggested team membership, including experts in the field of forensic pathology, experts in geriatrics, coroners and medical examiners, district and city attorneys, law enforcement, public administrators, ombudsmen and representatives from adult protective services.

San Diego County chose to set up the committee through a Memorandum of Agreement (MOA) between the District Attorney's Office, the Sheriff's Office, the Medical Examiner's Office, and the Health and Human Services Agency (which includes Aging and Independence Services). Representatives of these agencies are permanent members of the committee and rotate the chairmanship. The MOA provides guidelines for

membership of the committee, objectives, recommendations, and confidentiality. The objectives include identification of risk factors and the facilitation of communication between agencies in order to reduce the number of elder deaths due to abuse and neglect.

The Elder Death Review Team borrowed ideas from existing Domestic Violence and Child Fatality review teams. All information is considered confidential, and all members must sign a confidentiality agreement. Paperwork is kept to a minimum. The committee has opted to discuss only one case per meeting. Discussion goals include determination of the nature of the abuse or neglect, if any, whether it played a role in the death, and an assessment of its preventability. A case review-investigative report form was developed to summarize each case. The committee discussions conclude with recommendations, which can range from changing individual departmental policies to public education to proposing legislation.

The committee has had its share of growing pains, and some issues have yet to be resolved. However, the authors believe the development of a County Elder Death Review Team is one step in raising awareness of elder abuse and neglect and reducing its prevalence.

Elder Abuse, Elder Neglect, Elder Death Review

G49 Adolescent and Young Adult Suicide: A Ten-Year Retrospective Review of Kentucky Medical Examiner Cases

Lisa B. Shields, MD*, and Donna M. Hunsaker, MD, Office of the Chief Medical Examiner; 810 Barret Avenue, Louisville, KY 40204; John C. Hunsaker III, JD, MD, Office of the Associate Chief Medical Examiner; Department of Pathology & Laboratory Medicine, 100 Sower Boulevard, Suite 202, Frankfort, KY 40601-8272; and Michael K. Ward, BS, Kentucky Forensic Toxicology Laboratory, Office of Forensic Toxicology, 100 Sower Blvd, Frankfort, KY 40601

The goal of this presentation is to present a comprehensive review of findings gleaned from postmortem examinations on suicide victims between the ages of 11 and 24 in Kentucky between 1993 and 2002, and to offer strategies aimed at the prevention of adolescent and young adult suicide.

This presentation will impact the forensic community and/or humanity by showing how adolescence represents a tumultuous period in a young individual's life as the youth strives to gain independence and flourish into a productive member of society. This period of transformation is often associated with anxiety and stress, encouraging feelings of hopelessness, personal failure, and suicidal ideation. The prevalence of youth suicide by firearm necessitates restricting unsupervised household access to firearms and identifying adolescents and young adults who are at risk for suicide.

According to the *National Vital Statistics Report* in 2001, suicide, as a manner of death, ranked as the third leading cause of death in the United States between the ages of 15 and 24 and accounted for 3,971 deaths. The rate of completed suicide in this age group has tripled since 1950. The estimated ratio of attempted suicides to completed suicides for adolescents is 200:1, which is significantly higher than that of the general population, with an estimated 10-25 attempts for every completed suicide. A host of biopsychosocial factors contribute to adolescent suicidal behavior. The majority of adolescent suicide victims suffer from either single or combined psychiatric disorders, including affective and personality disorders, substance abuse, anxiety or conduct disorders, eating disorders, and aggressive and antisocial tendencies. Youths often display risk-taking behaviors, including reckless motor vehicular operation, running away from home, auto theft, gun carrying, lack of seatbelt use, assault, and truancy. A lack of a cohesive family unit may provoke suicidal ideation; specifically, poor parent-child communication, parental violence, and loss of a primary caregiver. Suicide clusters are most commonly associated

with youths ages 15 to 24, precipitated by either experiencing the suicide of a member of a young individual's peer group or gaining media exposure and imitating suicidal behavior.

This study presents 466 medical examiner cases of suicide ages 11 to 24 in Kentucky between 1993-2002, with 108 victims ages 11 to 17 and 358 victims ages 18 to 24. The majority of victims in both age groups were males (88.9% and 87.4%) and Caucasian (88% and 90.8%). A paucity of black females committed suicide, consisting of only 0.92% and 0.84% of victims in each group, respectively. The leading causes of death were the same for the two age groups, specifically, firearm injury (72.2% and 70.7%), hanging (22.2% and 18.7%), and drug intoxication (2.8% and 5.3%). The head was the most likely target of the firearm wound for both males and females, accounting for 93.6% and 85% of victims in each age group, respectively. Suicide peaked in September for group ages 11-17, most likely reflecting the tension associated with the initiation of a new school year. The highest percentage of cases for the group ages 18-24 was documented in January. Ten (9.2%) subjects ages 11-17 had previously attempted suicide, in most cases, by incised wounds of the upper extremities; 60% of these victims fatally succumbed to a cranial firearm wound. Of the 35 (9.8%) victims ages 18-24 who had previously attempted suicide, 48.6% died as a result of a firearm injury to the head and 31.4% selected hanging.

Toxicological studies constitute an important component in the investigation of a suicide. In the suicide group ages 11 to 17, blood and urine were collected in 93.5% and 72.2% of cases, respectively. Approximately 62% of victims in this group had negative blood toxicology, and 71.2% of urine toxicology screens yielded no drugs. The blood alcohol concentration (BAC) was negative in 83.2% of cases, while 7.9% had a BAC ≥ 0.1 mg%, and 8.9% < 0.1 mg%. A minority of victims had been prescribed psychoactive medications as discerned in the blood, specifically, benzodiazepines in 4.9% and antidepressants in 3.9%. Cannabinoids were detected by urine screen in 23.1% of the decedents. Of the victims ages 18 to 24, blood and urine were collected in 92.4% and 71.8% subjects, respectively. The blood toxicological results were negative in 40.3% of cases. The BAC was negative in 59.2% of cases, ≥ 0.1 mg% in 26.9%, and < 0.1 mg% in 13.9%. The following prescription psychoactive medications were quantitated in the blood: benzodiazepines (8.4%), opiates (6%), and antidepressants (5.1%). Urine screen revealed cannabinoids in 31.5% and cocaine in 8.2%.

This comprehensive analysis incorporates a myriad of factors that may have contributed to suicidal behavior, specifically, psychiatric illness, domestic turmoil, employment unrest, and legal difficulties.

Suicide, Adolescent, Firearm

G50 Which Field Method is Best? A Comparative Study of Four Entomological Methods for Sampling Forensically Important Arthropods on Human and Porcine Remains at the Anthropology Research Facility in Knoxville, Tennessee

Kenneth G. Schoenly, PhD*, Department of Biological Sciences, California State University, Stanislaus, Turlock, CA 95382; Neal H. Haskell, PhD, Department of Biology, Saint Joseph's College, Rensselaer, IN 47978; and Robert D. Hall, PhD, JD, Department of Entomology, 1-87 Agriculture Building, University of Missouri, Columbia, MO 65211

The goal of this presentation is to present to the forensic sciences community the latest findings from the Anthropology Research Facility (ARF) in Knoxville, Tennessee, on the topic of which field sampling methods, when used singly and in combination, yield the largest fraction of forensically-important insect species from human and porcine remains.

This presentation will impact the forensic community and/or humanity by providing recommendations on which field methods forensic entomologists and crime scene investigators should use when sampling forensically-important arthropods from human remains in medicolegal death investigations.

The obvious constraints imposed on the scientific study of human corpses speak to the urgency for forensic entomologists to have comparative field data on human and surrogate (non-primate) remains to insure that the recommendations offered for one are valid for the other. In 1989, the on-campus Anthropology Research Facility (ARF) at the University of Tennessee, Knoxville, became the site of the first comparative field test of four arthropod sampling methods used by forensic entomologists.

Over a 35-day period in summer, aerial sweep nets, pitfall traps, sticky traps, and hand collections were taken from one unembalmed, unautopsied human cadaver and two freshly-euthanized 50-lb pigs. (Due to limitations in procurement, replicate human corpses were unavailable in this study.) A third pig, also placed at the site, was not sampled in order to monitor possible sampling effects on rates of decay and arthropod succession. Depending on carcass age, the daily sampling schedule included up to four collections (early morning, noon, afternoon, early evening), for a total of 96 sampling periods and 1,370 individual samples; by season's end, the corpses at this site became the most intensively sampled remains of any previous study. Where arthropod life stages and taxonomic keys permitted, specimens were identified to the lowest possible taxon (family, genus or species). From the arthropod counts, the fraction of forensically-important arthropods captured by each method and combination of methods was calculated. Forensically-important taxa include members of the sarcophagous fauna (e.g., blow flies, flesh flies, hide beetles) and certain predators (e.g., rove beetles, clown beetles, ham beetles), both of which have been used as forensic indicators in medicolegal death investigations.

Based on analysis of 16 days of samples, different sampling methods captured between 35 and 100% of the forensically-important taxa and between 30 and 100% of the sampled individuals. Hand collection, when performed by an experienced forensic entomologist, was found to be the single best method for sampling forensically important insects at a crime scene, followed by aerial netting, pitfall traps, and sticky traps. Hand collection and aerial net sampling were found to offer the best combination of methods for sampling forensically-important insects. This ranking held regardless of whether the remains sampled were human or pig. Human-pig comparisons revealed a high degree of similarity in catch statistics, regardless of method, leading researchers to conclude that enough elements of the forensically-relevant fauna were found on pig carcasses in southeastern Tennessee to reflect what crime scene investigators are likely to find there on human remains in future death scene investigations.

The authors gratefully acknowledge the logistical and field assistance of the Anthropology Department of the University of Tennessee, Knoxville, and financial support of the National Institute of Justice (Grant #94-IJ-CX-0039).

As forensic entomologists they hope to see future field-tests and eventual adoption of these recommendations by crime scene investigators and other members of the forensic sciences community.

**Forensic Entomology, Anthropology Research Facility (ARF),
Field Sampling**

G51 The Decomposition of a Pig Carcass in a Mesophytic Biotope, Oahu, Hawaii

Anthony R. Russo, PhD, Chaminade University of Honolulu, Forensic Science, 3140 Waialae Avenue, Honolulu, HI 96816*

The goal of this presentation is to assist in the understanding of the stages of decomposition and the succession fauna on decomposing carcasses, an aid to estimation of postmortem interval.

This presentation will impact the forensic community and/or humanity by providing additional information confirming successional stages of decomposition and allied fauna.

