Kathryn Haden, MD*, Office of the Chief Medical Examiner, Northern Virginia District, 9797 Braddock Road, Fairfax, VA 22032; Jill Urban, MD, and Karen Hendley, The Southwestern Institute for Forensic Sciences, 5230 Medical Center Drive, Dallas, TX 75235

After attending this presentation, attendees will better understand a technique that can aid in the determination of range of fire in skeletal remains found with firearm injuries.

This presentation will impact the forensic community and/or humanity by providing a relatively quick and easy method for evaluation of firearm injuries in skeletal remains.

The goal of this presentation is to introduce forensic scientists to a technique that can aid in the determination of range of fire in skeletal remains found with firearm injuries.

Introduction: The scenario is not an uncommon one: a person goes off into a secluded area with the purpose of committing suicide by shooting themselves, and is later found in a decomposed or skeletal state. The presence of a weapon would certainly indicate a suicide; however, circumstances are not always as they appear. Remains can also be scattered and separated from the weapon, and weapons can be separated from the remains due to theft. When remains are decomposed or skeletal, the usual clues to range of fire, soot, and stippling are often lost or obscured. The authors present a technique that can aid in the determination of range of fire in the absence of visible soot.

The sodium rhodizonate staining technique is widely employed in crime laboratories to detect lead residue on clothing. The staining pattern obtained can then be compared to the implicated weapon and ammunition utilized to determine the possible range of fire. This technique employs spraying the garment with sodium rhodizonate, then sequentially overspraying with buffer and then hydrochloric acid. A pink color with buffer and then blue-purple color with acid is indicative of the presence of lead. This test has been employed on skin; however the authors demonstrate the technique on human and animal skulls.

Materials and Methods: Amputated heads from six previously slaughtered pigs were purchased for this experiment. Three different weapons and ammunition were utilized: a revolver with a non-jacketed bullet, a 9mm semi-automatic pistol with a copper-jacketed bullet, and a shotgun with 00 buckshot. Hard contact shots were fired with the weapon placed between the eyes on the upper portion of the snout. Distant shots were fired from 3 feet with the handguns and approximately 28 feet with the shotgun. The skin from the head was then removed and tested for traces of lead. The skulls were then boiled in water to aid in the removal of the remainder of the soft tissue. Once the soft tissues were removed, the skulls were re-assembled, if necessary, and tested for lead residue. All skulls were examined for visible lead prior to testing with sodium rhodizonate. Color changes were documented and photographed. A test was determined to be positive for lead if the color changed from pink with the buffer to purple-violet with the acid.

Results: The distant gunshot wound from the revolver with the unjacketed bullet showed faint positive staining of the bone around the outer surface of the defect, with no staining on the inside of the skull. Evaluation of the skin revealed a ¼ inch x ¼ inch area of positive staining with a few positive spots 6 inches from the wound. The distant gunshot wound from the semi-automatic weapon revealed no visible residue prior to testing. After testing, a small rim of lead partially encircled the skin wound and there were a few positive spots 4, 5, and 6 inches from the wound edges. There were no traces of lead on the skull. The shotgun inflicted multiple buck shot wounds which tested positive for traces of lead on the skin, but not the skull. All contact range wounds had visible residue on the skin prior to testing, and subsequently had brightly positive staining after testing with sodium rhodizonate. The outer surfaces of the skulls also showed positive staining, however the inner surfaces of the skulls also stained positively. Of note, the brains of the pigs were present at the time of the shooting. This finding was reproduced on two human skulls, one of known contact range and the other of presumed contact range.

Conclusion: Sodium rhodizonate may help determine range of fire in skeletal remains. Lead residue was detected inside the skulls with inflicted contact range firearm injuries, whereas it was only on the surface of the entrance wound, and in small amounts, of the distant wounds. More studies are currently underway to further explore these findings.

Sodium Rhodizonate, Skeletal Remains, Range of Fire

G78 A Modern “Martyr’s Crown”: A Fatal Case of Multiple Self-Inflicted Nail Gun Shots

Francesco Maria Morreale, MD*, Christoforo Pomara, MD, and Stefano D’Errico, MD, Institute of Legal Medicine, University of Foggia, Ospedali Riuniti, via L. Pinto 1, Foggia, I-71100, Italy; and Rocco Maglietta, MD, Hospital San Carlo, Potenza, I-85100, Italy

After attending this presentation, attendees will understand an atypical case of multiple nail gun shots in a 62-year-old man. The peculiarity of the case is represented from the surprising sequence of radiological images.

This presentation will impact the forensic community by underlying the role of a correct and complete radiological store in cases of foreign bodies injuries.

The case of a 62-year-old man, who was taken to the emergency room with multiple head wounds, is presented. He complained only of headache, and spontaneously declared that he had shot himself in the head with multiple nails from a nail gun, which he handed over to the physicians. He was conscious, oriented to place and time, and had no focal neurological or cognitive defects. Only the finding of a foreign metallic body on the surface of the scalp in the right temporal region alarmed the physicians, who immediately hospitalized the patient. Radiographs of the head demonstrated seven injuries with foreign metallic bodies inside. This reproduced the typical appearance of the “Martyr’s Crown.” A CT scan confirmed the presence of multiple nails penetrating the skull in the right (5) and left (2) temporal regions. A subarachnoid hemorrhage was also detected; the ventricular system was unremarkable. Four days after admission, a surgical approach was attempted to pull out nails, six of which were pulled out by cutting the scalp and temporal muscles; the last one, not on the surface, required a craniotomy. The patient awoke one hour after surgery, but his clinical condition rapidly worsened. He became comatose, and died after 10 days of hospitalization.

Few cases of unsuccessful attempted nail gun suicides are reported in literature, fewer cases of successful suicides are described most frequently the head and the left side of chest represent the preferred targets of the body.

Nail guns have been used since the 1950s, designed as a powerful industrial tool to drive nails into various hard surfaces with ease. Recent years have seen an increased diffusion in the domestic environment, too. The ease of use and speed of these tools enhance productivity at the cost of increased potential for traumatic injury. The nail gun fires a single nail or bolt, as projectiles, into wooden or metal surfaces. It could be compared to conventional firearms, being capable of firing projectiles of up to 10 cm into fully stressed concrete at a velocity up to 424 m/sec.

International literature records nail gun related injuries, sometimes lethal, with two categories of forensic interest: industrial accidents and suicide attempts

In conclusion, the case report represents an atypical case of nail gun suicide; highlights the rarity of the event in the literature, and points out the absence of any clinical sign until surgery.

Nail Gun, Successful Suicide, Cerebral Ischaemia

G79 .17 HMR – It’s Not Your Father’s .22

J.C. Upshaw Downs, MD*, Coastal Regional Laboratory Georgia Bureau of Investigation, 925A Mohawk Street, Savannah, GA 31419; and Ron Van Fleet, BS, Donelle L. Pyle, MS, and Shannon Walden, Georgia Bureau of Investigation, 925A Mohawk Street, Savannah, GA 31419

The goal of this presentation is to present a case study of a suicide employing a .17 HMR to familiarize the forensics community with this round and potential resulting injuries resultant there from.

Familiarity of the various forensic disciplines with new rounds should impact the forensic community and/or humanity by allowing recognition of same when encountered in a case, a potential significant benefit in cases where a weapon is recovered at the scene.

This case study involves the death of a 27-year-old male who had been involved in a physical altercation with his wife on the morning of his death. The wife exited the residence and, on hearing a gunshot, re-entered to find the decedent with a fatal intra-oral gunshot wound. Recovered from the scene were a box of .17 HMR rounds.

At autopsy, the subject had a $\frac{3}{4}$ inch stellate contact midline intra-oral gunshot wound with a surrounding $1\frac{1}{2}$ inch area of soot on the roof of the mouth. The shot fractured the floor of the skull and continued to the left parietal brain where the projectile was recovered at the brain surface. Typical subarachnoid hemorrhages and cortical contusions were associated with the wound. Externally, the decedent had an impression on his chest corresponding to a spent .17 HMR casing.

The .17 HMR TNT cartridge is marketed by CCI as a small varmint round with a hollow point tip for “explosive performance.” A follow-up, the .17 HMR GamePoint round was introduced in 2004, marketed as a “dimple-tip bullet [which] mushrooms like a big game bullet instead of fragmenting like a varmint bullet. This greatly reduces damage to edible meat!” A comparison of the .17 HMRs with the various CCI .22 cartridges (<http://www.cci-ammunition.com/default.asp>) shows velocities for the .17 (2375 & 2525 ft/sec) exceeding the .22 magnum (1875 ft/sec) and energy (250 & 241 ft-lbs) approaching the .22 magnum (312 ft-lbs) – see below.

Round	Weight (grains)	Velocity (ft/sec)	Energy (ft-lbs)
.22 short	29	1080	75
.22 long rifle	40	1235	135
.22 magnum	40	1875	312
.17 HMR GamePoint	20	2375	250
.17 HMR TNT	17	2525	241

A potential concern is an attempt (presumably by a novice) to fire such a .17 caliber from a .22 weapon. The .22 magnum may be able to chamber the .17 HMR, however, the 0.05 inch step-down from the casing to the bullet would provide for release of much of the propulsive gases. In theory, this might create problems for the shooter.

In summary, the .17 HMR round has significant velocity and energy. While causing far more damage than a typical .22 caliber round, the tissue destruction is markedly less than that seen with larger calibers.

Conclusion: Familiarity of the various forensic disciplines with new rounds should allow recognition of same when encountered in a case—a potential significant benefit in cases where a weapon is recovered at the scene.

Gunshot Wounds, Suicide, Firearms

G80 A Shot In the Dark? Investigating Accidental Gunshot Wounds

J.C. Upshaw Downs, MD*, Donelle L. Pyle, MS, Ron Van Fleet, BS, and Shannon Walden, Coastal Regional Laboratory Georgia Bureau of Investigation, 925A Mohawk Street, Savannah, GA 31419

The goal of this presentation is to provide a general review, using a case study, of proper investigation of lethal gunshot wounds and, in particular, recognition of the importance of scene investigation and firearms function testing in gunshot wound deaths. In addition, attendees will learn that a particular weapon (Tokarev CZ52) has a tendency, when dropped, to accidentally discharge due to a defective hammer drop safety.

This presentation will impact the forensic community and/or humanity by reviewing the overall investigation of a gunshot wound fatality with special attention to scene investigation, firearms examination, and reconstruction to allow for better recognition of manner of death in fatal cases. Proper death classification’s societal benefits are obvious, allowing insurance payments to be made or withheld where appropriate, and criminal prosecutions to proceed if indicated.

Most lethal gunshot wounds are suicides or homicides. True accidental gunshot fatalities are rare, particularly when the misnomer of

“hunting accidents” with firearms is excluded. With such a paucity of actual deaths due to accidental gunshot wounds, an almost imperceptible bias against recognition of such cases may develop.

Using the case study of the death of a 39-year-old male National Guardsman, the steps of a thorough case investigation, including scene investigation and reconstruction, are reviewed. Through processing of the scene in the case study, a gouge was recognized on the floor, near the body. This represented the impact point of the hammer mechanism on the floor, indicating that an accidental discharge was a real possibility.

The weapon employed should be examined, if possible, in all firearms deaths, particularly for function testing. In the presented fatality, the weapon employed was a Czech 7.62 mm caliber Tokarev (CZ52) pistol. The manufacturer of the pistol, Century International Arms, has issued a recall warning due to a defective hammer drop safety. Inspected weapons, recognized by a “Z” mark on the left side of the trigger guard, indicate the weapon has been “inspected to ensure proper operation in order to avoid grave bodily injury and/or property damage.”

On function testing, the decedent’s weapon was found to be functional with a trigger pull of $7 +/ - \frac{1}{4}$ pounds in single action mode. The holster was soiled with scattered gunpowder particles. Comparison of the flooring from the scene and the gun showed the slide and hammer had indeed caused the gouge. Video recorded re-enactment showed the gun would regularly discharge when dropped in a similar manner.

Using the location of the decedent’s wounds in combination with the gouge in the floor at the scene, a reconstruction of the decedent’s death proved consistent with the history of the victim having accidentally dropped the gun, resulting in his death.

Forensic pathology is not limited to the physical examination of a body. Utilizing available resources, including firearms examination and scene investigation, the medical examiner’s analysis of a fatality is enhanced, hopefully ensuring proper classification of deaths.

Gunshot Wounds, Accident, Safety

G81 Utilization of Automated Fingerprint Identification System (AFIS) to Aid in the Identification of Unknown Perpetrators to Close Unsolved Cases

Kelly L. Hickey, MD, Marcella F. Fierro, MD, and Timothy A. Powell, MPH, Office of the Chief Medical Examiner, 400 East Jackson Street, Richmond, VA 23219; and Robin Young, Division of Forensic Science, 700 North 5th Street, Richmond, VA 23219*

The goal of this presentation is to describe the processes and outcomes involved with the implementation and utilization of a fingerprint comparison system between the central district medical examiner’s office and the local law enforcement offices.

This presentation will impact the forensic community and/or humanity by helping law enforcement to close out “cold” case files and find persons involved in identity theft. The law enforcement and forensic communities will benefit from matching latent and ten print files to the deceased individuals, knowing that the case files can be closed and the offenders are permanently off the streets.

Hypothesis: Matching the fingerprints of deceased individuals from a specific profile with those in the Automated Fingerprint Identification System (AFIS) database could identify perpetrators who are deceased that may have committed unsolved crimes or have been involved with identity theft.

Introduction: The highest incidence group of perpetrators of violent crime is males aged 15-45. These individuals are also the highest group to undergo medicolegal autopsy. By submission of routine fingerprints of deceased males aged 15-45 into AFIS, two questions may be answered (1) identification of perpetrators in ten print file should be identified as deceased, so that case files can be closed involving these individuals, and (2) some of these individuals have not been previously arrested and do not

have a ten print fingerprint file but may be identified in the latent fingerprint files as suspects or perpetrators of crimes. The identification may also potentially uncover perpetrators of identity theft.

Methods and Materials: As a preliminary study, 50 consecutive males aged 15-45 are being fingerprinted as part of the medicolegal autopsy at the Office of the Chief Medical Examiner (OCME) Central District, Richmond, Virginia. The fingerprinting method utilizes fingerprint strips and ink pads. The fingers are cleaned and dried prior to printing. Four fingerprint strips are labeled with the individual’s personal identification. Two sets of fingerprints are taken. The fingerprints are then entered into the AFIS database by the fingerprint examiners of the Division of Forensic Sciences (DFS) for a search of the ten print and latent files. The results of the search are reported back to the OCME, and if a match does occur these results will be issued to the submitting law enforcement agency. Fingerprints that are not a match will be archived.

The number of decedents that match with the ten print and latent print files are calculated and assessed for statistical significance with regards to the cost/benefit based on the number of cases closed or solved based on the results of this information. The positive predictive value will be calculated to further define the value of this study.

Fingerprints, Perpetrators, AFIS

G82 Dead Hits: Matching Decedents’ DNA to Unsolved Crime Scenes

Todd M. Luckasevic, DO, Marcella F. Fierro, MD, and Timothy A. Powell, MPH, Office of the Chief Medical Examiner, 400 East Jackson Street, Richmond, VA 23219; and George C. Li, MS, Linda Johnston, BS, and Deanne F. Dabbs, MFS, Division of Forensic Science, 700 North 5th Street, Richmond, VA 23219*

The goal of this presentation is to determine the value of comparing DNA samples from decedents to DNA evidence left at unsolved crime scenes.

This presentation will impact the forensic community and/or humanity by providing closure to cold cases, ultimately impacting the family and friends of those who were victims of unsolved crimes. The forensic and law enforcement community would benefit from determining DNA matches or hits from unsolved crime scenes and knowing that the perpetrators of these violent acts are now deceased.