The decomposition of an exposed pig carcass (*Sus scrofa*) was monitored for approximately 43 days. The carcass progressed through fresh (2 days), bloat (3 days), decay (5 days), post decay (30 days), and skeletal (2 days) stages and attracted suites of necrophagous species as well as predators, parasites and opportunistic feeders. The calliphorid blow flies *Chrysomya rufifacies* and *C. megacephala* were initial colonizers and made up the bulk of the initial arthropod abundance; the coleopterans of families Histeridae, Dermestidae, Trogidae, Staphylinidae, Tenebrionidae and Cleridae appeared in later stages. Most maggot activity occurred during the bloat and decay stage, which lasted from day 3 through day 9 of exposure. By this time only 25% of the carcass remained. During peak maggot activity, the difference between internal carcass temperature and ambient air temperature peaked. The greatest number of taxa (22 of 27) and the lowest total abundance of arthropods were observed during post decay. A total of 27 taxa were identified, of which about 64% were dipterans and coleopterans combined. The suite of arthropod taxa identified in this study was not significantly different from other outdoor pig decomposition studies done in Hawaii.

Arthropod Succession, Maggot Masses, Forensic Science

G52 A Comparison of Pig and Human Tissue in Studies of Decomposition: Can Flies Tell the Difference?

Charlotte A. Wacker, MS, University of California, Davis-Department of Cell Biology and Human Anatomy, One Shields Avenue, Tupper Hall Room 3301, Davis, CA 95616; Lawrence Stutler, MS, University of New Haven, School of Public Safety and Professional Studies, 300 Orange Avenue, West Haven, CT 06516; Brandi J. Schmitt, MS, University of California, Davis-Department of Cell Biology and Human Anatomy, One Shields Avenue, Tupper Hall Room 3301, Davis, CA 95616; and Rebecca A. Bullard, MS and Robert B. Kimsey, PhD, University of California, Davis, Department of Entomology, One Shields Avenue, Davis, CA 95616*

The goal of this presentation is to provide preliminary studies that demonstrate how some forensically significant fly species may be attracted to different types of carrion in varying degrees and to determine if blowflies are differentially attracted to human or porcine carrion via olfaction.

This presentation will impact the forensic community and/or humanity by providing preliminary studies which indicate that currently practiced research methods may not deliver the most accurate results.

These studies asked whether adult scavenger insects respond differently to volatile compounds emanating from human or porcine remains, in an effort to determine if porcine surrogates may legitimately be substituted for human remains in forensic entomology research. No difference in the arthropod fauna attraction to either type of carrion was anticipated.

Natural insect populations were exposed to odors from human or pig tissue samples contained in traps that bar visual cues. Traps consisted of a small tub filled with carrion suspended within a covered five-gallon plastic bucket or 35-gallon plastic trashcan and above propylene glycol poured four centimeters deep. Holes six centimeters in diameter were drilled six centimeters below the rim of the outer bucket or trashcan to allow insects to have access to the carrion. Once inside the trap, insects drowned in the propylene glycol. They were periodically sieved from this preservative then rinsed and stored in ethanol. For identification to species, forensically significant insects were first rinsed in acetone then pinned.

In a preliminary experiment, equivalent weights of pig or human thigh and forearm tissue in five-gallon bucket traps were used. Eight species of

flies arrived at either carrion. Five were common to both types of carrion. Three species of flies were recovered solely from traps baited with human carrion, and no species were recovered exclusively from porcine carrion.

In the later experiment, employing 35-gallon trashcan traps, the plastic tubs were baited with a human or pig cephalic specimen. These tissues attracted a greater diversity of fly species, totaling 15. Eight of these were common to both types of carrion, three were found associated only with human tissue, and four only with porcine material.

Over both experiments, a total of 16 species of flies were collected and identified. Of these, 11 were found on both types of carrion. Two were consistently identified only on the human specimens, and four species were found solely on the porcine tissue.

Although the results of these experiments remain preliminary, they suggest that adult fly populations on human or porcine carrion may be qualitatively different. The impact on current methods of postmortem index (PMI) can only be determined through the collection of additional data sets.

Olfaction, Forensic Entomology, Carrion

G53 Inter-Observer Variability in Entomology-Based PMI Estimates: A Single Blind Study

Rebecca A. Bullard, MS, University of California, Davis, Department of Entomology, One Shields Avenue, Davis, CA 95616; Kenneth G. Schoenly, PhD, California State University, Stanislaus, Department of Biological Sciences, Turlock, CA 95382; and Robert Kimsey, PhD, University of California, Davis, Department of Entomology, One Shields Avenue, Davis, CA 95616*

Attendees will develop an understanding of the variability in current techniques used to estimate the postmortem interval based on entomological evidence. The primary goal of this presentation is to open a dialogue within the forensic entomology community regarding the development of uniform protocols.

This presentation will impact the forensic community and/or humanity by demonstrating a need within the forensic entomology community to standardize its methods and practices.

Although reports of the utility of arthropods in forensic investigation date as early as 1235 AD, the field of forensic entomology remains in its adolescence, with many avenues of basic research largely unexplored. In particular, the method by which the postmortem interval (PMI) is estimated, one of the most important applied methods in forensic entomology, remains a highly controversial and problematic process. Indeed, it would seem that there might be as many such methods as there are forensic entomologists. Herein the authors acknowledge the need for standardization of this process within the community, investigate the variation in methods employed by forensic entomologists in a single-blind study, and suggest elements of a uniform protocol. Accordingly, a simulated crime scene was arranged in which fresh human remains were exposed to insects at the outdoor decomposition facility operated by the University of California, Davis, Institute for Medicolegal and Surgical Sciences (IMSS). Following an undisclosed period of exposure (herein referred to as the PMI), researchers sampled insects from the remains, recorded typical crime scene and meteorological data, and photographed and videotaped the scene and data collection efforts. Copies of all materials were sent to a number of practicing forensic entomologists in North America who had previously agreed to participate and render a PMI estimate. The degree to which these estimates vary and bracket the actual PMI will be discussed.

Forensic Entomology, Postmortem Interval, Standards

G54 Viral Testing of Adult Mosquitoes Collected in West Virginia for West Nile Virus Using NASBA Assay

Justin M. Godby, BS, Marshall University, 1401 Forensic Science Drive, Huntington, WV 25701*

After attending this presentation, attendees will understand the collection methods for mosquitoes, testing of mosquito samples for viral RNA, and how forensic equipment and methods can be used for viral testing.

This presentation will impact the forensic community and/or humanity by demonstrating the use of forensic methods and procedures that can be used to implement viral testing of field collected samples.

Since its discovery in the United States in 1999, West Nile Virus has spread across North America. Though not endemic to the continent, mosquitoes of the genera *Culex* have become vectors of the serocomplex that causes West Nile. Public health concerns have prompted laboratories across the nation to develop reliable and rapid tests to detect the virus in order to initiate surveillance methods. By combining efforts between public health and forensic agencies, testing protocols can be developed and performed on not only possible vectors but also infected individuals. Current microbial forensic techniques and equipment can be manipulated to detect viral pathogens using analytical extraction methods. The West Virginia Department of Health and Human Resources, Division of Surveillance and Disease Control (WVDHHR/DSDC) in conjunction with the West Virginia Office of Laboratory Services (WVOLS), and the Marshall University Forensic Science Center (MUFSC), collected adult mosquitoes for viral RNA testing. Viral RNA was isolated and detected by Nucleic Acid Sequence Based Amplification (NASBA) to ensure appropriate quality control measures necessary in microbial forensics applications.

West Nile Virus, TaqMan®, RNA

G55 An Instructional DVD on Collecting Entomological Evidence for Court

Ryan K. Kimbirauskas, MS, Richard W. Merritt, PhD, and Eric M Benbow, PhD, Michigan State University, 243 Natural Science Building, East Lansing, MI 48824; John R. Wallace, PhD, Millersville University, 1 South George Street, Millersville, PA 17551; and Jeff K. Tomberlin, PhD, Texas A & M University, 1229 North U.S. Highway 281, Stephenville, TX 76401*

After attending this presentation, attendees will learn that there is now available a training video on how to properly collect, preserve, and process entomological evidence for court. This training aid will benefit law enforcement agencies, death scene investigators, medical examiners, and forensic entomologists.

This presentation will impact the forensic community and/or humanity by standardizing the practices which are critical to the development of postmortem intervals and the utilization of insects as evidence during criminal investigations.

This DVD was created by forensic entomologists to fulfill the immediate need to standardize practices for collecting entomological evidence. The material is intended to instruct forensic investigators on how to collect specimen samples and field data in a way that will be scientifically valuable and credible in court. The DVD includes an overview of forensic entomology and the decomposition of an animal model has been time-lapsed to demonstrate the association of insects with various stages of decay. Insects commonly found with human remains are shown and factors that influence

insect activity and development are described. Crime scene photographs and video are used to aid in the recognition of what information should be collected during death investigations. A list of equipment needed to process entomological evidence is given, and the collection and preservation of insect specimens is clearly demonstrated in a step-by-step procedure. The main purpose of this DVD is to standardize the practices that are critical to the development of postmortem intervals, and demonstrate the utilization of insects as evidence during criminal investigations. The entire training video is 25 minutes; however, the multi-media format provides self-paced instruction and allows the viewer to select specific modules for quick referencing.

Forensic Entomology, Collection, Evidence

G56 How Cadaver Decomposition in Soil is Affected by Moisture: Part I: A Field Experiment to Investigate Seasonal Effects

Mark Tibbett, PhD*, Centre for Land Rehabilitation, School of Earth and Geographical Sciences, University of Western Australia, Crawley, WA 6009, Australia; and David O. Carter, MSc, and David Yellowlees, PhD, School of Pharmacy and Molecular Sciences, James Cook University, Douglas, QLD 4811, Australia

After attending this presentation, attendees will understand how the rate of cadaver decomposition in soils can differ according the soil texture and season of burial.

This presentation will impact the forensic community and/or humanity by demonstrating the influence of seasonal variation in moisture on decomposition processes associated with cadavers buried in soils of contrasting texture.

Soil moisture resulting from rainfall affects decomposition processes by directly influencing the activity of soil organisms and the leaching of soluble materials. The amount and distribution of moisture in association with an organic resource, such as a cadaver, is dependent upon precipitation, uptake by vegetation and losses via evapotranspiration and drainage. These factors are, in part, influenced by soil texture (which is defined by the soil particle size distribution). The predominance of large soil particles (sand) results in greater pore space (the area between soil particles) and increased rates of drainage and aeration. Thus, a soil that is dominated by small soil particles (clay) may be subject to waterlogging. The most accurate assessment of the availability and distribution of moisture is the measurement of matric potential (the pressure with which moisture is held between soil particles). This measure can be used to determine the ease with which soil microorganisms can take up moisture.