Hypothesis: Submission of DNA samples from cases performed at Office of the Chief Medical Examiner (OCME) Central District, Richmond, Virginia, that meet the demographic profile of persons at risk for societal maladjustment for comparison with biological evidence left at scenes of unsolved crimes will result in the solving and closing of outstanding cases.

Introduction: A large percentage of medical examiner cases represent a high-risk group for societal maladjustment (crime) and for encounters with the legal system as felons. The felon data bank archives the DNA profiles of felons. The Division of Forensic Science (DFS) in Richmond, Virginia, also archives profiles of biologic evidence left at scenes of crimes by unknown perpetrators who are not in the data bank. Some perpetrators of crimes who have left biologic evidence profiled by DFS may die without ever being caught, convicted and entered into the felon data bank or compared with DNA evidence profiles.

A pilot study to establish identities among the three groups would assist law enforcement by: (1) solving and closing some outstanding cases upon identification of a decedent as the perpetrator of a crime where the decedent was not in the data bank but had left biological evidence, and (2) determining whether, in the future, continued comparison of the designated group of decedents would assist the law enforcement community by saving time, money, and record keeping in a futile search for presently unidentified, but now deceased, perpetrators of crime.

Materials and Methods: OCME Central pathologists collect and archive blood spots of all medicolegal cases. From these cases, a subset of 50 consecutive males aged 15 to 45 will be the focus of the pilot study. Prior to submitting samples to the data bank, a list of the individuals will be submitted to the data bank. Data bank staff will check the samples against the listed individuals that already exist in the data bank, and exclude from the study those who match by name. The remaining samples will then be submitted on a specially designed data bank Request for Examination (RFE) form, and will be assigned a unique sample number. The data bank profiles those samples utilizing standard DNA-STR profiling kits and enters the results in a specially created database (index), where they remain for an indefinite period of time for comparison purposes.

DNA profiles from these samples are compared against unidentified profiles obtained from crime scenes. If a match occurs, a certificate of analysis is issued to the submitting law enforcement agency, with a copy to the OCME Central. No certificate of analysis is issued for a search not resulting in a match. Matches or hits are presented to the police to correlate with the investigative information.

Results: The percentage of hits are calculated and assessed statistically for cost/benefit for law enforcement based on the number of cases actually closed/solved as the result of this information. Additionally, the predictive value positive will be calculated to further describe the efficacy of this study.

Conclusion: The major observation would be the establishment of identities or hits in cold cases.

DNA, Decedents, Cold Cases

G83 To Dye or Not to Dye: A Tale of the Blues

Sharon R. Crowley, RN, MN *, 122 Emeline Avenue, Santa Cruz, CA 95060; Brian L. Peterson, MD, Forensic Medical Group, 1860 Pennsylvania Avenue, Fairfield, CA 94533

After attending this presentation, attendees will be able to evaluate the reliability of toluidine blue dye application as part of the postmortem genital examination; be able to compare the results from photo-colposcopy at various magnifications vs. photo-colposcopy plus toluidine blue dye application; and be able to better understand the nature and appearance of postmortem anogenital anatomy at various intervals.

This presentation will impact the forensic community and/or humanity by helping to promote consistency and reliability among examiners; improving diagnostic acumen of examiners; and enhancing both antemortem and postmortem investigations and genital examinations.

Living with the Blues: **Richart** (1963) reported the use of 1% toluidine blue in more than 200 women as an *in vivo* staining method to delineate areas of neoplastic epithelium on the cervix. The intensity of the stain was closely related to the number of nuclei per unit area. **Collins et al.** (1966) studied 242 patients to determine the efficacy of the dye for outlining neoplastic areas on the vulva. **Lauber and Souma** (1982) utilized the dye as an adjunct in the evaluation of traumatic intercourse. Results were compared between a group of 22 rape victims and 22 controls that had engaged in consensual coitus. Both groups were examined ≤ 48 hours. Further investigation of toluidine blue by **McCauley et al.** (1987) evaluated the influence of race, parity, age, and other factors in 24 rape victims and 48 controls, all examined within 48 hours.

Dying with the Blues: In 1992, Bays and Lewman described 4 case studies of children, ages 3 months to 4 years, where toluidine blue was used at autopsy to aid in the detection of genital and anal injuries due to child sexual abuse. In 3 of the cases, the dye uptake revealed previously undetected lacerations and a patterned injury due to a foreign object. Use of colposcopy was documented in only one case; magnification was not specified. This autopsy was done 3 days after the disappearance of the child.

When DNA does the Blues: One study, by Hochmeister, Whelan, *et al.* (1997), studied vaginal swabs from women after consensual intercourse.

The postcoital swabs were directly exposed to toluidine blue and other destaining agents in order to determine if the dye had an adverse effect on recovery of DNA. Although there was no effect on either PCR or RFLP recovery, the sample size consisted of only 5 women and the collection time was only 6 hours post-coitus.

Rhythm of the Blues: As a general nuclear stain, toluidine blue, when used *in vivo*, depends on the presence or absence of a nucleated cell population at the exposed surface. Because many current protocols stem from the earlier studies, salient recommendations from those **methodologies** should be considered:

- Richart (1963), described proper decolorization as the most important part of the method. In very mild dysplasia with very small lesions, application of the acetic acid destaining agent in *too liberal* or *too vigorous* a manner might rapidly remove all the stain, even from areas of dysplasia.
- Lauber and Souma (1982) used lubricating jelly to decolorize. Like Richart, they stressed that it was essential to ensure that the tested area was wiped repeatedly with cotton balls until completely dry. They also described the use of finer stroking with a dry cotton tip applicator to differentiate lacerations from dye trapped in crevices.
- In addition to cervical mucous, columnar epithelium, and areas of inflammation, the concomitant presence of 23 categories of benign diseases will cause a **false positive** dye uptake in living subjects (Collins, 1966).
- **Application interval:** a great deal of variability exists in the application of this nuclear stain for documentation of traumatic intercourse in the living. Original studies were done on subjects who were examined within 48 hours. The effects of wound healing on dye application have not been studied. Programs that employ toluidine blue during extended intervals after reported sexual assault must consider the possibility of false positive dye uptake in areas of granulation tissue.
- Lauber and Souma recommended application of the dye **before** speculum insertion to avoid the possibility of findings due to iatrogenic trauma and to circumvent the known spermicidal effect of the dye *in vitro*. However, they also recommended procuring a *hanging drop vaginal specimen*, prior to application of the dye, in order to compare with a subsequent sample. Recent protocols do not recommend this step.
- Programs that use this nuclear stain vary significantly in their methodology, i.e., **timing** of dye application *before* or *after* speculum insertion. The Office of Criminal Justice Planning (OCJP) protocol in California recommends dye application at the *conclusion* of biological evidence collection.
- Early studies were done before colposcopy with magnified photographs was incorporated into sexual assault examinations. **Slaughter, Brown, Crowley, and Peck** (1997) saw no injuries with toluidine blue that were not already seen via colposcopy. However, 15X magnification was routinely used for inspection and photographs. Visualization at lesser magnifications may not allow the same level of scrutiny of the anogenital tissues. Photos taken *prior* to speculum insertion can establish the presence or absence of pre-existing injury. Likewise, when and if iatrogenic injury occurs, it can be documented as such.
- Subtle findings are an examiner issue. Follow-up exams are needed to understand those findings that may mimic trauma and to appreciate changes that occur with healing (Slaughter, personal communication).
- Antemortem use of the **victim as his/her own control**: when patients who present with acute genital injury are brought back for a follow-up examination, the resolution of injury and course of healing can be documented. For the rape-homicide victim, comparisons are best drawn from a baseline group of cases where the cause of death has a non-sexual etiology.

- **Postmortem artifact:** in addition to all of the conditions that affect dye uptake in the living, factors such as skin slip, mucosal autolysis, blood, and other secretions, may cause a false positive uptake during the postmortem interval.

Further study is needed to assess the efficacy and reliability of this nuclear stain as an adjunct to the postmortem genital examination. A prospective study of postmortem cases drawn from various causes of death will allow a comparison of toluidine blue and colposcopy. This subgroup will be part of a larger baseline study on the nature and appearance of the anogenital tissues at various postmortem intervals. When the understanding of what is normal and what is not in the postmortem interval is improved, the application of any staining adjuncts may then enhance, for pictorial purposes, what is already known to be present.

Colposcopy, Toluidine Blue Dye, Postmortem Genital Examinations

G84 Postmortem Monocular Indirect Ophthalmoscopy

Patrick E. Lantz, MD, Department of Pathology, Wake Forest University Health Sciences, Medical Center Boulevard, Winston-Salem, NC 27157; and Gill G.W. Adams, BSc, MBChB, Moorfields Eye Hospital, 162 City Road, London, EC1V 2PD, United Kingdom*

After attending this presentation, attendees will become aware of how to perform postmortem indirect ophthalmoscopy and how it differs from direct ophthalmoscopy.

This presentation will impact the forensic community and/or humanity by describing an efficient, low cost method to examine the posterior retina following death that permits a wide field of view compared with direct ophthalmoscopy.

Postmortem fundal examination can be conducted with a hand held direct ophthalmoscope, head mounted binocular indirect ophthalmoscope or by monocular indirect ophthalmoscopy. The direct ophthalmoscope provides a detailed monocular retinal inspection with high magnification (15x for an emmetrope, less in hyperopia and more in myopia), but a small field of view (6.5 - 10?). Unfortunately, postmortem corneal changes can make fundal examination less than optimal with the direct ophthalmoscope. Binocular indirect ophthalmoscopy, a technique for evaluating the entire ocular fundus, provides a stereoscopic, low magnification, wide-angle, moderate to high resolution view of the retina. However, the binocular indirect ophthalmoscope is moderately expensive and requires some training to properly use.

Monocular indirect ophthalmoscopy is performed using a bright focal light source (penlight, Finhoff transilluminator, headlamp, otorhinolaryngology headlight or light source from direct ophthalmoscope) and a high plus condensing lens. The decedent's eyelid is held open with an eyelid speculum while glycerin or an ophthalmic irrigating solution is used to keep the cornea moist during the examination. After dimming the room lights, the light source is positioned against the examiner's lateral canthus/cheek or between the examiner's eyes. The light source must be directed through the pupil to illuminate the fundus. The image of the retina is then projected out of the eye, and in an emmetropic eye with no refractive error the image of the fundus will be formed at infinity. An aspheric condensing lens is held between the thumb and index finger then placed in front of the eye, thus focusing the retinal image in front of the observer. Initially the condensing lens is held to one side of the decedent's eye until the pupillary red reflex is established and moved between the eye and the examiner (initially about 1-2 cm from the decedent's eye) and then slowly pulled towards the examiner and away from the decedent's eye until the image of the fundus fills the lens, usually about 3-5 cm or equivalent to the focal distance of the lens. Alignment of the condensing lens is critical. It must be held parallel with the plane of the iris; with the flat surface of the

lens facing the decedent's eye (position the surface rim of the lens with a silver ring towards the decedent's eye). The condensing lens must be centered in-line and perpendicular to the axis from the examiner's pupil to the decedent's pupil. Resting the examiner's little finger on the decedent's forehead is helpful as it helps stabilize the lens. The real inverted, laterally reversed image is less magnified than that of a direct ophthalmoscope, but the field of view is much larger.

Indirect ophthalmoscopy permits viewing of the posterior fundus and equator even if there is less than perfect anterior segment media; however, postmortem corneal clouding may cause the fundus to appear hazy. A disadvantage of the technique, as with conventional direct ophthalmoscopy, is the lack of a stereoscopic view; however, stereopsis can be achieved but this depends on the condensing lens, viewing distance, and interpupillary distance of the examiner. This technique is about as difficult as direct ophthalmoscopy to learn. Presently available aspheric lenses range from +14 to +40 diopters and come in different diameters. Lower power lenses provide higher magnification but offer a smaller field of view and must be held farther from the decedent's eye, making positioning of the lens less steady. Further investigation is needed to identify techniques that mitigate postmortem corneal clouding.

Postmortem Indirect Ophthalmoscopy, Direct Ophthalmoscopy, Ocular Fundus

G85 Multislice Computed Tomography In Forensic Pathology

Klaus Poulsen, MD, and Jørn Simonsen, MD, Institute of Forensic Medicine, Frederik Vs Vej 11, Copenhagen, 2100, Denmark*

Imaging in forensic pathology has been known for more than one hundred years, but used very little and only in selected cases such as shootings and battered child syndrome, in which cases traditional x-ray technique has been applied. The goal of this presentation is to introduce routine multislice computed tomography (CT) in forensic pathology.

This presentation will impact the forensic community and/or humanity by demonstrating how computed tomography can be a useful tool as a standard examination before autopsies.

The material consists of more than 1,000 consecutive cases which, before traditional postmortem examinations, were scanned in a CT-scanner (Siemens Somatom Plus4Exp). The results were compared with the results of the autopsies. The examiner records the results of the scanning and provides the description and the pictures to the autopsy pathologist, who then records his results.

All data are stored in optical discs or CD-ROM, and relevant expositions are developed and generated in 3-D images. The scanning procedure is very short – a few minutes – but the generation of the pictures takes approximately 20-40 minutes per case.

The preliminary evaluation shows that the method is especially valuable to demonstrate foreign bodies such as bullets and artificial joints etc., fractures of the skeleton and larynx, and also intracranial hemorrhages and hemorrhages from rupture of large vessels such ruptured aneurysms of the aorta. In some cases, radiographic calcification of the coronaries is so marked that it suggests the cause of death to be coronary insufficiency.

In the authors' opinion, the new method has come to stay in forensic pathology – in the future combined with MR-scanning which covers the soft tissue examination better. Since the method is non-invasive it is more in accordance with the increasing resistance to classic postmortem examinations.

The new non-invasive technique may also appeal to the hospital pathologist, due to the fact that when it has become routine the technique can replace many postmortem examinations in hospitals.

Computed Tomography, Virtopsy, CT-Scanning

G86 Murder in the Ancient Castle: A XIV Century Warrior Virtual Autopsy

Cristoforo Pomara, MD*, Institute of Legal Medicine, University of Foggia, Viale Pinto 1, Foggia, 71100, Italy; Angelo Marrone, MD, Diagnostic Imaging Department, ASL Foggia 2, Cerignola (Fg), Via Trinitapoli, Foggia, 71042, Italy; Stefano Ricci, MD, PhD, Anthropological Laboratory, Department of Environmental Science, University of Siena, Via Mattioli n. 4, Siena, 53100, Italy; Irene Riezzo, MD, Institute of Legal Medicine, University of Foggia, Viale Luigi Pinto, 1, Foggia, 71100, Italy

The goal of this presentation is to present a unique case of the discovery of human skeleton remains of a XIV century “warrior” murdered by a crossbow arrow found in the cervical spine. A virtual autopsy (“virtopsy”) was conducted with multislice Computed Tomography (MSCT) and X ray. The results of radiocarbon dating are also presented.

“There was a time, in a Tuscan castle, a brave knight valiantly died fighting a battle to defend the fortress: This is his story.” Thus could begin this exceptional report concerning a discovery in a medieval castle. A medieval murder by a crossbow is presented. In February of 2004, during restructuring of a medieval castle in a Tuscan country, a burial was discovered. The burial was found at the base of an ancient keep in the highest side of the hill where the castle was built within a rectangular room. This room was more recently used for animal shelter.

The burial was placed in a pit dug in barren clay, and contained easily recognizable human skeletal remains in supine position with the arms bent on the chest and the head protected by two large stones.

These skeletal remains constituted a primary sepulture in full space. The skeleton appeared completely preserved in each part. Anthropological examination confirmed that the remains belonged to a 30-40-year-old male with a stature of about 170 cm. The anterior surface of the left maxilla had a round bone defect with clean-cut outline, 22.10 x 14.65 mm. The alveolar processes of the left maxilla had a round bone defect with an irregular outline involving the second incisor, canine and first premolar, 17.88 x 10.64 mm. A galley dart stile was thrust between the second and the third cervical vertebrae. A complete x-ray study of the skeleton and an image-guided virtual autopsy with multislice computed tomography (MSCT) were made to analyse the correlation between radiologic images, anthropological data and macroscopic findings.

The x-ray study has confirmed the presence of the dart, classified as a “verrettone,” a kind of XIV century dart.

The 3-D reconstruction analysis of the maxillary alveolar wound demonstrated the traumatic origin due to the dart entrance wound. The MSCT was able to analyze and reconstruct the internal dart trajectory. The dart penetrated the spinal cord causing an instantaneous death due to a complete section of medulla oblongata.

No other traumatic lesions were found.

The radiocarbon test (database used: INTC AL 98) was performed to date the remains. It confirmed them as being from the XIV century.

In conclusion, the case reported represents a unique case of human skeletal remains from a XIV century homicide, killed by a crossbow arrow in the cervical spine. A complete study with modern techniques has been performed, using CT scan and x-ray imaging, DNA analysis and Carbon 14 examination to date remains.

Crossbow Homicide, Radiocarbon Test, Multi-slice Computed Tomography (MSCT)

G87 19th Century Autopsy Techniques: Failing to Meet 21st Century Forensic Science Needs

O'Brian C. Smith, MD*, and Teresa A. Campbell, MD, 381 Cherry Hollow CV, Cordova, TN 38018; Elayne J. Pope, MA, Department of Anthropology, University of Arkansas, Fayetteville, AR 72701; Chantal Ferraro, PhD, C.W. Post Campus, Long Island University, Brookville, NY 11548; and Alexandre Senilnikov, MD PhD, Regional Forensic Center, 1060 Madison AV, Memphis, TN 38104

After attending this presentation, attendees will be familiar with diagnostic medical procedures applicable to death investigation in lieu of an autopsy.

This presentation will impact the forensic community and/or humanity by refining the autopsy selection criteria, which will allow greater opportunity for use of advanced clinical techniques and achieve a higher quality of report for use in adjudicated cases.

The autopsy hit its heyday in the 1880s due to the European masters like Rene Laennec, Rudolf Virchow, and Ambroise August Tardieu to name a few. Subsequent improvements to the autopsy include use of Roentgen's x-ray device, photography replacing artwork, and increased utilization of laboratory studies including microbiology and immunology. In contrast, some technologies, notably histology, have fallen into decline at many forensic facilities. Currently, Jurgen Ludwig's multiple editions on autopsy practices are the most modern compendium of pathology techniques derived purely for the purposes of demonstration and diagnosis. Yet the traditional autopsy still relies upon narrative styles little changed over the years, with the exception that comparing lesions to articles of food has been replaced by standard nomenclature and metrics. The pictorial style of autopsy reporting has been very difficult to incorporate, despite the truth of a picture being worth a thousand words. Pre-printed diagrams marked with short annotations are used by some and in this digital age, many photographs are still made using film technology, despite the instant feedback and proven advantages of digital imaging.

A wide variety of disciplines are incorporated at the autopsy table [anthropology, bloodstain pattern interpretation, trace evidence, and clinicians] to provide focal expertise ensuring no stone goes unturned. Expectations of the pathologists include being a physician with clinical skills. Pathologists should be adept at crime scenes, and clinical physical exams including the ability to read a 12-lead ECG, x-rays and other diagnostic images. They also need to be conversant with surgeons regarding resuscitation and surgical decision making. It is beneficial to remain current with the latest pharmaceuticals. The majority of continuing education, journals read and textbooks procured are of a clinical nature, from family practice to the surgical and medical specialties, pediatrics and OB/GYN. Significant additions to autopsy protocols include the following:

- Invasive angiographic studies
- Advanced x-ray protocols for child deaths following AAP guidelines
- Bronchoscopy and endoscopy
- Intra-peritoneal lavage
- Epiluminescence
- Supra-vital staining
- Cardiac conduction dissections
- Cytology of fluids, fine needle aspirates and touch preps
- Needle biopsy for tissue culture
- Needle biopsy for gross and/or histologic diagnosis
- *In situ* retinal evaluation
- Retinal recovery and histologic evaluation
- Histologic dating of wounds
- Histologic evaluation of wounds for foreign materials
- Evaluation/interpretation of bloodstain patterns on victims and clothing

- Excision and retention of bone fractures for fractural analysis and toolmarks
- Soft tissue and osseous burn pattern interpretation
- Digital narrative/pictorial public record autopsy protocol
- Privileged pictorial autopsy protocol
- Review by cultural anthropology

In the practice of pathology, the traditional autopsy is a quaint expression of the best technology the 1880s had to offer. As with today's medicine, the practice of forensics has far more tools in its toolbox now than in the 19th century, mainly borrowed from clinical brethren. By using those tools and refining examinations with diagnostic procedures adopted from clinical colleagues, the percentage of persons needing autopsy to attain diagnosis has paralleled hospital autopsy experience and fallen to 14%. Because the new procedures with fewer autopsies save time, those most in need of autopsy; primarily homicides, child deaths and those too young to die, receive an Engineering Investigation quality autopsy averaging 12 hours of physician time per case. Thus, those cases requiring the highest standards of proof receive the greatest effort with the latest technology and the best reporting format.

Autopsy, Forensics, Pathology

G88 Diesel Fumes Do Kill: A Case of Fatal Carbon Monoxide Poisoning Directly Attributed to Diesel Fuel Exhaust

Sean M. Griffin, MS, and Donna M. Hunsaker, MD, Office of the Chief Medical Examiner and the University of Louisville Department of Pathology and Laboratory Medicine, 810 Baxter Avenue, Louisville, KY 40204-1702; Kiran Charturvedi, MD, University of Kentucky Medical Center Department of Pathology and Laboratory Medicine, University of Kentucky, 800 Rose Street, Lexington, KY 40536; Michael K. Ward, BS, KY State Forensic Toxicology Laboratory, 100 Sower Boulevard, Frankfort, KY 40601; and Andrea R. Terrell, PhD, American Institute of Toxicology, 2265 Executive Drive, # A, Indianapolis, IN 46241*

The goal of this presentation is to present a novel case of fatal carbon monoxide (CO) poisoning directly attributable to diesel fuel exhaust, a previously unreported and perhaps under-recognized source of CO.

This presentation will impact the forensic community and/or humanity by reporting to the forensic community an under-recognized and potentially fatal source of CO poisoning. Exhausts emitted from diesel fuel, although possessing lower levels of CO than exhaust from gasoline fuel, are nevertheless a conceivably dangerous source of CO. Through this three-part research project prompted by this single case, the authors aim to promote further awareness that CO intoxication can occur from inhalation of diesel exhausts, similar to open-air intoxication and, most importantly, to emphasize that it is preventable.

This presentation will fully examine a case of CO poisoning brought to autopsy as a possible work-related natural death in Louisville, Kentucky. The death was initially considered to be caused from complications of ischemic heart disease (IHD), pending toxicological analysis that included a CO level. The CO was ordered at the time of autopsy because the victim was found in the secure cab of a running diesel engine semi-trailer truck at a rest stop. When the toxicology results showed high levels of blood carboxyhemoglobin, the death was recertified as CO intoxication secondary to inhalation of [diesel] vehicular exhaust fumes. This case will illustrate how diesel fuel can potentially serve as a source of CO in fatal and nonfatal poisonings.

Often called the "silent killer," CO is the most common fatal poisoning in the United States, claiming 1,000 - 3,500 lives every year. Although suicides constitute the majority of fatalities in CO poisoning, accidents account for approximately 30% of annual deaths. CO is produced by the incomplete combustion of organic material, and high

concentrations can rapidly accumulate under many different scenarios. The most common sources of fatal CO intoxication are from inhaled fumes in fires or motor vehicle emissions. Typical accidental poisonings usually involve unsuspected increased CO levels in enclosed environments, which can include secured motor vehicles, closed residential or parking garages, car washes, homes, and even tents. Open air CO intoxication is a well-known potential hazard in boating-related activities. CO poisoning has been notoriously attributed to the inhalation of fumes emitted from the gasoline powered motor vehicular exhaust when personal-use automobiles were involved, even when the engine possessed a catalytic converter. In the U.S., a very small fraction of personal automobiles have a diesel engine. While it is known that diesel fuel combustion engines produce much lower levels of CO than gasoline engines, these CO emissions could certainly rise to lethal levels given a sufficient amount of time in an enclosed space and under suitable environmental conditions.

The case involves a moderately decomposed 52-year-old male truck driver found prone between the sleeper and driver compartments of a secure tractor trailer truck. The initial cause of death attributed to IHD was amended after the toxicology results from the Kentucky Office of Forensic Toxicology (OFT) showed a blood carboxyhemoglobin saturation of 67% by differential spectrophotometry. The amended cause of death was attributed to CO intoxication sustained from inhalation of motor vehicular exhaust. IHD was considered a significant factor contributing to his death.

Because of the unique source of fatal CO intoxication in this case, the contributory IHD, and the possible contaminants in the putrefied blood, a 10 year retrospective review was conducted of all non-fire related CO deaths autopsied at the Office of the Chief Medical Examiner in Louisville, KY from 1994-2003. The review compared this case to gross autopsy and toxicological findings and scene investigation of 116 postmortem cases. Specifically examined were severity of heart disease, degree of postmortem decomposition, and evidence of cherry red skin discoloration present at autopsy and scene description. In addition, for confirmation of the validity of the carboxyhemoglobin detection method used by the Kentucky OFT, blood samples from cases representing varying degrees of decomposition along with controls were submitted to two different commercial laboratories and one federal laboratory. The carboxyhemoglobin concentrations were measured using three different laboratory methods. The results from the commercial and federal laboratories were compared to the Kentucky OFT results and were found to show no statistically significant differences in measured carboxyhemoglobin concentration. Lastly, an extensive literature search and personal communication yielded no reported cases of fatal CO poisoning, accidental or suicidal, attributed to diesel fuel exhaust.

Carbon Monoxide, Diesel Fuel, Poisoning

G89 Sublingual Tablet Thwarts Opioid Addiction

William Vilensky, DO, RPh, Forensic & Educational Consultants, 2113 Harbourside Drive, Longboat Key, FL 34228*

The goal of this presentation is to offer information regarding a new tablet, buprenorphine, which when dissolved under the tongue (sublingual) prevents opiate/opioid withdrawal, craving and continued addiction, and reduces co-morbid diseases, crime, and healthcare costs.

This presentation will impact the medical, legal, and forensic community, and/or humanity by demonstrating a high degree of positive outcome results of maintained sobriety in its first year of use by motivated patients and private physicians utilizing buprenorphine.

The Center for Substance Abuse Treatment (CSAT) and The Substance Abuse and Mental Health Services Administration (SAMHSA), divisions of the U.S. Department of Health and Human Services (USHHS), have recognized that approximately 980,000 people in the U.S. are addicted to opioids while only 205%, 180,000, are treated. This innovative treatment allows the physician to prescribe this drug in the private office setting and is called Office Based Opioid Treatment (OBOT).

Opiates (morphine and codeine) and semi-synthetic and synthetic opioids (heroin, oxycodone, hydromorphone, hydrocodone, methadone, fentanyl) are abused by oral ingestion, nasal insufflation, transmucosal absorption (oral, nasal, rectal and vaginal) and injection. The amount of transmitted diseases from substance abuse, i.e., hepatitis, HIV and sexually transmitted diseases significantly elevate the cost of medical treatment and crime. The chemo-therapeutic drug for the past 32 years to detoxify from opioids and maintain sobriety has been methadone. Methadone itself is addicting, but enables the addict to live in society, maintain employment, and remain healthy and productive. However, the addicted patients with the primary, chronic, recurrent, neurobiological disorder of the brain (definition of addiction by the National Institute of Drug Abuse) must be treated daily by reporting to federal and state licensed narcotic treatment programs (NTP) each morning for their dose of methadone. This is time consuming and frequently reduces employability and disrupts the family homeostasis.

Buprenorphine is an agonist-antagonist opioid that is used as an analgesic in small doses by injection but stops opioid craving when given in high strengths as a sublingual tablet. The Drug Abuse Treatment Act of 2000 opened pathways for qualified physicians to prescribe a 30 day supply to patients from their offices and filled at pharmacies. This enables the addicted patient to receive treatment while making them more employable, able to leave welfare subsidies, provides social acceptability, enhances mentally and physical health, family acceptability and responsibility.

Two forms of the drug, manufactured under the names of Subutex® and Suboxone®, have been available since January 2003. The former, pure buprenorphine, induces the drug to a stable maintenance dose. The patient is then switched to the latter drug that is combined with a pure opioid antagonist, naloxone. If a patient tries to pulverize, solubilize, and inject it, the patient will experience rapid withdrawal symptoms.

The overall purpose is to educate and train physicians to treat addiction on the front line of medical practice by the family physician, internist or psychiatrist and thereby treat larger numbers of addicts not currently in treatment and involved in criminal events to support their addiction.

The physician must have a minimum of eight hours of training by government (CSAT) approved addiction specialty organizations.

To date, the reports of buprenorphine's use indicate it is well tolerated and well accepted. Patients can find certified physicians on a physician locator web-site. The benefits of these new drugs are to invite untreated addicts into a less formidable type healing program that eliminates the necessity of reporting to a NTP each morning and raises self-esteem. Since approximately 70% - 80% of inmates in the penal institutions are charged with committing a crime directly or indirectly related to drug abuse or the disease of addiction, it becomes more cost effective to build better lives rather than bigger prisons.

Subutex®, Suboxone®, OBOT

G90 An Analysis of 35 Ethylene Glycol Fatalities in Cook County, Illinois From 1993 Through 2003

J. Scott Denton, MD, Valerie Arangelovich, MD, Michel Humilier, MD, and Edmund R. Donoghue, MD, Cook County Medical Examiner's Office, 2121 West Harrison Street, Chicago, IL 60612*

After attending this presentation the participant will understand that suicide is the most common manner of death from ethylene glycol intoxication in Cook County, Illinois, followed by accident, and rarely undetermined; understand the common death investigation circumstances surrounding death from ethylene glycol intoxication; and understand that toxicology values, although important in determining the cause of death, cannot replace a thorough death investigation when determining manner of death.

This presentation will impact the forensic community and/or humanity by providing realization that homicidal ethylene glycol intoxication is very rare, with suicidal ingestion by far the most common manner of death. Although homicidal poisoning is possible, the determination of the manner of death by the medical examiner or forensic pathologist should rely on the circumstances of the death after a thorough investigation, and not based on toxicology values alone, which overlap with accidental and intentional ingestions.

Introduction: A cluster of alleged and convicted homicidal ethylene glycol poisoning deaths has recently been reported in the media. In light of these reports, the authors sought to retrospectively review the experience of the Cook County Medical Examiner's Office investigating deaths occurring from ethylene glycol intoxication in an 11 year period from 1993 through 2003.

Background: Ethylene glycol is a relatively inexpensive and easily obtainable liquid used predominately as an antifreeze-antiboil additive in motor vehicles, but is also found in detergents, paints, cosmetics, and de-icing products. It has a sweet taste, and is odorless and colorless, but commonly has fluorescent green or yellow dye added. It is an intoxicant with properties similar to ethanol when ingested, and is occasionally used as a substitute for ethanol when ethanol is not available. Several hours after ingestion, toxic effects of nausea, vomiting, convulsions, stupor, and coma can develop. Death usually occurs 24 to 48 hours later depending on the amount ingested, but can be delayed with medical intervention, as ethylene glycol causes metabolic acidosis, hyperosmolality, and tissue injury through its toxic metabolites.