In order to investigate the effect of soil texture and seasonal moisture variation on cadaver decomposition, a field experiment was conducted at two disparate field sites. Site 1 comprised a sandy loam soil (84% sand, 11.1% silt, 4.9% clay) and was located in Yabulu, Queensland, Australia (19°12'S, 146°36'E). Site 1 receives an average rainfall of 995 mm during the wet season (November-April) and 140 mm during the dry season (March-October). The mean maximum/minimum temperature during the wet season is 30.5 °C/27°C. Dry season mean maximum/minimum temperature equals 22.9 °C/16.7°C. Site 2 comprised a loamy sand soil (97.7% sand, 1.3% silt, 1% clay) and was located in Pallarenda, Queensland, Australia (19°11'S, 146°46'E). On average, Site 2 receives 1005.1 mm rainfall during the wet season and 120.3 mm rainfall during the dry season. The mean maximum/minimum temperature during the wet season is 30.7 °C/23.1°C. Dry season mean maximum/minimum temperature equals 26.9 °C/16.4°C. The resulting vegetation at the two sites was dominated by grasses with scattered trees. These characteristics are typical of a savannah ecosystem. Cadavers (*Rattus rattus*: ~18 g) were buried at a depth of 2.5 cm. Each cadaver was located in the centre of a 2 m² plot. Cadaver mass loss, soil microbial activity and nutrient concentration was measured over a period of 28 days in order to determine if an increase in

soil moisture during the wet season would result in an increased rate of cadaver decomposition. This experiment was replicated six times and controls (soil without cadaver) were used.

The soil at Site 1 reached a matric potential of -0.03 megapascals (MPa) (equivalent to 15% moisture content v/v) during the wet season and was a constant -1.5 MPa (55% v/v) during the dry season. The soil at Site 2 reached a matric potential of -0.005 MPa (25% v/v) during the wet season and -1.5 MPa (3% v/v) during the dry season. All decomposition processes were greater during the wet season as demonstrated by the quantification of cadaver mass loss, microbial activity and nutrient concentration. This is most likely due to an increase in the activity of soil organisms and the leaching of soluble cadaveric materials as an effect of rainfall. Some differences were observed between soils within seasons.

Cadaver Decomposition, Soils, Seasonal Effects

G57 How Cadaver Decomposition in Soil is Affected by Moisture: Part II: A Controlled Laboratory Experiment

David O. Carter, MSc*, School of Pharmacy and Molecular Sciences, James Cook University, Douglas, QLD 4811, Australia; Mark Tibbett, PhD, Centre for Land Rehabilitation, School of Earth and Geographical Sciences, University of Western Australia, Crawley, WA 6009, Australia; and David Yellowlees, PhD, School of Pharmacy and Molecular Sciences, James Cook University, Douglas, QLD 4811, Australia

After attending this presentation, attendees will understand the interaction between soil moisture and soil texture can have a significant effect on processes associated with cadaver decomposition in soils.

This presentation will impact the forensic community and/or humanity by demonstrating the influence of moisture on processes associated with cadaver decomposition in soils of contrasting texture.

Decomposition processes associated with an organic resource, such as a cadaver buried in soil, can be affected by the nature of the soil physico-chemical environment (e.g., soil texture, moisture status) and the activity of soil organisms. In a laboratory setting, matric potential (as defined in Part I) can be manipulated in order to test the effect of soil moisture status on decomposition processes associated with a cadaver buried in soil. Other measurements of soil moisture status, such as a simple gravimetric moisture content (g H₂O g⁻¹ dry soil) and the estimation of moisture content in relation to saturation or field capacity (% water holding capacity), do not provide an assessment of the availability of moisture to soil microorganisms. Hence, the calibration and maintenance of matric potential can be used to exclude the activity of larger organisms such as protozoa and nematodes. Peak soil microbial activity is typically associated with a matric potential of approximately -0.01 megapascals (MPa).

Soil from the sites described in Part I were sampled (0-10 cm depth) and sieved (2 mm) field fresh. The soil from Site 1 was a sandy loam soil. The soil from Site 2 was a loamy sand soil. Sieved soils (500 g) were weighed into sealable 2 L polyethylene incubation chambers and calibrated to a matric potential of -0.3 MPa (to simulate dry conditions) or -0.01 MPa (to simulate wet conditions). Following an equilibration period of seven days, juvenile cadavers (*Rattus rattus*: ~18 g) were buried at a depth of 2.5 cm and incubated at 22°C. Cadaver mass loss and soil microbial activity were measured over a period of 28 days in order to determine if an increase in soil moisture would result in an increased rate of cadaver decomposition. The present experiment also tested the hypothesis that burial in loamy sand soil will result in an increased rate of decomposition. This experiment was replicated 4 times and controls (soil without cadaver) were used.

In the sandy loam soil a matric potential of -0.3 MPa resulted in an increase in the rate of all decomposition processes. Conversely, increased decomposition was observed in the loamy sand soil calibrated to a matric potential of -0.01 MPa. Significant differences in the rate of decomposition processes were observed between soils of similar matric potential.

These contrasting results demonstrate that the rate of cadaver decomposition can be affected by an interaction between soil texture and moisture content. Reduced activity in the loamy sand calibrated to -0.3 MPa may be due to the inability of the soil microbiota to utilize the little water that is tightly bound between soil particles under dry conditions. Reduced activity in the sandy loam is likely due to a decreased diffusion coefficient of gases (e.g., O₂, CO₂) associated with an abundance of moisture and a high microbial demand for O₂ during the aerobic catabolism of an organic resource. These conditions may lead to anaerobiosis. Greater cadaver mass loss took place in the field experiment described in Part I. This phenomenon may be due to the presence of arthropods in a field setting. Unlike the findings from the field experiment in Part I, cadaver decomposition in soil from Site 1 decreased with an increase in moisture. This might indicate that the aerobic threshold for the sandy loam soil following cadaver burial is between -0.005 MPa and -0.001 MPa.

Cadaver Decomposition, Soil, Moisture

G58 Clinically Stable Skull Fracture and Fatal Acute Pneumonia: An Unexpected Combination

Christie L. Elliott, MD*, Forensic Pathology Consultants, PO Box 12815, Reno, NV 89510-2815

After attending this presentation, the forensic pathologist and treating clinician will be aware of an unexpected and rare complication of head injuries.

This presentation will impact the forensic community and/or humanity by educating the pathologist and the treating clinician about a rare but serious complication of clinically mild head injuries, and stimulating more studies in the area of possible treatments for this complication.

Aspiration pneumonia and acute meningitis are well-recognized complications in head-injured patients.¹⁻³ Most commonly, the pneumonia results from aspiration of gastric and oropharyngeal material into the lungs because of unconsciousness and/or altered gag and swallowing reflexes from the head injuries. Acute meningitis most often occurs in the presence of basilar skull fractures, which result in communication between the underlying sinuses and the CSF. Very little information is available in the medical literature addressing the issue of blood aspiration in head-injured patients, particularly those with maxillofacial injuries. The following case report will illustrate an unexpected complication of such an injury.

The patient was a 13-year-old female involved in a single car motor vehicle accident. She had epistaxis and abrasions and contusions of the face, but suffered no loss of consciousness or neurological symptoms. A CT scan showed non-displaced facial fractures, a small basilar skull fracture, and a right temporal cephalohematoma. She was admitted for observation and released the following day. Two days after discharge she returned to the emergency room with complaints of pain, dizziness, and weakness. Repeat CT scan of the head showed no acute changes. Chest x-ray was normal. She was afebrile, but mildly hypotensive (98/50) and tachycardic. This resolved with a fluid bolus. She was discharged home with pain medications. She was found semi-responsive the following morning and arrested shortly after. She was pronounced dead at the scene. An autopsy was performed the following day.

The postmortem examination revealed a normally developed adolescent female with soft tissue swelling and resolving contusions and abrasions of the face. Reflection of the scalp showed purulence of the right temporal soft tissues. Pertinent intracranial findings included hairline skull fractures across the orbital and ethmoid plates and the anterolateral left petrous ridge up into the left temporal bone. Grossly, the lungs were heavy, mottled red/tan, and slightly firm and edematous. Microscopic examination showed acute pneumonia, edema, and frank blood within the alveolar spaces. Cultures of lung tissue, CSF, and right temporal soft tissue were

positive for β-hemolytic Group A Streptococcus. The final autopsy diagnosis was acute bacterial pneumonia due to blood aspiration from blunt force craniocerebral injuries. The facial sinuses were thought to be the source of infection.

Review of the literature reveals no data or case reports specifically addressing the issue of blood aspiration and pneumonia in the head-injured patient, though several studies address the increased risk of pneumonia, and one explores the increased risk of pneumonia in head-injured patients who were carriers of *Staphylococcus aureus*.^{4,5} The method of inoculation was felt to be aspiration at the time of injury and/or from intubation. The patients in this and other studies suffered from severe head injuries and had been intubated, some requiring prolonged ventilator support. This case differs, in that the head injury was not severe. The patient experienced no loss of consciousness, neurological symptoms, or airway compromise. No information was found regarding studies of the use of prophylactic antibiotics in this patient population. Prior to this case, the standard of care at the treating medical center for patients with clinically stable maxillofacial and skull fractures did not include prophylactic antibiotic therapy. This case suggests that further study in this area is warranted.

Skull Fractures, Pneumonia, Head Injuries

G59 The Dangers of Dumpster Diving: Deaths Associated With Garbage Collection in the Tidewater Region of Virginia

Leah L. Bush, MD*, Office of the Chief Medical Examiner, Tidewater District, Commonwealth of Virginia, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510-1046; and Wendy M. Gunther, MD, Office of the Chief Medical Examiner, Tidewater District, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510-1046

After attending this presentation, attendees will be able to recognize characteristics of crush and asphyxial injury inflicted by garbage collection machinery on persons within dumpsters. Pertinent considerations in such deaths of the contribution of toxicology, natural disease, and history, and the effect on diagnosis of antemortem from frequently seen decomposition artifact will be reviewed. Public policy consequences of such deaths will also be briefly reviewed.

This presentation will impact the forensic community and/or humanity by reviewing an unusual but recurring situation in which homeless persons or others are crushed to death in garbage dumpsters. The presentation reviews, autopsy findings, mechanism of death, and role of artifacts of decomposition in determining cause of death.

Four cases accumulated over an 11 year period illustrate an infrequent, but recurring, danger for poor or homeless persons, who die during garbage collection.

In 1993, the fully clothed body of a 51-year-old man was found by employees of a sewage and trash processing plant when a garbage truck dumped out the trash collected from a dumpster in Norfolk, Virginia. At initial examination on scene, a gaping laceration was evident in the lower

abdomen, with exposed bladder wall. At autopsy, diffuse changes of decomposition did not obscure extensive crush injury, including cervical spine, femur, and iliosacral fractures, fragmentation of the liver, diaphragmatic rent with traumatic herniation of the stomach into the chest, and a ruptured ileocecal junction. These injuries were consistent with death during trash compaction.