Results and Analysis: During this 11 year period, 35 cases of fatal ethylene glycol intoxication were found in the Medical Examiner's Office computerized database. Retrospective analysis included review of the investigation and circumstances of the death; reports of follow-up investigations, including family interviews, autopsy reports, toxicology results; and any ancillary testing results. Temporally, one case occurred in 1993, no cases in 1994 or 1995, seven cases in 1996, eight cases in 1997, two in 1998, four in 1999, one in 2000, two in 2001, four in 2002, and six in 2003. Deaths were highest in October, April, and August, with only December having none. The average age was 43 years for both sexes, with a range of 25 to 73 years. There were 27 males and 8 females (ratio of 3.4 to 1). Twenty-eight were white and seven were black.

Manner of death was determined for the 35 deaths: 29 were suicides, 4 accidental, and 1 undetermined. There were no homicides. Of the suicidal determinations, ten left suicide notes or phone messages of intent. The four accidental determinations were related to chronic alcoholism and use of ethylene glycol as a substitute intoxicant. The one undetermined case could not be resolved between suicide and accident in a setting of chronic alcoholism and depression. Of the 29 suicide determinations, 14 had history of clinical depression, three had psychiatric diagnoses, and ten were going through a breakup in a long-standing relationship. Twenty-one had either commercial containers or cups of antifreeze at the scene. In examining where death or collapse from intoxication occurred, 28 were at their own home or apartment, 1 at work, 2 at their neighbor's home, 3 in motels, and one in a large department store. Of these 28 found at home, 11 were found in their bedroom, 4 in the basement, 1 in the kitchen, 1 inside a cabinet, 2 in the bathroom, and 7 had no specific location within the home noted.

Autopsy findings were nonspecific and consistent with drug ingestion with pulmonary and cerebral edema. Calcium oxalate crystals were found in renal tubules if death was not significantly delayed by treatment.

Ethylene glycol toxicology analysis was divided into three study groups: (1) those pronounced dead at the scene with postmortem analysis; (2) those found still alive and admitted to the hospital for a short period of time with postmortem toxicology; (3) those found still alive and admitted to the hospital, but subsequently died with antemortem hospital toxicology analysis only. There were 15 victims in the first group dead at the scene. The average blood ethylene glycol concentration on postmortem toxicology testing was 264 mg/dl (range 0 to 849 mg/dl). Average urine concentration was 1028 mg/dl (range 151 to 2193 mg/dl). The average ratio of blood to urine compared in individual cases was 0.31 (range 0.12

to 0.50). The manner of death for all members of this first group dead at the scene was suicide.

The second group was found alive and admitted to the hospital, but died after a short period of time, usually in the emergency room, and underwent autopsy with postmortem toxicology testing. All had metabolic acidosis and hyperosmolality while alive. Examples include two victims who both lived nine hours in the ER after a prior ingestion at unknown time. One had ethylene glycol in the blood of 626 mg/dl, bile 529 mg/dl, and vitreous 716 mg/dl. The second victim had ethylene glycol in the blood of 1141 mg/dl, bile 1134 mg/dl, and urine 561 mg/dl. In these two cases, bile seemed to parallel blood levels.

The third group was found alive and admitted to the hospital, but subsequently died, some after a long hospital course. This group tended to have large variable antemortem blood levels depending when testing was performed during the hospital course. The range of initial ethylene glycol in the blood was 143 to 864 mg/dl. All had documented metabolic acidosis and hyperosmolality, and all progressed to coma and death. Serial determinations of ethylene glycol blood levels were performed in many of the patients in this group and showed variable ethylene glycol metabolism rates. The half-life of ethylene glycol appeared to be less than 12 hours in this group where serial hospital blood measurements were taken.

Conclusion: In spite of the recent cluster of alleged and convicted ethylene glycol homicides reported in the media, none have been found in Cook County, Illinois, within the past 11 years. The majority of the Cook County deaths were from suicidal ingestion, with a few accidents in people using it as a substitute for alcohol. The results are similar to a prior reported cluster of non-fatal intentional ethylene glycol intoxications in Northeastern Illinois in 1996.¹ Toxicology values of ethylene glycol should not be used as a substitute for a thorough death investigation in determining manner of death.

Ethylene Glycol, Manner of Death, Toxicology

G91 Patterns of Illicit Drug Use of Prisoners in Police Custody in London, United Kingdom

Jason Payne-James, LLM, MB, FRCS, DFM*, Ian Wall, LLM, MRCGP, and Caroline Bailey, Forensic Healthcare Services, Ltd., 19 Speldhurst Road, Victoria Park, London, E9 7EH, United Kingdom

After attending this presentation, attendees will gain an understanding of the types of illicit drug use seen in prisoners in police custody in the U.K., and the characteristics of such drugs users.

This presentation will impact the forensic community and/or humanity by allowing understanding of the needs of the drug users and the need for forensic physicians to have a broad general medical background, and thus assisting in determining the type of training needed by forensic physicians to manage such patients in the police setting.

Various national and local strategies have been formulated and implemented directed at reducing illicit drug use, and crime associated with such drug use, in England & Wales. A number of these strategies directly involve police (including drug arrest referral workers in all police stations, drug testing for trigger offenses, needle exchange schemes), and thus directly or indirectly, forensic physicians.

Aims and Methods: Studies undertaken in 1992 identified the proportion of drugs users seen as part of the forensic physician workload and explored the characteristics of such drug users seen in police custody. The aim of the current study was to identify changes that have taken place in the last decade comparing the number and characteristics of drug users seen in police custody. A prospective, anonymised, structured questionnaire survey was undertaken of consecutive, self-admitted illicit drug users seen by forensic physicians in police custody within the Metropolitan Police Service in London, U.K.

Results: In a separate study 30% of detainees seen had dependence on heroin or crack cocaine (1992 – 11%). 113 drug users were studied in 2003.

95.4% gave their consent to participate in the study and complete the questionnaire. Of those consenting, 82% were male, 18% female. Mean age was 28.5y (range 18-49). 80% were unemployed; 29% had no fixed address (1992 – 10%); 65% were Caucasian (1992 – 85%); 18% were Bangladeshi (1992 – 4%). Significant mental health issues (e.g., schizophrenia) were present in 18%; 15% had significant alcohol use; 23% were married or had long term partners; 56% of partners/spouses used drugs. Heroin remains the most frequently used drug – in 93% of cases (1992 – 77%); crack cocaine was used by 87% (1992 – 30%); mean daily cost – heroin GBP 76 (range 20-240), crack GBP 81 (range 20-300). More than 50% of users inject crack and heroin simultaneously. 56% used the intravenous route (1992 – 72%); 25% had shared needles at least once (1992- 41.6%); 100% had accessible sources of clean needles; 6.4% were hepatitis B positive (1992 – 25.7%); 42% were aware of hepatitis prophylaxis (1992 – 9.7%); hepatitis C positive – 20.2% (not recorded in 1992); 3.6% were HIV positive. The mean total length of time of drug use was 7.5y (range 1 month – 20 years); 82% had served a previous prison sentence; 73% of prison sentences were drug-related (drug-defined – 21%, drug-inspired – 74%); 54% had used drugs in prison (1992- 82%); 11% had used needles in prison (1992- 30%); 3% of users stated they had started using in prison. 38% had been on some form of rehabilitation programs previously; 11% had been on Drug Treatment & Testing Orders (DTTO); 5.5% were currently on DTTOs at assessment; 32% had used the services of Drug Arrest Referral Teams in police stations; 10% were in contact with Drug Teams at the time of assessment.

Summary and Conclusions: National drug reduction strategies appear to have had little beneficial influence on patterns of drug use of the population seen in police custody. In the last decade there appears to be a substantial increase in the prevalence of drug use – particularly of crack cocaine. Treatment interventions are either not available, not followed through or not needed. In very general terms, the illicit drug use problem appears to have significantly worsened in the population seen in police custody, although there is evidence that suggests that within this population health education and harm reduction messages appear to have had some positive effects.

Drugs, Police Custody, Forensic Physicians

G92 Child Homicides in Hong Kong: A Retrospective Review of a Ten-Year Period From 1989-1998

Philip S.L. Beh, MBBS, DMJ*, Department of Pathology, The University of Hong Kong, Room 126, University Pathology Building, Queen Mary Hospital, Hong Kong, Hong Kong SAR, China; and R.G. Broadhurst, Department of Sociology, The University of Hong Kong, Room 126, Hong Kong SAR, China

After attending this presentation, attendees will understand the characteristics of child homicide in a predominantly Chinese population and thus be able to compare and contrast with characteristics in their own population.

This presentation will impact the forensic community and/or humanity by providing rare data on child homicide in a predominantly Chinese culture. It also represents a systematic review of all child homicides for all of Hong Kong in a ten year period. It shows similarities with other published material but will also highlight differences which may be cultural in nature.

This paper presents the findings of a retrospective review of all child homicide cases seen in Hong Kong in a ten-year period between 1989 and 1998. In this period there were a total of 799 homicide incidents, with 948 victims and 1666 offenders. Children younger than 4 accounted for 7.3% of victims (n = 69) and between ages 10-15, 8.8% of victims (n = 83). However, there was a much lower homicide rate between ages 5 and 10, accounting for only 2% (n = 19) of all homicide victims. These results are consistent with previous statistics that child homicide had a bimodal pattern, peaking in ‘very early childhood’ and ‘late adolescence’ (Christoffel)¹

Victim-offender relationships, causes of death and manner of death will also be discussed.

i Christoffel, K.K. (1984). Homicide in childhood: A public health problem in need of attention. *American Journal of Public Health*, 74(1), 68-70.

Child Homicide, Hong Kong, Retrospective Review

G93 Evolution of the Intentional Injury Infant Syndrome in Northern France

Gilles Tournel, MD*, Institut de Médecine Légale, 1, Place de Verdun, Lille, 59 000, France; Marie Desurmont, MD, Institut de Médecine Légale, 10 Rue F Villon, Lille, 59 000, France; Valéry C. Hédouin, MD, PhD, Institut de Médecine Légale, 1, Place de Verdun, Lille, 59 000, France; Didier Gosset, MD, PhD, Institut de Médecine Légale, 10 Rue F Villon, Lille, 59000, France

In northern France, child abuse represents a daily preoccupation in forensic medicine. The goal of this presentation is to retrospectively study infants hospitalized for subdural hematoma and examined in the forensic department for suspicion of child abuse.

This presentation will impact the forensic community and/or humanity by showing the importance of child abuse and Intentional Injury Infant Syndrome (IIIS) in northern France.

Patients and Methods: During a 36 month period (January, 1999, to December, 2001), 39 infants aged 1 month to 2 years, hospitalized for subdural hematoma, were examined or autopsied (eight cases). Clinical and paraclinical information was collected.

Results: Intracranial hematoma: 22 subdural hematomas were bilateral, 5 were interhemispheric and 12 were unilateral. Five infants had evidence of different ages of intracranial hematomas and 7 had chronic subdural hematomas. Some infants had associated skull fractures. Severe cerebral edema was present in 8 cases.

Ophthalmoscopic findings: 33/39 cases had abnormal ophthalmoscopic findings. Eighteen cases had retinal hemorrhages. Some cases were associated with retinoschisis (3), with other ocular haemorrhages (2), and/or with papilledema (3). Retinal haemorrhages were absent in six cases.

General examination: 25/39 had evidence of child abuse including bruises (12 cases), soft-tissues injuries (5 cases), rib fractures (6 cases), long bone fractures (2 cases), burns (1 case), bilateral testis injury (1 case), severe denutrition with growth and psychomotor retardation (6 cases).

Risk factors: 19 cases had antecedent evidence of child abuse or neglect in their family. Eighteen were first born and the only child. Thirteen infants had previously been abused; in 1 case, the mother was young (less than 18) and in another one she was psychotic.

Facts: In 11 cases, related facts were a history of shaken baby syndrome; in 8 other cases, the history was not correlated with the observed injuries. In 18 cases, injury mechanism was not explained by the caregivers. In two cases, the caregivers have affirmed that they played with their children.

Neuroimaging: In 27 cases, MRI was performed and was abnormal in all cases. They were compared with results obtained in CT imaging, and standard radiography.

Discussion and Conclusion: Only 33/39 subdural hematomas were associated with retinal hemorrhages and determined the classical description of "the shaken baby syndrome." The absence of a traumatic history or a history not correlated with the clinical signs is a major element for the diagnosis and is highly suggestive of child abuse. Associated injuries observed in 50% cases are also pertinent arguments. The use and the utility of neuroimaging to determine the time of the lesions and their origin is very important and discussed. A specific prevention of the IIIS should be developed in France.

IIIS, Child Abuse, Clinical Forensics

G94 Breath Holding Spells Associated With Unexpected Sudden Childhood Death

Kathryn K. Berg, MD*, Daniel W. Davis, MD, and Andrew M. Baker, MD, Hennepin County Medical Examiner's Office, 530 Chicago Avenue, Minneapolis, MN 55415

After attending this presentation, attendees will be able to recognize a medical condition that may account for sudden death in childhood (greater than 12 months old).

Breath holding spells (BHS) have traditionally been thought to be benign—"something that the patient will outgrow." However, clinical monitoring during some of these "spells" has resulted in the documentation of both severe bradycardia and dispersed QT intervals. A recent study reported ten patients with significant bradycardia that required permanent pacemaker placement.

The authors report the case of a 20-month-old Caucasian male, born by induction via membrane rupture and the use of pitocin at the gestational age of 38 weeks with APGAR scores of 7/8. He was noted to be a "slow starter," requiring vigorous sternal rubs to facilitate normal vital signs. In addition to this he had temperature instability that required his transfer to the Special Care Nursery for monitoring and isolette placement to maintain his temperature. He remained in the hospital for six days after his birth. After discharge he had what his parents described, and his doctor related, as "breath holding spells," occurring two to three times a week. These did not alarm his parents because his older sister also suffered from them. His spells were provoked by crying or coughing, and after those activities he occasionally had a quiet period with apparent apnea. These spells were associated with both pallor or cyanosis that could last for five to ten seconds. Multiple 911 calls were made when the apneic spells progressed into seizure activity lasting more than 30 seconds. At the age of seven weeks, following a coughing episode with an emergency room evaluation, he was found to have oxygen saturation of 88 to 89 percent. While the phlebotomist was drawing his blood he became apneic. He was given supplemental oxygen and became more alert. A follow up chest x-ray revealed a slightly enlarged cardiac silhouette. A subsequent echocardiogram was normal. He was worked up for gastroesophageal reflux disease and placed on omeprazole. In the last four months of his life he had a marked decrease in these episodes.

On the day of his death, while under the care of his aunt, he was placed in his crib after his lunch meal. No articles of potential respiratory compromise were in the crib. He awoke with a cry after his nap, and when his caregiver checked on him 20 minutes later, he was found unresponsive and a 911 was called. Attempts at resuscitation were unsuccessful.

Postmortem exam revealed no anatomic cause of death. Toxicology, blood cultures, histology, postmortem radiographs, and vitreous electrolytes were unremarkable. Detailed cardiac pathology was normal.

Breath holding spells are a frequently observed event in infancy and early childhood. Their association with sudden and unexpected death is rare. Typical cases begin between six and twelve months of age, and rarely last past age four. Breath holding spells have been associated with pallor and/or cyanosis, and severe cases involving convulsions have been described. Several causes and explanations have been proposed, but proof of etiology is not found in most cases. Autonomic dysfunction and paroxysmal vagal overactivity have been felt to play a significant role.

The death of this child represents a case of paroxysmal vagal overactivity with a fatal outcome. While rare, when the history is consistent with this premorbid diagnosis, and no alternative explanation is found, this cause of death should be a consideration.

Breath Holding Spells, Paroxysmal Vagal Overactivity, Sudden Unexpected Death in Childhood

G95 An Interdisciplinary Approach for Diagnosis and Age Estimation of Infants' Fractures in the Course of the Autopsy

Heike Klotzbach, MD, PhD, Institute of Legal Medicine, Hamburg University, Butenfeld 34, Hamburg, 22529, Germany; Guenther Delling, PhD, Institute of Pathology, Department of Osteo-Pathology, Hamburg University, Lottestrasse 2, Hamburg, 22529, Germany; Erich Richter, PhD, Institute of Radiology, Department of Pediatric Radiology, Martinistraße 52, Hamburg, 20246, Germany; and Klaus Pueschel, PhD, Institute of Legal Medicine, Hamburg University Butenfeld 34, Hamburg, 22529, Germany*

After attending this presentation, attendees will understand a scheme for diagnosis and age estimation of infants' fractures during autopsy.

This presentation will impact the forensic community and/or humanity by diagnosing and estimating the age of infants' fracture as an important contribution to the diagnosis of the battered child syndrome. Fractures of different ages are suspicious, and dating the fractures allows some scrutiny in assessing whether the ages are in accordance with the details given by the accused. Moreover, the implementation of an interdisciplinary approach involving forensic pathologists, osteopathologists, and radiologists allows use all resources and enhances cooperation with other disciplines.

Age assessment of infants' fractures plays an important role in the diagnosis of the battered child syndrome. In postmortem cases an interdisciplinary scheme involving careful external investigation, skeletal survey, autopsy, radiography, and osteo-histology has proven useful for dating infants' fractures. Four postmortem cases of infants with multiple fractures of different ages due to child abuse (a total of 48 osseous lesions) were evaluated. Early stages of fracture healing processes were dated histologically by the extent of periosteal thickening, osteoid production and calcification of soft callus. In advanced healing processes the osseous apposition rate defined by the width of the newly formed trabeculae was measured for age estimation of the fractures. Multiple influencing variables must be considered. Hence, dating the osseous lesions leads not to one single day, but to a time-interval when the fracture has occurred. The results of the cases presented indicate the forensic relevance of defining a time interval of the injury, which often allows some scrutiny in assessing whether the ages are in accordance with the details given by the accused. Also, fractures of different ages are a strong indicator of child abuse. Further work in this field will lead to more precise dating of infants' fractures.

Battered Child Syndrom, Infants' Fractures, Osteo-Histology

G96 Are Retinal Hemorrhages Diagnostic of Shaken Baby Syndrome? What Really Killed Baby Cooper

Christopher J. Plourd, JD, 1168 Union Street, Suite 303, San Diego, CA 92101-3818*

The goal of this presentation is to discuss the inherent limitations of the current state of medical knowledge regarding the specificity and causal connection of retinal hemorrhages and Shaken Baby Syndrome.

Bilateral extensive retinal hemorrhages accompanying evidence of childhood head trauma (subdural or subarachnoid hemorrhage) are considered virtually diagnostic (pathognomonic) of Shaken Baby Syndrome by most pediatricians and ophthalmologists. The association of retinal hemorrhages and Shaken Baby Syndrome, with or without impact, is a subject of increasing debate in the forensic medicolegal community. The purpose of this presentation is to describe the diagnostic dilemma presented by the suspected child abuse death case of 3 month 24 day old Baby Cooper, who was alleged to be the victim of Shaken Baby Syndrome (SBS) while in the care of his state licensed daycare provider.

On December 18th, 2002, Baby Cooper's daycare provider reported that he didn't look right as he lay sleeping 45 minutes after being placed down for his afternoon nap. Baby Cooper's "little cheeks were purple." He was picked up and it was described that "his little arms went limp." 911 was immediately called. Pending emergency personnel arrival, rescue breathing was started as the daycare provider talked to the 911 operator. The paramedics arrived within five minutes. By that time Baby Cooper was breathing again but had an irregular heart rhythm (bradycardia). Paramedic assessment in the field revealed no evidence of trauma. The daycare provider denied any intentional or accidental traumatic injury. Baby Cooper was quickly transported to San Diego Children's Hospital. Upon arrival, Emergency Department medical staff noted that Baby Cooper's pupils were fixed and dilated, he had no pulse, and could not breathe on his own. He was intubated and after 45 minutes of resuscitation, including CPR, Baby Cooper's heart began to beat on its own but his respirations had to be maintained on a ventilator. A CT scan two hours after hospital admission revealed brain swelling consistent with global hypoxic-ischemic injury, including complete obliteration of the sulci and basilar cisterns. The admitting pediatrician believed he saw a frontal lobe contusion on the CT scan. Abdominal and pelvic CT scans were negative. Possible blood was noted in the posterior chamber of baby Cooper's eyes. A neurological examination concluded that Baby Cooper was probably brain dead. A trauma surgeon examination concluded there was no external evidence of trauma except for a bruise on Baby Cooper's chest caused by the CPR done in the Emergency Department of the hospital. Baby Cooper's initial blood studies, done within one hour of hospital arrival, revealed that his blood sugar was 372, his blood gas had a pH of 7.02, his sodium level was elevated to 160 and his potassium was elevated to 11.5. Baby Cooper's initial coagulation studies revealed a severe coagulopathy (a PT of 17, a PPT of greater than >130, and a low fibrinogen level of 44). Three hours post hospital admission an ophthalmology examination revealed bilateral retinal hemorrhages extending out to the periphery. Chest x-ray noted the child's lungs to be hyperinflated. A complete skeletal survey the following day was negative. One hour before a blood culture draw, Baby Cooper received several IV injections of an antibiotic. Brain death was declared 48 hours after admission. Organ donation took place 64 hours after admission, preceded by anticoagulant therapy.

Baby Cooper's prior medical history included normal birth weight, a prolonged vaginal delivery, mild jaundice and significant head molding. At two weeks Baby Cooper underwent an unremarkable circumcision. At six weeks Baby Cooper was diagnosed with microcephaly (head circumference below the 5th percentile). Baby Cooper's diet consisted of maternal breast milk either via nursing or via bottle. In the month before hospital admission Baby Cooper had sporadic episodes of constipation (up to four days) and days when he would not eat well.

At autopsy, anoxic cerebral changes ("respirator brain") with some lymphocytic infiltration, questionable "Traumatic Axonal Injury" ("focal retraction balls") and superficial hemorrhagic injury of the upper spinal cord and cerebrum were noted. No frontal lobe contusion, subdural hematoma, subarachnoid hemorrhage, or other traumatic brain injury was present. Baby Cooper had extensive bilateral retinal hemorrhages, and unexplained subdural bleeding in the lower thoracic spinal column. Toxicology was negative. After two months, the medical examiner signed an amended death certificate and concluded that Baby Cooper was the victim of Shaken Baby Syndrome and ruled the manner of death as homicide.

The trial of the day care provider was a battle of conflicting medical experts. The prosecution contended that Baby Cooper died of Shaken Baby Syndrome because of the rapid onset of brain swelling, the superficial spinal cord and cerebral hemorrhagic injury and the bilateral retinal hemorrhages. Defense medical experts concluded that Baby Cooper stopped breathing because of a Sudden Infant Death Syndrome event (SIDS) that was resuscitated (known as "a near-miss SIDS" or a "resuscitated SIDS" case). All the findings at autopsy were the result of Baby Cooper being kept alive on a ventilator for more than two days before he was formally declared dead. The retinal hemorrhages were caused by

the child being given vigorous CPR while the lungs were hyperinflated. The severe anoxic changes with swelling caused the superficial hemorrhagic and cerebral injury due to crushing against the skull, together with a patient having a severe clotting disorder upon admission to the hospital.

At trial, based solely upon the medical findings, the prosecution claimed that the daycare provider became increasingly irritated with Baby Cooper's crying, and in a moment of frustration shook him to death. In her defense the daycare provider testified she did nothing to injure the child and called numerous character witnesses who testified that, over a fifteen year period, they had children in her daycare or were frequent visitors to the daycare. They testified to her love, understanding, and abilities to care for the needs of children. Character witnesses also testified that children were always well cared for, and that the daycare provider never lost her temper or became frustrated with a child. After two six-week jury trials (the first jury trial ended in a deadlock), the daycare provider was acquitted of all charges. The controversial medical evidence along with the character evidence convinced the jury that the daycare provider was not the type of person who would be capable of harming an infant child.

In reviewing a case of suspected Shaken Baby Syndrome death, all aspects of the case must be integrated before drawing any conclusion regarding cause and manner of death. Attention should be paid to post hospital admission medical treatment and diagnostic tests, along with a careful evaluation of secondary effects of medical care. Extensive peripheral retinal hemorrhages are part of a constellation of findings helpful to diagnose some cases of Shaken Baby Syndrome. Retinal hemorrhages in the absence of specific brain injury (subdural hemorrhage, subarachnoid hemorrhage, or contusions) present a diagnostic dilemma.

Shaken Baby Syndrome, Retinal Hemorrhages, SIDS

G97 Fatal Craniocerebral Trauma With Hemorrhagic Retinopathy in an Infant: Abuse or Accident?

Amy M. Tharp, MD, and Patrick E. Lantz, MD, Department of Pathology, Wake Forest University Health Sciences, Medical Center Boulevard, Winston-Salem, NC 27157*

After attending this presentation, attendees will be aware of the limitations of certain ocular findings that are considered diagnostic for inflicted childhood neurotrauma and remember the importance of a thorough investigation before determining if a fatal pediatric head injury is intentional or unintentional.

This presentation will impact the forensic community and/or humanity by demonstrating the importance of a thorough investigation for all cases of fatal pediatric head injury.

Severe hemorrhagic retinopathy, retinoschisis and perimacular folds have been considered characteristic of inflicted childhood neurotrauma (Shaken Baby Syndrome), rarely occurring in children with intracranial hemorrhage from other causes. Observational reports and evidence-based inquiries have begun to question those assumptions. This is a report of a case of a 7-month-old infant who was left in the care of his 11-year-old brother and 10-year-old cousin for about two hours. When his mother returned from the store she found the infant unresponsive. He was transported to the local hospital where a cranial CT scan showed a non-displaced skull fracture adjacent to the coronal suture with widening of the sagittal suture, an extensive scalp hematoma, and a mixed density left subdural hematoma. Cerebral edema was noted, with diffuse effacement of the sulci over the left cerebral hemisphere and a suggestion of transtentorial herniation. After the infant was transferred to a tertiary medical center, a pediatric ophthalmology consult reported extensive bilateral retinal hemorrhages with premacular subhyaloid hemorrhage in the right eye and macular edema of the left eye consistent with a non-accidental head injury. A skeletal survey revealed no fractures other than the parietal skull fracture described on the initial cranial CT examination. A repeat cranial CT scan

showed poor gray-white differentiation consistent with severe anoxic brain injury. Clinical brain death was determined about 20 hours after admission.

Major findings at the autopsy included multiple (6) contemporaneous acute skull fractures (consistent with a crush injury from quasi-static loading), subscalpular extravasated blood, subgaleal and epidural hemorrhage, subdural hematoma, diffuse subarachnoid hemorrhage, severe anoxic brain injury and a right cortical cerebral contusion. Postmortem ophthalmologic findings consisted of extensive bilateral retinal hemorrhages; intrascleral hemorrhages; retinoschisis and a perimacular retinal fold in the right eye; macular edema of the left eye; and intradural, subdural, and subarachnoid hemorrhage of the optic nerves.

Subsequent investigation revealed that the 10-year-old cousin had placed the infant in a baby carriage and taken him and his sister outside while the 11-year-old brother played basketball with friends. Investigators doubted her story that when she came back inside she lifted the infant out of the stroller with one hand and put the stroller away with her other hand. Subsequent investigation and examination of the stroller showed that if the frame latch was not secure, releasing the latch on the handle would permit the stroller to collapse and lurch forward into the legs of the young babysitter, causing her to fall onto the stroller. Recent evidence-based reports have questioned the diagnostic specificity of certain ocular findings in infants/young children with brain injuries. Statements in the medical literature that retinoschisis and perimacular circular folds are diagnostic of shaken baby syndrome are not supported by objective scientific evidence. It is imperative that ocular findings are not viewed out of context and a thorough investigation is conducted before determining whether a fatal pediatric head injury is intentional or unintentional.

Shaken Baby Syndrome, Inflicted Childhood Neurotrauma, Retinal Hemorrhages

G98 The Evidence-Based Medicine Paradigm Shift and Forensic Pathology

M.G.F. Gilliland, MD, Brody School of Medicine at East Carolina, Department Pathology and Laboratory Medicine, Brody 7 S 10, Greenville, NC 27834*

Attendees will learn that the concepts of Evidence-Based Medicine are not being used in forensic pathology writings, although some of the terminology is being applied in polemics about the Shaken Baby Syndrome.

This presentation will impact the forensic community and/or humanity by assisting forensic pathologists in being better able to judge the validity of assertions about Abusive Head Injury and/or Shaken Baby Syndrome couched in terms of Evidence Based Medicine.

Hypothesis: The term Evidence-Based Medicine (EBM) has, so far, been utilized in the Forensic Pathology context to gain entry to the current literature for an editorial, an opinion paper, and a single case report, all attempting to discredit the concept of Shaken Baby Syndrome. Such papers might not be given as much consideration without the appearance of fluency with the issues raised by EBM.

Synopsis: Evidence-Based Medicine (EBM) is an approach to scientific decision-making in selecting treatments for well-defined diseases. Prospective, double-blinded, randomized controlled trials (RCTs) of therapies are given the highest weight, while other forms of comparing health interventions are ranked lower in the EBM hierarchy. The term Evidence-Based as used in the forensic pathology literature to date asserts that no evidence exists, or only weak evidence exists, for what is called Shaken Baby Syndrome. EBM nomenclature has not been used in other contexts to establish or refute other diagnoses in health-related papers, whether in medicine, respiratory care, or dentistry.

Evidence-Based Medicine (EBM) concepts were introduced to a broad readership in a publication in the Journal of the American Medical Association in 1992. The then editor of the JAMA, George Lundberg, referred to the JAMA itself as "The Journal of Physician Behavior

Change.” He was describing his vision for the impact of the articles presented in the Journal. EBM has rapidly achieved widespread acceptance and is achieving “Physician Behavior Change.” Print and electronic journals have sprung up to publish articles using the term, and at times even applying the concepts.

Use of the term “Evidence-Based Medicine” has not been uniformly associated with appropriate appreciation of EBM’s goals nor application of its techniques. Reviewing the actual EBM literature reveals multiple articles complaining that others use their terminology but not their concepts. Still other articles discuss the phenomenon of EBM and urge further study of the validity of its assumptions. Much of the literature dealing with the results from applying EBM describe large studies (called mega-studies) and substitutes for mega-studies by literature analyses (called meta-analyses), both seeking to achieve more “Statistical Power” (statistical significance) by comparisons of treatment in similar, large groups. Additionally, other articles call for Evidence-Based comparisons of various forms of intervention from toilet-training to cancer treatments.

A review of the literature accessed through PubMed (<http://www.ncbi.nlm.nih.gov/PubMed>) searching for the terms “Evidence-Based Medicine” and “Shaken Baby” reveals only three papers: one is a literature review, the second is a single case report with a brief literature review, and the third is a comment published in the same issue as the case report. Both of the literature reviews fail to provide a citation to describe the classifications used to assert the weakness(es) of existing “Evidence.”

Determining whether the terminology from EBM is used accurately or not requires the reader to review the goals and techniques of EBM. Such a review leads one to realize that the terms and techniques of EBM are misapplied in these three publications. Abusive Head Injury is not a “treatment” applied prospectively and randomly with case-controls (RCTs) in a mega-study.

The published reports of cases, case series, or studies involving Abusive Head Injuries or Shaken Babies are not legitimate subjects for meta-analyses: Those studies which support statistical inference (have sufficient “Statistical Power” on their own) gain no benefit from having their populations and selection criteria diluted. Those studies which do not support statistical inference are too dissimilar both in their populations and selection criteria to be legitimately combined. When such heterogeneous populations are combined for analysis, the result is at best an admixture, not the blend meta-analysis seeks. It is a priori apparent that every attempted meta-analyses of such disparate groupings must lack all true “Statistical Power,” whether for or against any given hypothesis.