The decedent proved to be a homeless man with a history of heavy alcohol intake, last seen by his family two to three days before his body was found. Although investigation never proved what he was doing in the dumpster, it was possible that he was either looking for recyclable items, or may have fallen asleep there. Toxicology showed ethanol at 0.15 mg %.

In October of 1994, the body of a 48-year-old woman was found in the Hampton, Virginia landfill. At external examination, there were multiple abrasions and contusions, with areas of confluent contusion; the face was suffused, with dark purple contusions of the lips, and surrounding both orbits. At autopsy, there was severe crush injury, with fracture, dislocation, and transection of the cervical spine at both C1 and C7, and bilateral rib fractures with flail chest. There was also a healed myocardial infarct. She proved to be a vagrant from the neighboring city of Virginia Beach, with a history of diabetes and psychiatric problems, who was known to go through trash depots looking for salvageable materials. Toxicology showed a high but not lethal level of carbamazepine, with butalbital and oxazepam. It appeared that she might have climbed into a dumpster, collapsed from the toxic effects of her drugs or from a cardiac event, was later picked up by the trash-compacting truck, and was then crushed.

In November of 1994, the body of a 37-year-old man was found after a non-compacting trash truck dumped out its load at a sewage and trash processing plant. He did not have any crush injuries. Autopsy showed diffuse bilateral scleral and conjunctival hemorrhages, purple suffusion of the face, marked edema of the face and lips, epiglottal petechiae, contusions of the neck structure, and further contusions of the chest and back. Death was ascribed to traumatic asphyxia, which he would have sustained when tons of trash were placed over his body. Toxicology showed numerous toluene derivatives. Although investigation did not show how he entered the dumpster, he may have been seeking a place to inhale glue vapors, and could have been overcome by the drug.

In 2004, the crushed and decomposing body of a 60-year-old homeless man was found at a dump site near housing debris. Autopsy was able to show, despite extensive decomposition, that crush injuries had occurred antemortem. He had been known to sleep in an abandoned house that was demolished six days previously. Public reaction to the death caused re-evaluation of housing demolition policies.

This discussion will review the mechanism of death, immediate and underlying causes of death, contribution of natural disease and toxicology, and obstacles to determination of cause produced by decomposition, for persons dying in trash compactors. Review of these cases may heighten awareness of the dangers encountered by homeless persons foraging in dumpsters.

Garbage Dumpsters, Crush Injury, Traumatic Asphyxia

G60 The Differential Diagnosis Between Bioterrorism and Zoonosis and Spread to Humans: A Pathological Evaluation

Maurice Rogev, MD, Zamenhof 11, Tel Aviv 64373, Israel*

After attending this presentation, attendees will understand how recent episodes of international unrest have raised the danger of the use of "weaponized microbiological organisms" in terror attacks. At the same time, the ever present danger of the transmission of diseases from either domestic animals or from those who live in natural surroundings creates serious differential diagnostic issues. This presentation will outline an approach to the identification of the infecting microorganism and etiology that the forensic practitioner will be expected to make.

This presentation will impact the forensic community and/or humanity by assisting the medicolegal experts in learning how to identify terrorist attacks using micro-organisms that are naturally present in animals and can infect humans. These organisms having undergone weaponization.

Recent episodes of international unrest raised the danger of the use of "weaponized microbiological organisms" in terror attacks. At the same time, the ever-present danger of the transmission of diseases from either domestic animals or from those who live in natural surroundings creates serious differential diagnostic issues. This presentation will outline an approach to the identification of the infecting microorganism and etiology that the forensic practitioner will be expected to make.

Differential Diagnosis, Zoonoses Terror Exposure, Human Infection

G61 Suicides Among Youth in Geneva, Switzerland From 1993 to 2002

Guillaume Perret, Département de Psychiatrie, Clinique de Psychiatrie Adulte, HUG, Secteur Jonction, Bvd Saint-Georges 16-18, Geneva, 1205, Switzerland; Abliz Abdureheman, MD, Institut Universitaire de Médecine Légale de Genève, 9 Av de Champel, Geneva, 1211, Switzerland; Maja Perret-Catipovic, PhD, Département de Psychiatrie, Unité, Bd de la Cluse 51, Geneva, 1205, Switzerland; and Romano La Harpe, MD, Institut Universitaire de Médecine Légale de Genève, C.M.U. 9 av de Champel, Geneva, 1211, Switzerland*

After attending this presentation, attendees will understand the importance of knowing the circumstances of deaths in suicides among youth to help clinicians in their work in youth suicide prevention programs. The effort should be made to collect clinical data during medicolegal investigations.

This presentation will impact the forensic community and/or humanity by demonstrating how suicides among youth are such a tragic event, and that it is sometimes difficult to collect complete clinical information or do a full medicolegal investigation. Sparing the family from too many questions might be one of the reasons. In Geneva, Switzerland, lack of crucial information for clinicians who work to prevent suicides among youth is often observed. This study may help to create a close collaboration between suicides prevention programs and forensic medicine.

In Switzerland, suicides represent the leading cause of death in the age group 20 to 24 years, and the second most common cause of death in the 15 to 19 year age range. During the 1990s, the number of suicides in those age groups has remained stable, and has even decreased in Geneva between 1975 and 1996. The aim of this study was to look whether this tendency persisted during the years from 1993 to 2003. The authors analyzed all cases of suicide among youth less than 25 years of age in Geneva during this period. Suicide was defined through police and medicolegal investigations. Sixty-five suicides were found involving 50 male (77%) and 15 female (23%) victims. The minimum age was 12 years, and most of the victims were 18 years old or older (89%). No increase in the number of suicides throughout the years was found in the range being between 1 and 11 cases per year. For males, use of firearms was the most common method (38%), followed by fall from height (30%), hanging (16%), and drowning (10%). For females, fall from height was the most frequent (40%), followed by use of firearms and medication overdose (20% each), hanging (13%), and drowning (7%). Only 43% of the cases had toxicological testing, and the main drugs found were benzodiazepines, cannabis and cocaine. Blood alcohol concentration was analyzed in 53% of all deaths. Among them, 32% tested positive, half of them with a concentration below 52.5 mg/dL. Clinical data in medical charts were often incomplete, lacking in more than 70% of the cases. Although this study has brought very useful information about the circumstances of death, helping to better characterize suicide in youth, in Geneva, an effort should be made to collect more clinical data during medicolegal investigations. These data would be of help to clinicians who work in youth suicide prevention programs.

Suicides, Youth, Epidemiology

G62 Suffocation by Mistaken Use of a Biohazard Hood as a “Spit” Hood

K. Alan Stormo, MD*, Jeffrey M. Jentzen, MD, Mary K. Mainland, MD, John R. Teggatz, MD, and Victor V. Frolov, MD, Milwaukee County Medical Examiner, 933 West Highland Avenue, Milwaukee, WI 53233

The goal of this presentation is to document a case of mistaken use of a biohazard hood as a spit hood resulting in suffocation, and show resulting experimental re-enactment of such use including time and oxygen studies.

This presentation will impact the forensic community and/or humanity by demonstrating the danger of the improper use of the device, and by presenting data related to time necessary to become severely compromised by improper use.

A 20-year-old male was found to be in possession of drug paraphernalia and was arrested. While being transported to the police station he became belligerent, combative, and attempted to spit on the transporting officer. He was restrained with a car seatbelt with his hands cuffed behind him; a biohazard hood was placed over his head to contain the spitting. On arrival at the police department 8-10 minutes later he was found unresponsive; resuscitation was unsuccessful and he was pronounced dead in the local hospital ER.

The Quick 2000 is a widely available biohazard escape hood, which has a nose clip, a mouthpiece for breathing and a tight neck dam. Breathing into the mask without use of the mouthpiece rapidly depletes the oxygen and increases CO₂. Informal experiments demonstrate severe air hunger in two to two and one-half minutes if the mouthpiece is not used. Data from more formal experiments with oxygen and CO₂ studies will be presented.

Asphyxia, Suffocation, Biohazard Hood

G63 Unsuspected Pheochromocytoma Discovered During Autopsy After Sudden and Unexpected Death in an Expectant Mother

Sophie Gromb, PhD*, Nadia Khaldi, MD, Larbi Benali, MD, Mathurin Djodjo, MD, and Alain Miras, PhD, Department of Forensic Medicine - EA 3676 - IFR 99 of Public Health, CHU Pellegrin - Place Amélie Rabéon, Bordeaux, 33076, France

The goal of this presentation is to present a case report of sudden death due to pheochromocytoma (PC), and emphasize the necessity of complete autopsy and histological analysis in different tissues in which metastases can develop.

This presentation will impact the forensic community and/or humanity by showing the necessity to perform an autopsy in every case of sudden death in order to determine the cause of death for medical (responsibility), psychological (family), and epidemiological reasons (prevention of disease in the other members of the family); and demonstrating the importance of a complete autopsy and the necessity of histological analysis.

Case Report: An autopsy case of a PC in a 42-year-old asymptomatic and expectant mother is reported, without previously suspected PC. She was pregnant (her last period was 34 weeks ago), and had appointments with her obstetrician regularly. Her last visit to a doctor was 15 days before death, and all had been found normal. She didn't have abdominal pain or hypertension. Several days before death, she suffered asthenia, dyspnea, and chest pain. One morning, during a walk, she felt faint without other symptoms (nausea, vomiting, etc.), and this occurred again several minutes later. A loss of consciousness occurred and, in spite of the intervention of intensive care for more than one hour, she died in heart failure and cardiogenic shock.

Autopsy demonstrated rib fractures consistent with CPR, a normal thyroid gland, gastritis, polyvisceral edema, very intensive pulmonary edema, an enlarged heart, normal coronary arteries, no intravascular coagulation (pulmonary or other), brain edema, and a tumor in the left adrenal gland (60 g). The fetus and uterus were normal. Histological examination confirmed the adrenal tumor was a pheochromocytoma. Toxicology studies were negative.

Discussion : Adrenal PC is usually a benign catecholamine-producing tumor (90%) of the sympathetic nervous system. The incidence is 0.05% in all autopsies (McNeil *et al.*, 2000) and sudden death occurred in 8.9% of the cases (Casanova *et al.*, 1993). The PC is bilateral in 50.5% of cases and left in 63.5%. The diagnosis is difficult because, generally, PCs develop for a long time with non specific symptoms (or without classical constitutional symptoms), until explosive syndromes appear, related to catecholamine excess, with severe hypertension, acute pancreatitis, hyperacute myocardial ischemia, cerebral hemorrhage, cardiogenic shock, congestive heart failure, and sudden death. Sudden death is the only sign in 1.5% of cases. Several diagnostic methods are available to increase the detection and the diagnosis (meta- and normetanephrine in urine is one of the best sensitive screening tests; abdominal MRI - scintigraphy with meta-iodo-benzyl-guanidine for visualization). It is important to note that the heart weight is increased in 95% of the patients.