Evidence-Based Medicine, Abusive Head Injury, Shaken Baby Syndrome

G99 Sequential SIDS or Double Homicide? Challenges of Delayed Investigation of Potential “Subtle” Child Homicides

Stacy A. Drake, MSN, RN, Teresa Royer, MSN, RN, Stephen K. Wilson, MD, Dwayne A. Wolf, MD, PhD, Ashraf Mozayani, PharmD, PhD, and Luis A. Sanchez, MD, Harris County Medical Examiner Office, 1885 Old Spanish Trail, Houston, TX 77054*

After attending this presentation, attendees will understand the challenges of delayed investigation in sequential infant deaths.

This presentation will impact the forensic community and/or humanity by demonstrating successful coordination of investigation of sequential childhood deaths. Experience illustrates a truism that needs to be remembered in all death investigation; namely, that all autopsy, biochemical and toxicologic data must be considered in the context of a coordinated investigation.

A stepfather placed his five-month old white female child on a living room love seat for a nap at 9:00 a.m.. According to police records, the step-father went to sleep across the room on a couch. He awoke a few hours later to find the infant unresponsive. The infant was transported to the regional hospital where she was pulseless and apneic with a rectal temperature of 93.0° F. The initial police investigative report made no mention of syringes or insulin at the scene of death. Little information regarding the stepfather’s medical history or background was obtained at that time.

At autopsy, the infant was normally developed and well nourished, with a length and weight appropriate for age. No contusions, abrasions, scars, or other signs of old or recent trauma were noted. Evidence of medical intervention included an intraosseous catheter in the right tibia, a single needle puncture wound in the left antecubital fossa, three needle puncture wounds in the right antecubital fossa, and a single needle puncture wound on the anterior right lower leg. No additional puncture wounds were seen. Postmortem x-rays revealed no acute or old skeletal lesions. There were no petechial hemorrhages in any of the internal thoracic organs, and no congenital organ anomalies were identified. Abundant hemosiderin-laden pulmonary macrophages were detected. Additional postmortem microscopic, microbiologic, and toxicologic studies were unrevealing. Vitreous glucose levels were not obtained due to insufficient sample quantity. The cause of death was classified as sudden infant death syndrome (SIDS).

Two years after the first child’s death, the couple had moved to a different location, in a different police jurisdiction. A two-month-old male sibling was discovered by the father not breathing. Emergency medical personnel arrived to find the child unresponsive and pulseless on the sofa, with the father, again the sole caregiver, pointing toward the child without attempting resuscitation. The local hospital documented a rectal temperature of 92.6° F approximately one-hour and ten minutes after the father claimed the child was last known to be alive. Autopsy revealed a developmentally normal child, with no injuries. Gross and microscopic examination did not reveal evidence of natural disease, although abundant hemosiderin-laden macrophages were detected in the lungs. Resuscitative attempts had been aggressive and puncture marks were in the bilateral femoral areas; however, no other sites suspicious for injection were noted at autopsy. Postmortem microbiology and metabolic screening were non-contributory. Toxicology for standard drugs of abuse, salicylate and acetaminophen was negative. Vitreous fluid was not obtained. Because of additional investigative information, a postmortem blood test for insulin and C-peptide was done. Although the ratio of insulin to C-peptide was suspicious for exogenous insulin injection, the relative postmortem stability of these compounds is not known.

After the second case was reported to the medical examiner office, a coordinated investigation into both of these cases was initiated, with re-evaluation of the first death. Following a comprehensive investigation, utilizing both correlative interpretations and essential interagency cooperation, the cause and manner of death in the initial case was changed to undetermined, while the second case was similarly left as undetermined. These cases illustrate several points to be considered in sequential child death investigations. First, multijurisdictional and multiagency coordination was crucial because the family moved into another police jurisdiction before the second death. Secondly, no suspicious circumstances came to light during initial investigation of the first child death. In retrospect, some red flags were evident and should have been detected with current investigative protocols. Third, interpretation and differential diagnostic implications of hemosiderin-laden pulmonary macrophages in infants will be briefly described. Finally, the difficulty of interpretation of postmortem insulin and C-peptide levels will be described. Limited experimental data obtained during attempted validation of this postmortem biochemical test will be presented.

SIDS, Insulin, Sequential Deaths

G100 Case Presentation: Infant Death Due to Epidermolysis Bullosa

Eugene L. Hart, MD, Bonita Fung, MD, Ana Lopez, MD, and Luis A. Sanchez, MD, Harris County Medical Examiner's Office, 1885 Old Spanish Trail, Houston, TX 77054-2098*

The goal of this presentation is to acquaint the forensic community with the manifestations of epidermolysis bullosa, so that they might include this disease process in their differential when confronted with similar infant deaths.

When confronted with an infant death, this presentation will impact the forensic community and/or humanity by demonstrating the importance for the forensic staff to consider the possibility of a natural disease process with manifestations that could mimic traumatic injuries. The skin lesions of epidermolysis could be mistaken for thermal injuries if a thorough history is not available, and if the possibility of a disease is not considered.

This presentation reviews a case of death caused by complications of epidermolysis bullosa in a 17-month-old Asian infant. This child began to form skin bullae in the diaper area days after birth; these soon spread to include the extremities and face. A biopsy-proven diagnosis of epidermolysis bullosa simplex (Dowling-Meara subtype) was given at age 2 months. Mucosal involvement became apparent when white plaques were noticed in the oral cavity. Recurrent reflux hindered feeding, and resulted in a lack of adequate weight gain. Persistent respiratory difficulties necessitated tracheostomy tube placement at the age of 4 months. The tracheostomy site soon became infected; although treated, a mucoid discharge, on occasion culture-positive for *Staphylococcus aureus* and *Pseudomonas aeruginosa*, continued to drain from the tracheostomy site. A gastrostomy tube was placed at the age of 5 months, due to the child's difficulty swallowing. By his seventeenth month of life, the child's condition had seemed to stabilize and even slightly improve, when, one afternoon, he was found gasping for air; when the father attempted to suction the tracheostomy site, the child stopped breathing. An ambulance transported the child to a nearby hospital, where he was pronounced dead.

An autopsy was performed by the medical examiner's office. The small-for-age body had numerous scattered skin lesions, ranging from unruptured, thin-roofed bullae containing clear fluid, to superficial, red, weeping erosions, to red-brown, dried erosions with a crusted base. The teeth were dysplastic. The fingernails and toenails were absent; the nailbeds had erosions. The oropharyngeal and laryngeal mucosae were markedly edematous, with multifocal ulceration, scarring, and stenosis. The trachea and mainstem bronchi had superficial mucosal erosions as well. Hematoxylin-eosin stained sections of these mucosal erosions had extensive chronic inflammation and submucosal fibrosis. Sections of lung parenchyma had mucus plugs in scattered bronchioles. There was no evidence of trauma. The cause of death was listed as: "Complications of epidermolysis bullosa."

Epidermolysis bullosa is a group of rare genetic disorders that result in fragile epithelium that splits and blisters when subjected to minor trauma. Subtypes are classified by the level of the disrupted epithelium or by genetic basis in newer classifications. Epidermolysis bullosa simplex, due to mutations in genes forming keratins, results in splitting within the superficial layers of the epidermis. Junctional epidermolysis bullosa is due to mutations in genes forming hemidesmosomes or anchoring filaments, and results in separation of the basal cell layer from the basement membrane. Dystrophic epidermolysis bullosa is a result of mutation of the gene forming type VII collagen, and causes separation of the epidermis from the underlying dermis. These disorders range from mild to lethal, and can present at birth or later in life.

When presented with an infant death, it is important for the forensic staff to consider the possibility of a natural disease process with manifestations that could mimic traumatic injuries. The skin lesions of epidermolysis bullosa could be mistaken for thermal injuries if a thorough history is not available, and if the possibility of a disease process is not considered.

Epidermolysis Bullosa, EB, Epidermolysis Bullosa Simplex

G101 Child Abuse by Another Child: Can it Happen?

Darinka Mileusnic-Polchan, MD, PhD, University of Tennessee Medical Center; Knox County Medical Examiner's Office, 1924 Alcoa Highway, Knoxville, TN 37920; and Sharon O'Connor, Cook County Office of the Medical Examiner, 2121 West Harrison Street, Chicago, IL 60612*

The goal of this presentation is to recognize and appreciate child abuse by another child as a special entity with far reaching professional, ethical, and social consequences.

This presentation will impact the forensic community and/or humanity by demonstrating how child abuse by another child is an extremely rare occurrence; however, when it happens it should be promptly recognized. To assure proper handling of these distressing cases in an efficient and sensible manner, team work of all involved investigators, pathologists, clinicians, and social workers appears to be of paramount importance.

In this presentation the authors describe a rare and unusual variant of child abuse in which the investigation focused on ruling out a preschool child as the perpetrator. The first part of the presentation outlines the investigative process, highlighting the importance of the alternative approach to examination and specific methods during the inquiry of the suspects. Following that the authors discuss autopsy findings such as the complex nature of the injuries and particularly the peculiar ocular involvement. Correlation between the pathology and proposed mechanism(s) of injury is emphasized.

Secondly, ethical, social, and professional issues concerning all involved parties in this daunting and disturbing case are analyzed. Differing opinions and crucial disagreements among child abuse experts regarding workup and findings in this case are disconcerting. These fundamental differences might reflect to a certain extent doubts and emerging crises that are becoming increasingly apparent in the child abuse field. In the end the authors analyze these issues in terms of outcome and follow-up of this tragic event.

Blunt Force Injuries, Retinal Hemorrhage, Social Services

G102 Acute Pancreatitis in a 2½-Year-Old Child: A Fatal Therapeutic Complication of Polyethylene Glycol (PEG)-L-Asparaginase

Cristin M. Rolf, MD, and Heather Worne, BS, University of Kentucky, Department of Pathology and Laboratory Medicine/ Office of the Associate Chief Medical Examiner, Kentucky Justice and Public Safety Cabinet, 100 Sower Boulevard, Suite 202, Frankfort, KY 40601-8272*

The goal of this presentation is to present to the forensic community a case report and review of an unusual cause of acute pancreatitis. The authors discuss therapeutic effects and complications of the administration of PEG-asparaginase as a chemotherapeutic agent.

This presentation will impact the forensic community and/or humanity by heightening awareness in the forensic community of an unusual cause of acute pancreatitis, stressing the importance of gathering health history in a patient diagnosed with acute pancreatitis, and informing the medical community of this possible complication of the use of PEG-asparaginase and to raise the index of suspicion so that preventative measures may be applied.

This presentation consists of a case study of a female toddler who died suddenly from acute pancreatitis, a complication of chemotherapeutic intervention for Acute Lymphoblastic Leukemia (ALL). The authors review the pathogenesis, incidence, and diagnostic workup of PEG-L-asparaginase-induced acute pancreatitis.

A 2 ½-year-old white female was diagnosed with ALL after the onset of easy bruising, nosebleeds, and lower leg (shin) pain. Induction therapy consisted of an antineoplastic and palliative regimen of vincristine, dexamethasone, pegaspargase (PEG), cytarabine, and methotrexate. Remission was induced as the blast counts, which initially ranged from 10 to 14% on peripheral smear, became essentially absent. The therapy was complicated by hypertension and sinus bradycardia, which prompted treatment with enalapril, an angiotensin-converting enzyme inhibitor. The symptoms resolved by discharge. For approximately one week thereafter, the patient's blood count remained free of leukemic cells. Approximately two weeks post induction chemotherapy, the patient developed abdominal pain without fever. The patient's mother attributed two episodes of vomiting to dexamethasone prescribed to the patient. On the morning of death her mother administered an over-the-counter oral stomach remedy and reported that the toddler had difficulty breathing. The emergency medical service was notified and transported the patient to the hospital where, despite aggressive resuscitation attempts she was pronounced dead in the emergency department.

Due to the sudden and clinically unexpected nature of the patient's death while in apparent remission, an autopsy was requested by the local coroner. At autopsy the body was that of a normal but pale female child with no congenital anomalies. Internal examination exhibited hemorrhagic ascites with petechiae of the small bowel mesentery and omentum. The pancreatic tail was enlarged and violaceous. Microscopical examination revealed multifocal necrosis, hemorrhage, and acute inflammatory cellular infiltrates in the pancreatic parenchyma. Inflammation extended to the peripancreatic fat, small intestine and appendiceal wall. Other findings included hepatic steatosis and a focal intraluminal thrombus in a pulmonary artery of the right lower lobe. Histopathological examination of the post-mortem bone marrow confirmed the presence of all three hematopoietic cell lines, but severe autolytic change precluded unequivocal recognition of blasts. No gallstones, structural anomalies of the gastrointestinal tract, or other risk factors for pancreatitis were noted. The cause of death was ascribed to acute hemorrhagic pancreatitis with the contributing factor of ALL, status post chemotherapeutic intervention (PEG-asparaginase).

Asparaginase is an enzyme manufactured by certain bacteria, plants and animals. *Escherichia coli* bacteria supply asparaginase used for medical purposes. Asparaginase catalyzes the hydrolysis of the amino acid, asparagine, to aspartic acid. Neoplastic cells, especially those of ALL, have low levels of asparagine synthetase. For this reason they fail to produce sufficient asparagine to survive and require an exogenous source of the amino acid. Asparaginase, a chemotherapeutic agent for ALL, eliminates exogenous asparagine by hydrolyzing serum asparagine into nonfunctional aspartic acid and ammonia. Asparagine is needed by ALL cells to build proteins for cellular structure and enzymes. Documented complications of asparaginase include allergic reactions, chemical hepatotoxicity, thromboembolic coagulopathies, hyperglycemia, and acute pancreatitis. Clinical acute pancreatitis is noted in about 1% of patients receiving asparaginase, and rarely results in death.

Asparaginase is used in several forms in conjunction with other chemotherapeutic agents to combat ALL. The L-asparaginase form produced by *E. coli* has been reported to have a lower rate of acute pancreatitis than that of asparaginase alone. In an effort to reduce the incidence of immunogenicity, polyethylene glycol (PEG) is added to L-asparaginase.

PEG-asparaginase therapy is a known cause of acute pancreatitis in the absence of other risk factors. The implications for the patient can be serious: in rare instances significant morbidity and, as this case study demonstrates, even mortality may occur. Acute pancreatitis must be considered in the differential diagnosis of gastrointestinal symptoms in the leukemic patient treated with PEG-asparaginase.

Fatal Acute Pancreatitis, PEG-asparaginase, Acute Lymphoblastic Leukemia

G103 Increased Risk of Sudden Infant Death Syndrome (SIDS) Among Infants Harboring the Apolipoprotein E-4 Allele: Genetic and Pathologic Similarities to Alzheimer's Disease (AD)

D. Larry Sparks, PhD*, Sun Health Research Institute, 10515 West Santa Fe Drive, Sun City, AZ 85351; Rob Friedland, MD, Bob Petersen, PhD, Ellen Grady, MS, and Sandra Richardson, PhD, Case Western Reserve University, 10900 Euclid Avenue, Cleveland, OH 44106; and Cristin M. Rolf, MD, and John C. Hunsaker III, MD, JD, Division of Medical Examiner Services, Kentucky Justice and Public Safety Cabinet, 100 Sower Boulevard, Suite 202, Frankfort, KY 40601-8272

After attending this presentation, attendees will learn that there is increased apoptotic neurodegeneration in SIDS, which may constitute the proximate cause of death, and that similar to AD, the risk of SIDS may be enhanced among those individuals harboring the Apolipoprotein E-4 allele.

Because of the 96% incidence of increased numbers of Alz-50 immunoreactive neurons in SIDS, this microscopic feature may be useful in establishing the criteria for an objective diagnosis, if convincingly confirmed. This presentation will impact the forensic community and/or humanity by providing direction for future investigation, along the lines of altered cholesterol metabolism in SIDS, and the relationship between the severity of Alz-50 pathology and dose of the ApoE-4 allele.

Introduction: A number of studies suggest a neuropathologic overlap between Sudden Infant Death Syndrome (SIDS) and the dementing disorder Alzheimer's disease (AD). AD is a neurodegenerative disease characterized by the pathologic presence of neurofibrillary tangles and accumulation of the peptide β -amyloid, predominantly in the temporal cortex and hippocampus. Pre-tangles (early form of the neurofibrillary tangle) and degenerating neurons in AD and increased numbers of neurons in SIDS medulla and temporal cortex are reactive with Alz-50 antibody compared to respective control populations. Likewise, increased levels of the neurotoxin β -amyloid are uniformly present in AD brain and have been observed in the temporal lobe of many SIDS infants. Studies of non-demented individuals with coronary artery disease (CAD) suggest that Alz-50 immunoreactive neurons occur in advance of AD-like β -amyloid accumulation. An increased risk of developing AD is associated with increased frequency of the Apolipoprotein E-4 (ApoE-4) genotype. Three ApoE alleles taken two at a time are possible (2/2, 2/3, 3/3, 2/4, 3/4 and 4/4). Likewise, there is an increased risk of CAD if an individual retains the ApoE-4 genotype, reportedly because of associated elevations in circulating cholesterol levels. Elevated circulating cholesterol is prevalent in AD and cholesterol is emerging as a factor promoting production of β -amyloid in the disorder. Furthermore, CAD in early life increases the risk of developing AD.

Scientific Objectives: (1) Determine if there is increased prevalence of the ApoE-4 genotype among infants dying of SIDS compared to age-matched infants dying of known causes; (2) Provide previously published data indicating that Alz-50 antibody highlights neurons undergoing apoptosis; (3) Demonstrate that there are significantly increased numbers of Alz-50 immunoreactive neurons throughout the length of the respiratory nuclei in the medulla of SIDS infants, thus suggesting that neurodegeneration may underlie the cause of SIDS.

Methods: The authors investigated 115 infants > 4 weeks of age and < 12 months of age (81 SIDS and 34 non-SIDS) for ApoE genotype. The cause of death was diagnosed using 1991 NICHD criteria for SIDS and standard protocols for known causes (non-SIDS). ApoE-4 genotype was evaluated in brain tissue using real-time PCR methods. Temporal cortex and medulla from a subset of these infants were evaluated for Alz-50 immunoreactive neurons in 50 μ m vibratome sections. Some sections were

counterstained for condensed DNA (apoptotic bodies) with propidium iodide subsequent to Alz-50 immunohistochemistry and RNAase treatment (to degrade all RNA).

Results: The mean age at death was 94.5 ± 7.8 days among infants with the E-4 allele and 93.2 ± 12.4 days among infants without the E-4 allele. The ApoE-4 allele occurred in 29.95% of the infant population and was absent in 70.15% of the infants. The ApoE-4 allele frequency was increased in SIDS (16.75%) compared to infants dying of known causes (7.6%); this difference was significant using the Armitage's trend test ($P < 0.05$) and marginally significant ($P = 0.086$) using a linear-by-linear chi square assessment. There was a 2.2-fold increased risk of SIDS (OR, 0.76 – 6.46) if an infant harbored the ApoE-4 allele.

Ninety-six percent of SIDS infants exhibit significantly greater numbers of Alz-50 immunoreactive neurons in temporal lobe and throughout the extent of, and exclusively in the dorsal and ventral respiratory nuclei and the reticular activating nuclei of, the dorsal medulla. Essentially all Alz-50 immunoreactive neurons in SIDS brain exhibit condensed bodies of DNA stained by propidium iodide (apoptotic bodies). Such apoptotic bodies were confined to the nuclear envelope and did not occur in the absence of an Alz-50 immunoreactive neuron.

Discussion: There is a greater than 2-fold increase in the ApoE-4 allele frequency among infants dying of SIDS compared to age-matched infants dying of known causes. This is similar to the just over 2-fold increase in the ApoE-4 genotype among individuals with AD compared to age-matched non-demented non-heart disease controls. This genetic difference in SIDS is concomitant with a marked increase in features suggestive of early AD neuropathology. Because of the anatomic link between the location of enhanced apoptosis in the medulla and control of involuntary respiration and arousal from sleep, SIDS may be a neurodegenerative disorder of infancy. Future multi-site studies will be required to confirm this possibility. Due to the link between ApoE genotype and cholesterol metabolism, investigation of cholesterol levels in SIDS brains and circulation may be fruitful.

Conclusions: SIDS may be the AD of infancy, and as in AD, the influence of ApoE genotype may contribute to the severity of neuropathology in SIDS.

SIDS, Alzheimers-Like Neuropathology, Apolipoprotein E Genotype

G104 Ano-Genital Findings in Sexually Abused Children in Cases With a Conviction

Lene Aagaard Nielsen, MD, and Soren J. Mikkelsen, MD, Children and Adolescent Psychiatric Hospital, University Hospital of Aarhus, 66 H. Selmersvej, Risskov, DK-8000, Denmark; and Annie Vesterby, MD, DMSci*, Department of Forensic Medicine, University of Aarhus, Children and Adolescent Psychiatric Hospital of Aarhus, P. Sabroes Gade 15, Aarhus, DK-8000, Denmark

After attending this presentation, attendees will understand that ano-genital findings at colposcopic examination are not major determinants for conviction at court.

This presentation will impact the forensic community and/or humanity by assisting professionals in understanding that specific physical findings of the ano-genital area are seldom found in sexually abused children; the history told by the child remains paramount in cases of sexual abuse.

The department of Forensic Medicine, Aarhus, Jutland, Denmark, performs, at the request of the police, colposcopic examinations of children suspected to be sexually abused. Included in the research during the period from January 1, 1996 to September 1, 2002, were 482 children, giving an incidence of 1,48/ 10,000 children from birth to 16 years of age in Jutland, Denmark. This study includes those cases in which the perpetrators were convicted at court because of substantial evidence of sexual abuse of the child.

Results: One Hundred sixty-five perpetrators were convicted at court, involving 149 girls and 11 boys, with a median victim age of 13.5 years for boys and 10.6 years for girls (range 0-15 years of age). Forty-one children reported touching of genitals; 22 attempts of vaginal, anal, or oral penetration, 21 vaginal penetration; 5 anal penetration; 10 fellatio; and 33 a combination of the above (the rest were other or unknown). Twelve children were examined within 24 hours after the last sexual assault, 36 within a week and the rest more than a week later.

Colposcopic findings: Sixty-one girls had normal internal genital findings (vagina, hymen, vestibulum, labia minor). Ninety-one had abnormal findings, all non-specific findings except for 10 who had lesions. One hundred thirty-three had normal external genital findings (labia majora, perineum, perianal area). Fifteen girls had abnormal external genitals, of which six were lesions of the labia majora or/and perineum. Two boys had abnormal but non-specific findings of the penis and four of the anus. Abnormal findings of the anus were found in 22 girls; of the abnormal anal findings, seven were lesions. Thirty girls had an incomplete cleft of the hymen, but only eight were complete posterior clefts.

Abnormal ano-genital findings were not significantly correlated to conviction at court; however, the age of the child was.

Conclusion: The history from the child, not physical findings, remains the single most important feature in cases of sexual abuse.

Child Sexual Abuse, Colposcopic Examination, Conviction at Court

G105 The Contribution of Computerized Image Analysis to the Diagnosis of Munchausen Syndrome by Proxy

Beat Horisberger, MD*, and Patrice Mangin, MD, PhD, Institute of Legal Medicine, University of Lausanne, Rue du Bugnon 21, Lausanne, 1005, Switzerland

After attending this presentation, attendees will understand the difficulty in diagnosing child abuse, in particular Munchausen syndrome by proxy, and understand the advantages of computerized image analysis for child abuse diagnosis.

This presentation will impact the forensic community and/or humanity by demonstrating the use of new technologies, such as computerized image analysis, when child abuse is suspected

Munchausen syndrome by proxy cannot be diagnosed by objective means unless the perpetrator is caught in flagrante delicto (such as when using video surveillance). A psychiatric report on its own does not constitute sufficient proof for such a diagnosis. The authors present a case that shows how new diagnostic means may be useful in the practice of clinical forensic medicine in general, and in the case of the Munchausen syndrome by proxy in particular.

The case concerns a female infant with a past history of hematomas described as "spontaneous" by the pediatricians. The investigation started when the infant, aged three months, was admitted to the hospital for a fracture of the skull, thought to be accidental on the basis of the initial findings. A clinical forensic examination and forensic diaphanscopy casted serious doubt on the accidental version of the fracture of the skull. Multiple hematomas, invisible to the naked eye, were also revealed, leading to complementary medical imaging analyses. As investigations proceeded, evidence supporting the hypothesis of infant abuse was mounting. In spite of the authors' negative recommendation, the hospital physicians allowed the mother to take the child home for the weekend. On Sunday night, the mother brought the child back for emergency hospitalization. The infant

presented with numerous petechiae on her head, with the exception of two areas: a digitiform zone on the scalp and a triangular zone in the nasobuccal region. Petechiae were also present on the upper part of the thorax and at the basis of the upper limbs. A number of hematomas, invisible to the naked eye, were revealed by forensic diaphanoscopy on the anterior side of the thorax. The lesional picture was consistent with a thoracic compression leading to the obstruction of the respiratory tract, in the context of an attempted asphyxia.

A key issue remained: who was the perpetrator of this child abuse?

The answer was provided using computerized analysis of the images obtained from the digitiform lesion on the infant's scalp and the mother's and father's fingers. The mother was identified as the perpetrator of the acts using objective criteria, in the particular context of Munchausen syndrome by proxy.

Child Abuse, Computerized Image Analysis, Munchausen Syndrome by Proxy

Pathology/Biology

G1 Penetrating Wound of Head by Slingshot: Medicolegal Aspects

*Bhanwar Lal Bhootra, MD**, Forensic Pathology Services, Limpopo Province, PO Box 1944, Polokwane, 0700, South Africa

After attending this presentation, attendees will understand the occurrence of medicolegal problems when medical doctor conducts incomplete/improper examination of head wound; and understand the consequences of negligent conduct of doctor during trial.

This case of slingshot intracranial head injury is very unusual. Attention of medical officers is once again drawn to the medicolegal problems that can be caused by the improper/incomplete examination of wound.

The author autopsied an unusual case of penetrating wound of head by slingshot (piece of stone).

The case was initially discharged from casualty after stitching the head wound. The patient died at home of intracranial infection. Autopsy revealed a skull fracture and intracranial stone piece.

This case highlights that no head injury should be ignored as trivial injury. Careful examination of the wound could have prevented a fatality and possible medico-legal problems.

Head Injury, Slingshot, Homicide

G2 Suicide by Hanging in Children

Ziadi Arbia and Chadly Ali, MD, Department of Forensic Medicine, University Hospital Fattouma Bourguiba, Monastir, 5000, Tunisia*

After attending this presentation, attendees will consider cases of hanging in children and the consequences of suicide in children.

Death from hanging is common in suicide youth. There's no large series dealing with such a death but numbers communicated even though small are significant.

Aim: we aimed to examine the epidemiology and pathology findings of 16 cases of suicide from hanging in children and suggest prevention.

Material and Methods: we considered cases of suicidal death from hanging in children referred to the department of forensic medicine of the university hospital Fattouma Bourguiba of Monastir from 1991 to 2002.

Sixteen cases of children committed suicide by hanging were reported. These cases were preceded by age, gender, manner of death, past history, surrounding circumstances and pathology findings.

Results: the 16 children were found dead. The age range was 11 to 17. The greatest share of suicide was found in the age of 17. The majority was males (15/16). Rope for ligature was more common, string was used in 2 cases. A previous suicide attempt was reported in 1 case. Two cases were with a borderline personality and one case was with a medical history of juvenile diabetes. In 14 cases, hanging occurred within the decedent's home. We couldn't provide a statistic valid seasonal risk. However afternoon seems to be the most chosen time for hanging (10/16). Complete suspension was seen in all cases. Most of children were from rural areas.

The autopsy showed usual external injuries of asphyxial death. No injuries of the larynx or trachea were reported. Contusion hemorrhage of neck muscles was found. Petechial hemorrhage was not seen.

Conclusion: death from hanging in children is rare. Our report is a contribution to several series dealing with such a death. Prevention is possible in some cases by parental supervision and by providing education and mental health care to adolescent. It's important to carry out prospective studies in order to determine the specific character of such occurrence, so we can provide a specific prevention measures.

Suicide, Death From Hanging, Children

G3 The Effects of Liquid Bleach on Pig Decomposition in Southeastern Pennsylvania

Lauren E. Way and John R. Wallace, PhD, Department of Biology, Millersville University, PO Box 1002, Millersville, PA 17551*

After attending this presentation, the participant will understand the effect of liquid bleach on carrion decomposition. This poster has two objectives to compare the rate of decomposition in pigs treated with and without bleach; and demonstrate the importance of understanding the impact chemicals have on corpses for criminal investigative purposes.

This study demonstrates that an easily accessible and common household chemical such as bleach can significantly influence decomposition rates and postmortem interval (PMI), leading to the possible incorrect estimate in the time of death of a victim.

Suspected use of bleach on the victim in a recent homicide trial in San Diego, CA, led the prosecutor to question if bleach on a body would affect a flies reproductive cycle. This case not only exemplified how forensic entomologists were unable to corroborate estimations of a post-mortem interval (PMI), but also how the effect of such chemicals may influence arthropod colonization and utilization (if any) of a corpse, thus affecting PMI estimations.

To date, empirical studies published on the effect of controlled substances and other chemicals such as pesticides, have examined the effect on particular insects and provided logical implications of the potential impact on a PMI estimate. However, few field studies exist on how decomposition is influenced by any chemical substance. We hypothesized that the topical application via dousing of common household bleach would negatively impact insect colonization of pig carcasses directly, and indirectly slow decomposition.

The objective for our first experiment was to determine the effect of bleach on pig decomposition. In two later experiments we are comparing decomposition rates between habitats, each with and without bleach treatments, and determining the rate of degradation of bleach between habitats. Stillborn pig carcasses were used in this study. Control pigs (n=3/habitat), i.e., not treated with bleach and experimental pigs (n=3/habitat), i.e., treated topically with a dousing (≈ 4 liters) of Ultra Clorox® liquid bleach, were placed onto individual plastic trays inside separate animal Have-a-Hart® cages. In experiment 1, all cages were placed in an open field exposed to full sunlight. For experiment 2 and 3, cages will be placed in an open field (full sun light) and a wooded area (complete shade). Temperature probes (Tidbits®) were inserted into two pigs, 1 control and 1 doused, to monitor internal temperatures. Daily temperatures were recorded from a local weather station and a max/min thermometer located in the open field. Temperature data was used to determine degree-day totals for each habitat. The pigs were observed daily to record physical changes in decomposition. The pigs were weighed to the nearest gram to monitor percent weight loss. Dead/live insects were sampled from the pigs on days 2, 7, 14, 21, and 28 and preserved for identification.

Five stages of decomposition were easily distinguishable for the control and doused or bleach treated pig: fresh, bloat, decay, post-decay, and dry. The use of bleach appeared to affect the physical aspects of decomposition. Decomposition in the control pig progressed from the fresh to dry stage in 11 days. Preliminary results showed that bleach dousing slowed decomposition of pigs by 7 days. Insect colonization on experimental pigs was similar to control pigs, however insect feeding was negatively impacted through observations of dead maggots and a recolonization period on day 10.