Conclusion: Diagnosis is often difficult, and many PCs are not recognized during life. Clinicians should be aware of the symptoms of PC, as early diagnosis is very important in order to perform a laparoscopic adrenalectomy. In addition, some symptoms are the same as acute drug intoxication. PCs are usually curable if diagnosed and treated properly, and, in certain cases, this diagnosis necessitates prompt surgical intervention.

During autopsy, certain tumors are observed with increased frequency in patients with PC, including thyroid carcinoma, liver tumor, prostate carcinoma, malignant melanoma, carcinoma of the uterine cervix, and breast carcinoma.

Pheochromocytoma, Sudden Death, Autopsy

G64 Modeling Languages in Forensic Pathology

Gilbert E. Corrigan, MD, PhD*, East Baton Rouge Coroner's Office, 4030 T.B. Hearndon Avenue, Baton Rouge, LA 70807

After attending this presentation, attendees will understand the importance and utility of modern modeling computer techniques in forensic pathology from Microsoft Word® (MS Word), to Microsoft Visio® (MS Visio), to Universal Modeling Language Two (UML2).

This presentation will impact the forensic community and/or humanity by demonstrating the importance and utility of modeling to solving forensic pathology problems.

In forensic informatics, modeling is an underemployed but important computer technique. Models illustrate concepts, analyze processes and relationships, and communicate with efficiency and clarity. Models show the first definitions of processes at their inception; they precede the formal formulation of the computer application. Current computer applications in MS Word®, MS Visio®, and UML2 may be used by forensic scientists to compose models; however, increasing specificity and precision require more study and attention as the applications mature and enlarge.

Models provide computer programmers with the initial structure of their applications; models also work to provide scientists their first formulations of the details of their work. Models act to provide actual representations of concepts and ideas. Referral by scientists to the available models allows the definition of objects and relationships valuable to extension of their thoughts. Such models teach, communicate, illustrate, standardize, lead thinking, require attention, precede other actions, require syntax, provide transmission and transfer, and act to standardize operations. The models by structural and behavioral analysis are classified as class

diagrams, package diagrams, object diagrams, use case diagrams, sequence diagrams, collaboration diagrams, state charts, activity diagrams, power diagrams, component diagrams, deployment diagrams, engineering diagrams, flow charts, and brainstorming diagrams.

Current applications providing computer modeling activities have been under formal development by computer scientists for over thirty years and are in their third generation of development. Forensic scientists find modeling possible with the word processing application MS Word®, and MS Visio® which is evolving into a more complex, capable and inexpensive modeling tool. The more advanced UML2 applications have the capacity to create and manage large models over the expanse of large organizations and corporations with the precision and accuracy needed in sophisticated scientific activities. Many commercial scientific modeling applications are available; however, to date no formal set of forensic symbols or diagrams are recognized or developed.

Little formal recognition has been given to modeling in the forensic or pathology literature so that the complexities, multiplicities, and composites inherent in the data often are either ignored or not represented.

Forensic models are limited in number and are without the standardization found in UML2. Note that the development of models is not easy work and requires analytic time and clear conceptualization of ideas. Modeling is blocked by poor definitions and is inefficient when topics are diffuse and poorly understood.

Demonstrations of functional models in forensic scene investigation and forensic pathology are presented.

Forensic Informatics, Modeling Languages, Forensic Death Investigation

G65 Polyarteritis Nodosa as a Rare Case of Sudden Death in Postmortem Diagnosis

Wolfgang A. Keil, MD, and Felicitas Dahlmann, MD, Institute of Forensic Medicine, Ludwig-Maximilians-University Munich, Frauenlobstraße 7a, Munich, D80337, Germany; and Andrea M. Berzlanovich, MD, Institute of Forensic Medicine, Medical University Vienna, Sensengasse 2, Vienna, A1090, Austria*

After attending this presentation, attendees will understand that, in the correct setting, among the common natural disease causes of sudden death of forensic importance, sometimes very rare diagnoses must be considered. In these cases, systemic vasculitis and systemic autoimmune diseases may play a role. To detect these rare diseases as causes of death, classic histology may need to be supplemented by immunohistochemical and serological examination of tissues and other samples.

This presentation will impact the forensic community by demonstrating the first reported case of polyarteritis nodosa playing a role within the context of a sudden unexpected death.

Worldwide, most unexpected sudden deaths of forensic interest by natural causes are due to cardiovascular diseases. In these cases, acute myocardial infarction and arteriosclerosis of the coronary arteries are the leading entities. In contrast to this, sudden deaths due to vasculitis are a rarity. Polyarteritis nodosa occurs three times more often in men than in women. The diagnosis of the disease is often incorrect.

A 21-year-old female student from Sweden came to Munich after vacationing in Greece with her parents. She was previously healthy, apart from a cold with fever a few weeks before her holidays which was treated with antibiotics. In Greece she complained of having back pain located near the right kidney and at a disco at Munich she got dizzy and collapsed. The day after, she became increasingly short of breath. In the afternoon she was found lifeless in the apartment of a friend with blood around her nose and mouth. She was brought into a hospital immediately.

She remained unconscious and was diagnosed with hypoxic edema of the brain. The initial presumption of drug intoxication was disproved by toxicological analysis.

She died with unclear symptoms three days after her collapse. As cause of death, the physicians of the hospital signed "Lung failure in pneumonia," as they suspected an atypical infection of the lungs.

The autopsy showed hemorrhagic lung edema. Weights of the lungs were: right 1085 g, left 1040 g. There was abundant bloody mucus in the respiratory passages, with some coagulated blood in the bronchi. Cultures of tracheal secretions were negative.

The histological examination revealed an intra- and extra capillary proliferative glomerulonephritis with crescents and focal segmental necrosis of the glomerular loops consistent with rapidly progressive glomerulonephritis. The lungs showed siderophages indicating older bleeding in addition to the fresh bleeding.

The clinical, laboratory and autopsy findings suggested either Wegener's disease or microscopic polyarteritis nodosa. The diagnosis was made by analysis of autoantibodies; the lack of cANCA indicated the diagnosis polyarteritis nodosa. The differential diagnosis will be critically discussed.

This may be the first reported case of polyarteritis nodosa playing a role within the context of a sudden unexpected death.

Polyarteritis nodosa, Sudden Unexpected Death, Immunohistochemistry

G66 Autopsy Findings in Hypothermia: A Five Year Retrospective Study

Patricia A. Aronica-Pollak, MD, Jack M. Titus, MD, and David R. Fowler, MD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD 21201*

After attending this presentation, attendees will understand the anatomic, toxicological, and investigatory findings associated with hypothermia deaths during the past five years in Maryland.

This presentation will impact the forensic community and/or humanity by providing information on the findings associated with hypothermia deaths with special emphasis on the gross autopsy findings.

To date, there are no recognized pathognomonic findings in hypothermia-associated deaths. Certain findings have been seen in greater frequency in hypothermia. These include paradoxical undressing, gastric mucosal ulcers, hemorrhagic pancreatitis, and pulmonary edema. It has been suggested that gastric ulcers and pancreatic changes are seen more frequently following resuscitation. Paradoxical undressing occurs when the body temperature is low, presumably causing mental confusion, possibly giving the sensation of extreme warmth, and leading to the removal of one's clothing. This confusion may also lead to a characteristic pattern of bruising on the extremities (elbows, wrists, hands, knees) as one wanders about in a confused state.

This poster will present the findings from a retrospective review of 145 cases investigated by the Office of the Chief Medical Examiner for the state of Maryland during the years 1999-2003, in which hypothermia was the cause of death or a contributory cause of death. The cases were assessed for association with drowning, natural disease, ethanol and drug intoxication, appearance of gastric ulcers, gross hemorrhagic changes of the pancreas, combined lung weights, evidence of paradoxical undressing, and contusions of the extremities.

Of the 145 cases, 19 were not included due to incomplete available data. Of the remaining 126 cases, 13 (9.7%) were associated with drowning. Only one of the drowning cases showed evidence of gastric ulcers. None had pancreatic changes. As expected, average combined lung weight was increased at 1067 grams (range 410-2310). Five of the 13 (38.5%) had ethanol levels over 0.08 g/dL. Drug intoxication was not noted in any of the drowning cases. Natural disease contributed in one case. Paradoxical undressing and contusion patterns on the extremities were not observed in the drowning cases.

Of the remaining 113 non-drowning cases in which full autopsy examinations had been performed, 83 (73.5%) were male with an average age of 56 years (range 19-91). Natural diseases such as cardiovascular disease, acetonemia, and dementia were associated with 59 (52.2%) of cases. Ethanol levels were over 0.08 g/dL in 33 (29.2%) cases. In 17 (15%) cases, drug intoxication contributed to death. Drugs involved included morphine, cocaine, methadone, meperidine, trazadone, oxycodone and acetaminophen.

Stomach ulcers were seen in 39 (34.5%) of the cases. Of these 39, 11 (28.2%) had been resuscitated. Sixteen (14%) of the 113 cases had gross visible changes in the pancreas. Of these 16, 5 (31.3%) had been resuscitated. Resuscitation occurred in 14 (12.4%) of the 113 cases in which no changes in the pancreas or stomach were noted. The average combined lung weight was 1050 grams, with a range of 400 to 2710 grams.

Paradoxical undressing occurred in 6 cases, with an additional 8 more potential cases (combined 12%). Pink-brown bruising was noted on the upper extremities in 24 (21%) cases and on the lower extremities in 25 (22%) cases. The contusions were often on the elbows, posterior wrists, the backs of the hands, and knees. Of the 14 total cases of potential paradoxical undressing, only 4 were associated with these contusions. Therefore, this pattern of bruising may represent a different type of confusional state possibly different than the thermoregulatory disturbances.

Hypothermia as a cause of death can only be determined through thorough investigation, as there are no autopsy findings which are noted in all cases. However, this study does provide further confidence in the diagnosis with the presence of other findings. The gastric ulcers were the most frequently associated finding. The contusions on the upper extremities and lower extremities, especially on the posterior surfaces of the arms, wrists and hands, are the next most common findings. Gross changes of the pancreas, visible as hemorrhage, were also noted, but less frequently. The pulmonary edema was difficult to assess as many of the hypothermia cases also had heart disease and drug and alcohol intoxication contributing to the cause of death. Paradoxical undressing, while uncommon, remains a real phenomenon that is potentially confused with criminal acts.

Hypothermia, Paradoxical Undressing, Gastric Ulcers

G67 Color Me Guilty: The Role of Paint Transfer in Weapon Linkage

Diane Scala-Barnett, MD, and Julie M. Saul, BA, Lucas County Coroner's Office, 2595 Arlington Avenue, Toledo, OH 43614-2674*

After attending this presentation, attendees will be alerted to examine for the presence of paint transfer onto bone as a means of weapon linkage, and be prepared to modify their specimen preparation techniques accordingly.

This presentation will impact the forensic community and/or humanity by demonstrating how paint transfer is commonly used for forensic linkage in vehicle related cases, although it may be overlooked in analyzing bone trauma.

Transfer evidence can be an important part of an investigation. Transfer evidence may relate to transfer of blood from one object to another, often leaving a distinctive contact transfer pattern that may be linked to a specific weapon.

Paint transfer also yields valuable information. Paint transfer usually relates to paint chips/fragments transferred from one vehicle to another (or onto a victim or structure) during a collision. This information aids in identifying a vehicle model and year based on analysis of the paint. It may even identify a specific vehicle.

Hair and fibers are transferred from one person or place to another – evidence of contact. DNA is transferred from a person to an object or another person. Fingerprints are transferred from one individual to another individual or an object.

Two cases will be presented involving paint transfer onto human bone through blunt force: in one case blue paint from a baseball bat and in the other the black surface (under flaking paint) of an old metal railing. Both cases involve severe blunt force trauma to the head. This is a phenomenon that had not been noted previously.

Case 1: In 1995 a 65-year-old male was found dead, the victim of a severe beating by an assailant who "came in like a raging bull with a baseball bat" (according to the Detective). At autopsy, Diane Scala-Barnett, MD, Deputy Coroner of Lucas County, Ohio, requested that Julie Saul, Director of the Forensic Anthropology Laboratory in that office, reconstruct the fragmented skull and determine what could be learned from the resulting fracture pattern. Blue paint chips and wood splinters were found in the soft tissue at wound edges of the mouth and scalp.

Traces of blue paint were noted on a few small fragments; therefore, initial cleaning was accomplished using only warm water in order to preserve pigment. Ultimately, five fragments were found to have blue paint embedded in the surface. Other bone fragments were cleaned and degreased using normal procedures.

Thirty-six fragments were reassembled. The fracture pattern indicated that the skull had been shattered with one blow, probably administered while the right side of the victim's head was against a hard surface – likely to be the floor. This was confirmed by bloodstain evidence at the scene.

The five bone fragments with embedded blue paint lined up together at one edge of the single impact area, located approximately on the left parietal eminence. The force of the blow at that point had driven blue paint from the baseball bat into the fracture edges.

Case 2: In 2004 a 40-year-old woman was found dead of severe blunt force injuries to the head. At autopsy, several distinctive patterned scalp lacerations were noted, along with bruises on the neck, face, chest and abdomen. A bitmark was present on the left breast. Retraction of the scalp revealed distinctive patterns on the skull beneath the scalp lacerations. These contact transfer patterns (not fractures) were formed by embedded black pigment, and corresponded well to the overlying scalp lacerations.

In this case, the instrument was not a broad, smooth object such as the baseball bat used in the earlier case, but a portion of an old iron fence railing with shapes that corresponded to both the lacerations and pigment contact transfer patterns.

In both cases, transfer of color (and/or pattern) onto cranial bone through blunt force yielded valuable information regarding the instrument used.

Although paint transfer is commonly used for forensic linkage in vehicle related cases, it may be overlooked in analyzing bone trauma.

Blunt Force, Paint Transfer, Trace Evidence

G68 The Role of Forensic Insects in Deposition of Pollen at a Death Scene

Rebecca J. Kirby, Anita L. Guedea, Phillip L. Watson, PhD, Roger E. Mitchell, PhD, and Scott M. Herron, PhD, Ferris State University, Department of Biology, Big Rapids, MI 49307*

The goal of this presentation is to investigate the importance of pollen transfer by insect visitors to a death scene.

This presentation will impact the forensic community and/or humanity by demonstrating the effect, if any, of forensically important insects on the deposition of both anemophilous and zoogamous pollen at a death scene. The importance of the findings could be critical in showing whether pollen evidence is subject to the uncertainty of insect visitors at a crime scene.

This poster will present the evidence of pollen deposition at mock crime death scenes with and without insect involvement. Pollen can be transferred to the death scene by wind (anemophilous) and by animals (zoogamous), particularly insects. It was the original purpose of the experiment to document the normal pollen assemblage in mock crime

scenes. This pollen assemblage at these mock crime studies was compared with the resident pollen on the pigs which were not local.

For over five years, one of the courses in the forensic biology program at Ferris State University has used pigs in a mock crime setting to teach students techniques associated with death scenes, including forensic entomology, botany, and anthropology. These mock crime settings are done under strict animal rights protocols. During these mock crime scenes, pollen collections have been done for baseline data on the pollen assemblages found during different times of the year.

In a series of insect inclusion and exclusion experiments, the pollen assemblages were collected at the mock crime scene. The original question attempting to be answered was the effect, if any, of the insects visiting the mock crime scene and deposition of both anemophilous and zoogamous pollen. The importance of the finding could be critical in showing whether pollen evidence is local or is subject to the uncertainty of insect visitors at a crime scene.

Insect, Pollen, Palynology

G69 Experimental Evaluation of Rigor Mortis - The Influence of the Central Nervous System on the Evolution of the Intensity of Rigor Mortis

Thomas Krompecher, MD*, André Gilles, MD, Conxita Brandt-Casadevall, MD, Beat Horisberger, MD, and Patrice Mangin, MD, Institut Universitaire de Médecine Légale, Rue du Bugnon 21, Lausanne, 1005, Switzerland

The goal of this presentation is to present the development of the intensity of rigor mortis after the disconnection of different parts of the central nervous system.

This presentation will impact the forensic community and/or humanity by providing a better understanding of the development of rigor mortis under different conditions.

In 1811, the French physician and chemist P. H. Nysten published the first scientific description of rigor mortis. The law named after him states that "Cadaveric rigidity affects successively the masticatory muscles, those of the face and the neck, those of the trunk and arms and finally those of the lower limbs." It is often added that resolution occurs in the same order. The development of rigor mortis is thus descending, a finding thought to be related to the varying distances between the different muscles and the central nervous system. However, Nysten himself noticed that the destruction of the CNS did not affect the order of the development of rigidity.

In 1904, Fuchs described the brain as the initial site of death, followed by the proximal part of the spinal cord, and suggested that the process then progressed towards the caudal spinal cord: the presumed impulsions influencing the development of rigor mortis arose from catabolic changes in the nerve cells.

In 1819, Busch observed that the removal of the brain and spinal cord resulted in an early onset of rigidity; moreover, rigidity was more pronounced and lasted longer.

In experiments conducted on animals, Eiselberg (1881) demonstrated that when the sciatic nerve was sectioned on one side, in over 70% of cases rigidity developed later than on the contralateral side.

Gendre (1885) and Aust (1886) confirmed this finding. Aust, in particular, obtained this result in 12 out of a total of 13 experiments. Having conducted *in vivo* sectioning of the left side of the spinal cord in rabbits (underneath the pyramidal crossing), Bierfreund (1888) made the following statement: "I was very surprised to find that after a few hours following death, the right half of the body became very rigid, while the left half remained almost normally mobilisable." Bierfreund thought that the "accelerating" effect of the central nervous system on the appearance of

cadaveric rigidity was the result of a weak excitation of the muscular system, and if this excitation really did exist, it was too weak to cause a visible contraction. To prove this hypothesis, Bierfreund conducted animal experiments that involved weak irritation by the sciatic nerve. The results were the very opposite of what he had hoped for.

The experimental results described above and some others are partially contradictory. Therefore, it remains unclear what role the nervous system may play in the development of cadaveric rigidity.

Some years ago, a method to increase understanding of rigor mortis through the objective measurement of the intensity of cadaveric rigidity in rats was developed. The principle of the method is to determine the force required to cause a movement of small amplitude (4 mm) in the limb under examination. Since the movement doesn't break rigor mortis, serial measurements can be conducted. The apparatus used measures the resistance caused by rigor mortis in the knee and hip joints of rats. This method has been used in the past to evaluate the influence of several pre-mortem and postmortem factors (i.e., body weight, muscular mass, age, physical exercise, ambient temperature, various causes of death, electrocution) on the development of rigor mortis.

In present investigations, experiments are performed that at least partially clarifies the influence of the central nervous system on the development of rigor mortis.

Experimentation: Animals: male albino rats, weighing approx. 300 g.

Measurement time points: 10 min, 1h, 2h, 3h, 4h, 5h, 6h, 8h, 12h, 16h, and 24h postmortem.

Measurements were made on the hind limbs of the animals.

Group N°1: control

Group N°2: medulla oblongata section

Group N°3: destruction of spinal chord with a needle introduced in the spinal canal

Group N°4: sciatic nerve section

Results: No significant difference was found in the development of the intensity of rigor mortis among the four groups.

Conclusion: In "normal" conditions, the central nervous system has no significant influence on the intensity or on the time course of the rigor mortis. These experiments do not exclude the possibility of the influence of the CNS on the development of cadaveric rigidity in some pathological conditions.

Rigor Mortis, Central Nervous System, Rats

G70 β -Phenylethylamine as a Biomarker in Mechanical Asphyxia-Related Fatalities

Wen-Ling Lin, PhD*, and Kai-Ping Shaw, MD, PhD*, Institute of Forensic Medicine, Ministry of Justice, Republic of China, 161-1, Section 2, Keelung Road, Taipei, 106, Taiwan, Republic of China

The goal of this presentation is to establish β -Phenylethylamine (PEA) as a biomarker of asphyxia during medicolegal investigation by characterizing the rate-limited step of oxygen-dependent monoamine oxidase B (MAOB).

This presentation will impact the forensic community and/or humanity by showing how the elevation of PEA concentration in blood may play a crucial role in asphyxia-related fatalities. A PEA blood level higher than 2.7 μ g/ml can play a diagnostic role in the determination of asphyxia during the medicolegal investigation. An endogenous substance, PEA allows forensic scientists to develop a state-of-the-art biomarker using the rate-limiting step of MAOB to specify the cause of death in asphyxia.

Identification of asphyxia depends on various non-specific parameters in forensic medicine, such as signs of petechial hemorrhages, cyanosis, engorgement of right heart chambers, lung congestion, and a variety of signs in mechanical asphyxia. The cause of death in asphyxia depends on the history and the exclusion of other causes. It is imperative to develop a quantitative and specific biomarker to interpret the scientific evidence and to ensure a precise diagnosis of asphyxia during the medicolegal investigation. PEA, a specific substrate of MAOB, is a biogenic amine and acts as a sympathomimetic amine through its release of dopamine. The rate-limiting step of the MAOB activity of monoamine deamination is a highly oxygen-dependent phenomenon. The hypothesis is that reduction of the activity of MAOB during the hypoxic status could cause an accumulation of PEA in human body fluids.

A retrospective study consisted of forty-one cases of mechanical asphyxia and thirty-seven cases unrelated to asphyxia that were collected from the Institute of Forensic Medicine, Ministry of Justice, during medicolegal investigation in Taiwan. There were sixteen strangulation fatalities where the causes of death were by manual strangulation (hand or ligature) or hanging. In twenty-five cases of suffocation with mostly choking on food, fixing a pad or gag over the face, and drowning were concluded to be the causes of death. The control group of fatalities unrelated to asphyxia included sudden death by cardiac failure, gunshot injury, violence, and traffic and falling accidents. *In vitro* study in human platelets and *in vivo* animal models in rats were used to monitor the PEA alteration during the hypoxic status. Gas chromatography/mass spectrometry was performed to determine the PEA concentrations of each forensic fatality's body fluids and of each animal specimen.

The PEA blood concentrations of strangulation, suffocation and control cases were $34.2 \pm 7.7 \mu\text{g/ml}$ (mean \pm SEM, n=16), $33.0 \pm 6.7 \mu\text{g/ml}$ (n=25) and $0.16 \pm 0.03 \mu\text{g/ml}$ (n=37), respectively. The PEA blood levels of asphyxia-related fatalities were significantly higher than those of control cases ($p<0.005$). There was no difference in PEA blood levels between suffocation and strangulation cases. The PEA urine concentrations of strangulation, suffocation and control cases were $1.5 \pm 1.1 \mu\text{g/ml}$ (n=8), $0.3 \pm 0.2 \mu\text{g/ml}$ (n=9) and $0.2 \pm 0.1 \mu\text{g/ml}$ (n=12), respectively. The PEA gastric content concentrations in strangulation, suffocation and control cases ranged from 0.03 to $124.1 \mu\text{g/ml}$ with no statistical difference between asphyxia and control group. The postmortem interval for the asphyxia and control groups was 4.3 ± 0.8 days and 5.0 ± 1.0 days, respectively. The PEA profile was not affected by postmortem alteration up to 13 days. Decreasing oxidative activity of MAOB and accumulation of PEA are observed during a hypoxic status in human platelets. An animal model to induce a hypoxic status in rats resulted in elevation of PEA blood levels up to two to four times the control value.

In conclusion, elevation of PEA concentration in blood may play a crucial role in asphyxia-related fatalities. The PEA blood level higher than $2.7 \mu\text{g/ml}$ can play a diagnostic role in determining asphyxia during the medicolegal investigation. An endogenous substance, PEA allows forensic scientists to develop a state-of-the-art biomarker using the rate-limiting step of MAOB to specify the cause of death in asphyxia.

β -Phenylethylamine, Asphyxia, Strangulation

G71 Forensic Pathologists and the NICHD Brain and Tissue Bank for Developmental Disorders

Ling Li, MD, David R. Fowler, MD, and Ana Rubio, MD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD 21201; and Ronald Zielke, PhD, University of Maryland, Department of Pediatrics, Brain, and Tissue Bank for Developmental Disorders, 655 West Baltimore Street, Baltimore, MD 21201*

After attending this presentation, attendees will be able to recognize the significant contribution of forensic pathologists to medical research by

support of the activities of the NICHD Brain and Tissue Bank for Developmental Disorders.

This presentation will impact the forensic community and/or humanity by showing the significant contribution of forensic pathologists to medical research involving the use of postmortem human tissues.

Medical developments have increased the use of human tissues, especially for research purposes. The National Institute of Child Health and Human Development (NICHD), in 1991, established a Brain and Tissue Bank at the University of Maryland with a collaborating retrieval site at the University of Miami. Establishment of the Bank was in response to requests by family support groups for increased research on developmental disorders affecting children and young adults.

The Bank obtains donors through efforts by support groups and forensic pathologists. Through a coordinated outreach effort to support groups the Bank has registered over 2400 potential donors. The efforts have resulted in donation of autopsy tissue from nearly 1000 donors with over 100 different developmental disorders.

The legal and ethical issues regarding the use of human tissues donated for medical research have received great public attention. To protect the deceased's body from being used for postmortem research that is incompatible with the deceased or their families' wishes and values, informed consent is obtained for all tissue donations. The Bank provides the means for tissue donors to leave a legacy that will benefit future generations. A partial list of disorders includes adrenoleukodystrophy, autism, chromosomal disorders, metabolic disorders, Prader-Willi syndrome, sudden infant death syndrome, and tuberous sclerosis. Tissue from an additional 2000 donors has been obtained from local hospitals and the Office of the Chief Medical Examiner in Maryland. Tissue is stored formalin fixed and frozen at -80°C . The Bank has collected over 55,000 tissue samples.

The availability of normal control tissue is critical to studying developmental disorders. The ONLY source of control tissue is from accident victims who come under the jurisdiction of medical examiners. Support by the Office of the Chief Medical Examiner of Maryland has enabled donation of tissue from normal individuals as well as individuals with autism, chromosomal disorders, Prader-Willi syndrome, etc. In fact, disorders that are not inherently life threatening, such as autism, rarely come to autopsy unless death is accidental. The participation of medical examiners throughout the United States has enhanced the collection of tissues from normal donors (especially under 17 years of age) and donors with rare disorders.

The Bank serves an additional role: making the tissue available to qualified researchers. To date the Bank has distributed 12,000 tissue samples to 360 researchers in 11 countries. These researchers have published 150 full-length publications and an equal number of abstracts based on studies utilizing tissue from the Bank.

This report focuses on the role of forensic pathologists in medical research by support of activities of the Brain and Tissue Bank for developmental disorders. The mechanisms of how to obtain informed consent from the families of the newly dead is also addressed.

Forensic Pathologists, Tissue Donation, Medical Research

G72 Causes of Death Among People in the Prison of Loos (Northern France), 1997-2003

Gilles Tournel, MD, Anne A. Bécart-Robert, DDS, PhD, Valéry C. Hédouin, MD, PhD, and Didier Gosset, MD, PhD, Institut de Médecine Légale, 1, Place de Verdun, Lille, 59 000, France*

People in prison are more likely to die prematurely, especially of violent causes, than people who are not in custody. Some of these deaths could be avoided. The goal of this presentation is to study the causes of death (violent and natural) among people in the prison of Loos.

This presentation will impact the forensic community and/or humanity by explaining what problems are present in French jails.

Methods: The authors examined the causes of death in both prisons of Loos for detainees in custody and sentenced detainees, from 1997 to 2003. The collected data included age, sex, work, cause of the death, location of the death, and history of addiction. The causes of death were categorized as violent (accidental intoxication, suicide, or homicide) or natural (cancer, cardiovascular disease).

Results: Forty-nine persons died in prison during the studied period: 47 male and 2 females ranging in age from 17 to 54 years. The average age was 30 years. There were 34 suicides, 4 natural deaths, and 11 deaths involving the presence of drugs or alcohol. In France, all deaths in prison (natural, homicide, accident, suicide, toxic) are autopsied and findings are described.

In this study the cases of suicides are described more precisely. Among the people who committed suicide, 30% were jailed after conviction for a sexual assault (34 of the 49 cases). Among them, 17 had already been sentenced and the others were waiting for a judgment. The position of the body and the presence of another detainee in the cell was studied. The method of suicide was mainly hanging with a large tie (29/34).

Discussion: The high number of deaths in custody resulting from self-harmful behavior has important implications for the criminal justice system and the penitentiary administration. The authorities have a high responsibility to prevent deaths in jail. It is important to develop a preventive health systems inside the jails to prevent suicides. Psychiatric treatments and therapy must be introduced to reduce the risks. An awareness of these causes might be of assistance in developing mechanisms to further reduce fatalities in this setting.

Prison, Death, Suicide

G73 Rathke's Cleft Cyst: Alleged "Brain Tumor" in a Middle-Aged Cocaine Abuser

Bridget B. Eutener, BS*, and Karen B. Looman, Pathology Resident Program, Eastern Virginia Medical School, 700 West Olney Road, Norfolk, VA 23510-1046; Wendy M. Gunther, MD, Office of the Chief Medical Examiner, Tidewater District, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510-1046

This presentation, will show the histology of a congenital anomaly that may present in a forensic case as a history of "brain tumor."

A 47-year-old female complained of chest pains at home, but failed to seek medical treatment. She collapsed at home later that day in the presence of a family member. She had a history of chronic cocaine use, and relatives were concerned that she might have used the drug on the day of her death. Her only other condition was an unclear history, according to the family, of a "brain tumor." The tumor had reportedly been present for some time, but she had received no recent medical care or treatment for it.

At autopsy, gross inspection of the uncal region revealed an enlarged tan-brown mass beneath the pituitary stalk. The stalk itself was fluctuant to pressure, but did not appear to be enlarged. Sectioning of the brain revealed a focal 0.4 cm diameter mass, with an apparent necrotic or caseous center, abutting the optic chiasm on one side, and the mammillary bodies on the other. Microscopic evaluation revealed the mass to be cystic, with a true wall of squamous epithelium, surrounding a center of amorphous fluid and squames. This is believed to be a Rathke's cleft cyst.

Rathke's cleft cysts are found in all age groups, but mean occurrence is 40-50 years. They are typically asymptomatic and found incidentally at autopsy. During embryologic development, Rathke's pouch is formed from an evagination of oral ectoderm that grows toward the midbrain. When the anterior lobe of the pituitary gland is formed from this ectoderm, the pouch is reduced to a residual cleft. Cysts are formed when the cleft persists, becomes enlarged, and its secretions accumulate. The cyst fluid

can be yellow and thin, or green or brown thick mucus. It is lined with columnar or cuboidal epithelium in most cases, but mixed cell epithelium or pseudostratified squamous epithelium has been found. Ciliated columnar cells and goblet cells are also present in a majority of the cases. Most Rathke's cleft cysts are asymptomatic, but they can produce a mass effect causing headaches, visual changes, and pituitary dysfunction. Pituitary histology in this case appeared normal. Rathke's cleft cysts are usually located within the sella turcica. Rarely, they are found in a suprasellar location, as in this case.

Death was due to the complications of chronic cocaine abuse, with hypertensive and atherosclerotic cardiovascular disease. The family could be assured that the "brain tumor" had been located at autopsy, but had nothing to do with her death.

Rathke's Cleft Cyst, Rathke's Pouch, Forensic Pathology

G74 Microscopic Soft Tissue Decomposition and Time Since Death

Murray K. Marks, PhD*, and Mariateresa A. Tersigni, MA, University of Tennessee, Department of Anthropology, 250 South Stadium Hall, Knoxville, TN 37996; and Darinka X. Mileusnic, MD, PhD, University of Tennessee Medical Center, Knox County Medical Examiner's Office, 1924 Alcoa Highway, Knoxville, TN 37920

After attending this presentation, attendees will understand the histological soft tissue demise associated with long-term understanding of rigor mortis.

This presentation will impact the forensic community and/or humanity by qualifying the changes that occur at a histological level as a body decomposes; specifically, the temperatures at which each of the layers of tissue lyse during this process.

Introduction: The stages of human soft tissue decomposition are universally accepted as autolysis and putrefaction with subsequent macroscopic disfigurement. While the visual signals have been long recognized and appreciated by pathology, the schedule and precise histological deterioration of epidermal, dermal, fat, and muscle tissue have never been quantified let alone qualified. And, even though biochemistry characterizes these events, this study focuses only on structure. This study provides a longitudinal histological validation of the process in order to more accurately design future research regarding soft tissue decomposition.

Materials and Methods: At the outdoor decomposition research facility at The University of Tennessee, eight identical landmarks on six cadavers were biopsied for two weeks following death, and examined with light and electron microscopy for temporal patterning. These sites were the ventral chest (pectoral region), shoulder (deltoid region), ventral upper arm (biceps), ventral forearm (flexors), lateral hip (gluteal), ventral upper leg (rectus femoris), dorsal lower leg (gastrocnemius/soleus), and sole of foot (plantar aponeurosis/flexor digitorum brevis). Each site was biopsied once each day for the 14 day period. Biopsy sites were paraffin sealed, and adjacent puncture sites selected during the decomposition process. Biopsies were prepared by routine formalin-fixed histological methods at The University of Tennessee Medical Center and examined using a Leica ZX900 light microscope and an Olympus XNC environmental scanning electron microscope.

Results: The cell death associated with decomposition more closely resembles the characteristics of clinically documented cell necrosis as opposed to the apoptotic events of programmed cell death. That is, the cells of decomposing tissue go through an expansion and explosion process, which causes a breakdown of the cell membrane resulting in the expulsion of their cytoplasmic contents into the extracellular matrix rather than simply shriveling into a condensed mass and breaking apart as in apoptosis. Each of the layers (epidermis, dermis, lipid and muscle fibre) experience the same type of cell death, although they do not occur in the same temporal period. The loss of muscle fibre structure was observed at 270 degree days.

The epidermis structure was lost at 150 degree days. The dermis cell structure was maintained until 230 degree days. Fat cell structure was last to fail at 450 degree days.

As part of a recent endeavor to understand the cellular aspect of soft tissue decomposition, this study provides validation of the cellular death process that is the hallmark of initial decomposition. Thus, this research provides a baseline for future experimental design.

Time Since Death, Soft Tissue Decomposition, Histology

G75 An Atypical Gunshot Wound With Absence of a Weapon? The Value of a Thorough Scene Investigation

Clare H. Cunliffe, MD, Office of the Medical Examiner, County of Cook, 2121 West Harrison Street, Chicago, IL 60612*

The goal of this presentation is to increase awareness of zip guns when investigating scenes in which a weapon is not apparent, and to aid in the recognition of the atypical wounds they produce.

This presentation will impact the forensic community and/or humanity by alerting the forensic community to the possible use of a zip gun in likely cases of suicidal gunshot wounds where a weapon is not initially apparent at scene investigation, and an atypical gunshot wound of entrance is present at autopsy.

This presentation will describe the case of a 43-year-old male auto mechanic with depression found dead at work. The body was found on the floor of a washroom stall at the auto body shop where he worked. The deceased had sustained a contact gunshot wound of the forehead, and no weapon was found at the scene during initial investigation. A claw hammer was present in a pool of blood beneath the victim's right arm, and blood spatter was present on the hand and arm.

The deceased's social history strongly suggested that the wound was self-inflicted. Two possibilities were considered; firstly, that the gun had been removed from the scene prior to the investigator's arrival, and secondly, that the case actually represented a homicide.

Autopsy revealed an atypical lacerated contact gunshot wound of the forehead, with a retained medium caliber lead bullet within the posterior scalp. The case was pended for police investigation.

Subsequently, a simple zip-gun fashioned from a piece of pipe, a connector and an air-hose nozzle, along with a pin, was found on the floor at the scene by a co-worker who was cleaning the stall, and the police were notified. On closer examination, a .38 caliber cartridge case was found embedded in the pipe. The conclusion reached was that the deceased had committed suicide using a zip gun constructed from available auto shop parts, and fired the weapon using the hammer found adjacent to him. Due to the nature of the scene and the innocuous appearance of the weapon, the mechanism of the injury and the manner of death were not immediately obvious.

In the United States, zip guns were popular in poor, inner city areas during the 1950s, since they were easy to manufacture from cheap, commonly available materials. Frequently, they were constructed from a piece of wood, a metal barrel such as a car antenna, and a firing pin made from a nail. The simplest zip guns consisted of a piece of metal pipe with a cartridge inserted at one end. To fire the weapon, the protruding cartridge base was struck with a hammer. Because the diameter of the bullet was frequently smaller than that of the unrifled barrel, the bullet would be unstable and tumble upon leaving the barrel. The resulting low velocity and instability of the bullet made zip guns only suitable for short-range use. Today, conventional firearms are less costly and simple to acquire, making zip guns almost obsolete.

Because zip guns are rarely seen, investigators and pathologists may be unfamiliar with their construction and appearance, and the type of wounds they produce.

This case will serve to alert pathologists and investigators to the possible use of a zip gun in likely cases of suicidal gunshot wounds where a weapon is not apparent upon initial inspection of the scene, and an atypical gunshot wound of entrance is present at autopsy.

Zip Guns, Atypical Wounds, Scene Investigation

G76 Suicide or Homicide - The Importance of Forensic Evidence: A Case Study

Giancarlo Di Vella, MD, PhD, Alessandra Arpaio, MD, Claudia Liuzzi, MD, and Francesco Vinci, MD, University of Bari, Di.M.I.M.P. - Sezione di Medicina Legale - Policlinico, Bari, 70125, Italy*

Participants will develop a better understanding of the role and the importance of correlating autopsy findings and evidence from scene examination defining the manner of death.

This presentation will impact the forensic community and/or humanity by demonstrating the difficulties in defining a suicide case that may be considered unusual with respect to evidence recovered from the death scene, the background of the deceased, and the connection of the suicide to an earlier murder.

Traditionally, the most common method of committing suicide by women is via drug overdose. Some statistical reports indicate that since the mid 1980s there has been a significant increase in the number of female suicides involving the use of a firearm. The most common wound site reported in such suicides is the head, and the handgun is the most common weapon utilized by women to commit suicide. Investigation of suicides in most instances tends to be straightforward, however there are some suicides which are very problematic. The determination of the cause and manner of death requires proper evaluation of the autopsy findings, in addition to various findings relating to the scene examination. In suicides, the type of weapon used and the existence of a motive or intent are crucial in the reconstruction of events leading to death. The following report describes a suicide case that may be considered unusual with respect to evidence recovered from the death scene, the background of the deceased, and the connection of the suicide to an earlier murder. In the early morning of January 17, 2004, the local police in Bari, Italy were alerted to the death of a 24-year-old female, by a young man who was fully clothed, with the exception of his pants. The young man informed police that he had witnessed a suicide of a woman whose body was located under a local bridge, a short distance from the police station. Inspection of the death scene by police revealed the young woman to be lying on the ground next to the open door of her automobile. The deceased, who was wearing a very broad rimmed hat, exhibited a single gunshot wound to the front of the head. A small handgun was recovered next to the deceased by the police. While being interviewed at the scene, the informant told police that young woman was his secret mistress, and that he had received numerous calls the previous evening from the woman. During the telephone conversations the male informant noted that the young woman was very distraught, and insisted that they meet beneath the bridge. Upon arriving beneath the bridge, the informant approached the woman as she was ranting about their past, at which point she placed a handgun against the top of her head and pulled the trigger. The informant at this point ran to the woman, then held her in a desperate attempt to revive her.

Examination of the car of the deceased by police led to the recovery of a short note which had been written by the woman, and which stated that she wished she could have prevented the murder of her mother. After a short examination of the scene, the police became very suspicious of the informant and arrested him in connection with the death of the woman. Further investigation of the suspect revealed that he had recently received several very expensive gifts from the father of the deceased, who was unaware that the suspect was married. Unknown to the Italian authorities at the time of the suspect's arrest, the German Police had an arrest warrant

out for the young woman and her boyfriend. Two years prior, the deceased and her boyfriend murdered her mother in Germany. The mother had been bludgeoned, then run over with a motor vehicle to make it appear as if the death was an automobile accident.

The crime scene investigation reported that the body of the deceased was located next to the open door of her BMW. She was in a seated position on the pavement, with legs flexed, and her head and shoulders positioned back in the space between the opened door and the driver's seat. Her clothes exhibited no evidence of tears or rearrangement, with the exception of her hat which exhibited a circular defect in the front with traces of blood. Located next to the right hand of the deceased was a Baby – Browning .25 caliber handgun, model 1932. An empty shell casing of the same caliber was recovered from beneath the body of the deceased. The postmortem condition of the deceased as reported by the medical examiner at the scene noted a core body temperature of approximately 28° Celsius, minimal lividity changes and relatively little evidence of rigor. Inspection of the car revealed many items of value including jewellery, cash, and an airline ticket for a flight to Paris that was scheduled the same day as the death. The autopsy confirmed that the muzzle of the handgun was against the brim of the hat worn by the deceased when it was discharged. Soot, primer residue, and spent gunpowder particles were observed in and around the circular defect site on the hat. Analysis for primer residues were found to be positive on each hand of the victim, in particular on the external metacarpal surface between the first and second digits. A metal jacketed .25 caliber bullet was recovered from within the skull. Considering the cerebral lesions, it was evident that the bullet had passed through the frontal bone and the right frontal lobe, before crossing the midbrain and ending up in the left cerebellar lobe. Toxicological analysis was negative; however, sperm was identified from the anus of the deceased. DNA analysis of the sperm found it not to match the DNA profile of the suspect. Ballistic examination of the recovered bullet and cartridge revealed them to have been fired by the .25 caliber Baby – Browning recovered next to the deceased. One point of debate in the investigation was the possibility of positioning of the handgun by the deceased to commit suicide. The Baby – Browning, model 1932, possesses a three-stage safety system to avoid accidental discharge: it cannot be discharged with the magazine removed, even if a cartridge has been loaded. A manual safety is located on the left side of the weapon, along with a secondary safety which is located on the grip which blocks the trigger except when the pistol is held firmly in the hand, ready for shooting. Latent fingerprints on the handgun were identified as belonging the deceased. The autopsy and ballistic findings strongly supported the notion that the deceased had fired the weapon. A reconstruction of the incident revealed that the woman held the handgun with both hands, with her finger wrapped around the back of the butt, and that she utilized her thumb to depress the trigger. The small amount of gunshot residue detected on the clothing of the suspect boyfriend was attributed to contamination while holding the deceased after the discharge of the weapon. The combined findings of the forensic investigation convinced prosecutors and police to reconsider the manner of death as a suicide. The complete details of this investigation will be presented.