The rate of decomposition as a function of weight loss was most rapid for the control pig. Decomposition rates for pigs treated with bleach tended to be similar initially but slowed overtime possibly due to decreased insect activity. Accumulated degree-days estimates were less for control pigs and significantly greater for pigs treated with bleach in full sunlight.

Results from the first experiment focused on the first objective of our study, the effect of bleach on pig decomposition. These results show that decomposition was slowed by the presence of bleach on the pigs. Our preliminary evidence suggests that decomposition and lack of insect activity may influence PMI estimations when bleach is topically applied to a corpse. We are currently conducting two additional experiments to examine the effects of habitat on the rate of decomposition, as well as extraction and detection techniques of bleach from carrion flesh.

Forensic Entomology, Bleach, Postmortem Interval

G4 The Use of Whole Body Donors in Forensic Research

Charlotte A. Wacker, MS and Brandi J. Schmitt, MS, University of California, One Shields Avenue, 3301 Tupper Hall, Davis, CA 95616*

After attending this presentation, the attendees will learn how whole body donors can facilitate research in forensic science.

Whole body donors are used everyday for the advancement of medical research and education. These studies include, but are not limited to, surgical trials, biomechanical research, and emergency procedures, as well as the academics of anatomy as it is taught through dissection. On the contrary, research in forensic science is generally prompted by current casework and is performed as a byproduct of an investigation. It is important to note that the use of whole body donors for studies could help answer questions before cases even occur. Many fields within the realm of forensic science can benefit from these altruists in our society. Included are the disciplines of forensic entomology, odontology, pathology, biology, anthropology, and toxicology and can extend into aspects of the physical sciences as well.

One location has facilitated human donor studies important to the associated fields. However, they are conducted in a manner that is specific for the climate, flora and fauna of that area. In other areas, decomposition studies and the like have been performed with the use of porcine materials as a substitute for human materials. These studies are not reported here as invalid, but in order to apply the most appropriate and applicable science to matters of evidence, it is imperative that the most realistic methods and materials are used. Recognizably, the diversity of these United States requires the application of continuous studies to varied geographical areas and academic disciplines to achieve the best and most accurate results.

Thousands of people each year become donors to the 112 university sanctioned whole body donation programs throughout the U.S. The lack of research is not due to the unavailability of human specimens, but is a result of low numbers of requests by appropriate researchers. This may be attributed to the idea that many researchers are just not aware of the possibilities that exist for their projects. Questions regarding the ethical uses of whole bodies for science may further reduce the use of human remains by forensic researchers. It is the intention of the writers to provide a comprehensive presentation of the utilization of whole body donors to facilitate forensic research in the most appropriate manner possible.

Whole Body Donor, Forensic Research, Forensic Science

G5 Pediatric Homicides Related to Burn Injury

William F. Zaloga, DO, Wake Forest University Baptist Medical Center, Department of Pathology, Medical Center Drive, Winston-Salem, NC 27157; Kimberly A. Collins, MD, Medical University of South Carolina, 171 Ashley Avenue, Charleston, SC 29425*

After attending this presentation, attendees will be able to assign manner of death with more confidence in pediatric homicides related to burn injury.

This presentation will impact the forensic community and/or humanity by adding to and supporting the current literature of pediatric burn related homicides.

Burn related injuries and fatalities are usually thermal but may be placed into six categories: fire (including smoke inhalation injuries), scald, contact with a hot object, electrical, chemical, and ultraviolet radiation (sun). Many injuries are mistakenly referred to as "accidents" because they occur suddenly and are seen as unpredictable and uncontrollable; however, injuries often occur in predictable patterns.

We reviewed all forensic cases referred to the Medical University of South Carolina Forensic Pathology Section over the 28-year period from January 1975 through December 2002. All cases with victims 17 years of age and younger were analyzed and included in the study. We examined the age, sex, and race of the victims; type of burn injury; reported location; time of year; cause and manner of death; scene history; any perpetrator; injury-death time interval; and the autopsy and toxicology findings.

In our study there were 124 cases of pediatric burn related fatalities. The ages ranged from 6 months to 17 years. Categorized, the cases were 121 fire related fatalities (97%, 1 fire due to high voltage electrocution), and 3 scald fatalities. There were no burn related fatalities from contact with hot objects, chemicals, or ultraviolet radiation. Ninety of the burn related fatalities were in the 0-5 year age group (73%), with a peak (29 cases) in the 2 year age group.

The manner of the burn related deaths was also analyzed with 108 accidents, 12 homicides, and 4 undetermined. No cases were classified as suicide. Eleven of 12 burn-related homicides also occurred at the home (9 of 12 fire related and 3 of 12 scalds) with all of the victims in the 1-8 year age group. The perpetrator of the arsons was the mother in 5 cases, the sister in 1 case, and undetermined in 2 cases. Homicide involved a car fire in 1 case in which the father caused an explosion with an accelerant. The scald death perpetrators were the father, mother's boyfriend, and an aunt.

This retrospective study and review of the literature may reveal patterns useful for evaluation of manner of death. By recognizing scene characteristics, potential perpetrators, and children at risk we can better classify pediatric burn related fatalities.

Pediatric, Burns, Homicide

G6 Insect Succession Studies on Pig Carrion in Southwest Virginia and the Effects of Antemortem Ethanol Ingestion on Insect Succession and Development

Kimberly L. Tabor, BA, MS, Richard D. Fell, PhD, and Carlyle C. Brewster, PhD, Virginia Tech, 216 Price Hall, Blacksburg, VA 24061; Kevin Pelzer, DVM, Virginia Tech School of Veterinary Medicine, Blacksburg, VA 24061; George S. Behonick, PhD, Department of Criminal Justice Services, Division of Forensic Sciences, 6600 Northside High School Road, Roanoke, VA 24019*

The goal of this presentation is to present the results of the effects of antemortem ethanol ingestion on insect development patterns on pig

carrion; and to present the results of insect succession studies performed on pig carcasses during different seasons over a two year period.

This presentation will impact the forensic community and/or humanity by presenting research which describes an interdisciplinary animal model, incorporating the expertise of forensic entomology and forensic toxicology, in characterizing factors that may or may not influence the succession and development of insect taxa on postmortem remains. As a collateral forthcoming project, the model will provide the means to investigate the feasibility of using biochemical markers of ethanol consumption (fatty acid ethyl esters) in discerning antemortem ingestion of ethanol from postmortem neo-formation during decomposition.

Learning Objective: one method of estimating the postmortem interval (PMI) uses results from studies on the faunal progression or succession patterns of carrion arthropods. The pattern of insect succession is specific to the location and environmental conditions in which a carcass occurs. Because taxa can vary greatly with locale, particularly at the species level, it is important to identify the forensically important insects that are specific to an area. To date, no such data have been published for the southwest Virginia region. It is possible that factors such as antemortem ingestion of ethanol or drugs can affect succession patterns and insect development rates, thereby rendering a PMI estimation based on insect evidence inaccurate.

Succession studies were performed over three seasons for two years using untreated pig carrion. Over 57 insect taxa were collected and identified. An occurrence matrix showing dominant species on a seasonal basis is presented.

In an additional study, two pigs (weighing 57 and 66 kg) were intravenously dosed with a mixture of 95% ethanol and saline using an intravenous catheter inserted into an ear vein and by oral gavage. Two untreated pigs of similar weight (53 and 49 kg) were used as controls. Antemortem blood samples were collected from both groups 15 minutes following delivery of ethanol to the treated animals. Euthanasia immediately followed the collection of blood samples. Loin meat was removed from each carcass to be used as a rearing medium for field development studies of the black blow fly, *Phormia regina*. The carcasses were placed under cages in a partially wooded field within one hour of death. Insects were collected and an occurrence matrix was developed. Results of the succession studies indicate no differences in the insect taxa collected from ethanol-treated versus control pigs. Decomposition rates were similar for all animals.

All four carcasses were necropsied in the field two days post-mortem. Blood, tissue and maggot homogenate specimens were analyzed for ethanol by headspace gas chromatography (HSGC) utilizing a HP 7694 HS Sampler configured to an AgilentGC-6890 PlusTM with a flame ionization detector (FID). The column was a Restek Rtx-BAC1TM and the internal standard utilized was n-propanol. Total run time was four minutes. The limit of quantitation (LOQ) is 0.01%.

For the development studies, *P. regina* egg clusters were collected from carcasses and placed in rearing cups containing pieces of loin meat from either treated or control pigs (n=6 each). The rearing cups were kept outdoors to monitor development under natural conditions. Temperature and relative humidity were recorded at the site using HOBO[®] data loggers. Following egg hatch, six maggots were removed from each rearing cup every eight hours until pupation. Size and larval stage were recorded for each sample interval. The time from pupation until adult emergence was also determined. Preliminary data indicate no difference in development on meat from ethanol-treated versus control animals. However, the concentration of ethanol in the loin meat of treated animals (0.07%) was only slightly higher than that of controls (ND). Additional *in vitro* studies using meat fortified with higher concentrations of ethanol are being conducted to determine if alcohol can affect maggot development.

An ethanol vitreous humor concentration of 0.14% was obtained for one animal (No. 2) and the loin ethanol concentrations (No. 1 and 2)

of 0.07% suggest distribution within the pig model similar to that encountered in the vitreous and skeletal muscle of humans. The experimental paradigm seems to provide a reasonably comparable model to human postmortem tissues and fluids for elucidating the influence or effect of antemortem ingestion of ethanol on insect succession and development. The postmortem blood ethanol determinations in animals 3 and 4 are consistent with postmortem neo-formation encountered in decomposition. Maggot specimens analyzed as homogenates obtained from animals 1 and 2 had higher ethanol concentrations when compared to the control, untreated animals (No. 3 and No. 4). The low ethanol concentrations observed in the control animal maggot specimens are possibly the result of postmortem neo-formation during decomposition or being a metabolic by-product attributed to maggot and bacterial interaction. Additional data from a second experiment, derived from serial collection of maggot masses over a period of five days, from ethanol-treated and control animals is provided in the poster.

ETHANOL RESULTS-% (WEIGHT BY VOLUME)

Animal No.	Antemortem	Postmortem	Loin	Maggots
	Blood	Blood		
1	0.14	0.11	0.07	0.06
2	0.16	0.10	0.07	0.04
3	ND	0.02	ND	0.02
4	ND	0.01	ND	0.02

Animals 1&2 ethanol-treated

Animals 3&4 non-treated controls

ND indicates not detected

The research describes an interdisciplinary animal model, incorporating the expertise of forensic entomology and forensic toxicology, in characterizing factors that may or may not influence the succession and development of insect taxa on postmortem remains. As a collateral forthcoming project, the model will provide the means to investigate the feasibility of using biochemical markers of ethanol consumption (fatty acid ethyl esters) in discerning antemortem ingestion of ethanol from postmortem neo-formation during decomposition. (The Virginia Tech Animal Care Committee approved this study).

Forensic Entomology, Ethanol, Maggots

G7 The Detection of Saliva: Factors Affecting the Phadebas® Press and Tube Tests

Melissa S Kell, BSc, Wendy Lalonde, BSc, Roger Frappier, MSc, and Jonathan Newman, BSc, Centre of Forensic Sciences, 25 Grosvenor Street, Toronto, ON M7A 2G8, Canada*

The goal of this paper is to present to the forensic community, the findings from a study conducted to assess a test employed to detect saliva in forensic casework samples.

Forensic biologists will learn of the relative merits of the Phadebas test for the detection of amylase applied quantitatively as a Tube Test and semi-quantitatively as a Press Test.

It is often necessary for a forensic biologist to locate and identify saliva stains in casework. Not only is saliva important as a source of DNA, its presence in various circumstances can corroborate aspects of an account of a crime. Unlike blood, which is usually evident by visible, red-brown staining, often saliva does not contain any visible components, making the "stains" difficult to observe. Therefore, chemical methods are used to locate saliva stains.

At the Centre of Forensic Sciences, the localization and identification of saliva is determined using the Phadebas[®] Amylase Test (Pharmacia and Upjohn Diagnostics AB, Uppsala, Sweden). This assay

is used to detect the digestive enzyme α -amylase, which is found in high quantities in saliva. The test can be performed in two ways: the press test (Willott and Griffiths, 1980) and the tube test (Willott, 1974). In this study, three variables were assessed to determine their effects on both the press and tube tests: 1) the quantity of amylase in a person's saliva, 2) the type of substrate on which saliva is deposited, and 3) the mixing of saliva with a second body fluid, either blood or semen. A second aim of the study was to evaluate the effectiveness of both tests to determine if the tube test is always necessary to perform in addition to the press test, and to determine the required duration of the press test.

Neat and diluted saliva from thirty individuals was used to stain cotton. Ninety percent of the neat saliva stains were detected in less than 10 minutes using the press test, and all neat saliva stains had amylase activities greater than 0.03 International Units (IU) (Willott, 1974) using the tube test. Overall, the tube test showed higher sensitivity. Press and tube tests were then performed on stains made from saliva from individuals covering a range of amylase levels on the following substrates: cotton, polyester, a blend of 95% acrylic 5% spandex, silk, satin, corduroy, denim, and white S & S #903 filter paper (Schleicher & Schuell Bioscience). The press test could detect saliva more readily on thinner, less absorbent fabrics, while higher amylase activities were obtained with thicker fabrics using the tube test. Experimentation was also done to determine how the deposition of saliva in the presence of semen and blood affects the press and tube tests. Stains were made of saliva and either blood or semen in three different ways: 1) mixing prior to deposition, 2) depositing saliva, letting it dry then depositing the other body fluid on top, and 3) depositing the other body fluid first, letting it dry then depositing saliva on top. Semen did not interfere with the detection of saliva using the press or tube tests, regardless of the method of deposition. Blood did not interfere with the detection of saliva using the tube test, but when the press test was performed there were some instances where the result took longer to appear or did not appear within the 20-minute test period.

Overall, the press test is sufficient for detecting saliva stains in most cases if administered for 40 minutes. The limitations discussed must be considered when blood is present on the sample to be tested, or if the substrate fabric is heavy / thick (e.g., denim).

Saliva, Phadebas, Amylase

G8 Places to Commit Suicide

Istvan F. Szentmariay, MD*, Institute of Forensic Medicine, Semmelweis University, Ulloji UT 93, Budapest, H-1091, Hungary

NO ABSTRACT PROVIDED.

Suicide, Place of Death, Methods of Suicides

G9 Dramatic Rise in Methadone-Related Deaths in Oklahoma 1990-2002

Ronalod F. Distefano, DO*, Office of the Chief Medical Examiner, State of Oklahoma, 1115 West 17th Street, Tulsa, OK 74107

After attending this presentation, attendees will have awareness of dramatic increase in methadone-related deaths and potential explanation of why they occur. This trend is evolving nationwide and there is every expectation that it will continue.

This presentation will impact the forensic community and/or humanity by making the forensic community aware of the emerging epidemic of deaths related to this drug and the reasons for it. Unique aspects of its pharmacology interacting with ignorance of this by physicians, patients, and substance abusers have resulted in an emerging

tragedy. The forensic community needs to enlighten the broader community as part of its public health and public safety missions.

Deaths attributed to the toxic effects of methadone, alone or in combination with other drugs, have dramatically increased in the State of Oklahoma during the study period. Tabulation of these deaths on an annual basis from records of the Office of the Chief Medical Examiner of the State of Oklahoma demonstrates this trend. A comparison of deaths in the three-year period 1990–1992 versus 2000–2002 shows 7 versus 140 respectively. This parallels a dramatic rise in the prescribing of methadone in the state, particularly for the treatment of chronic pain. Possible rationales for this increase including unique aspects of the pharmacology of methadone are discussed.

Methadone, Deaths, Chronic Pain

G10 Fatal Botox®-Induced Anaphylaxis? A Case Report

Melissa Li, MD*, University of Florida College of Medicine, PO Box 100275, 1600 SW Archer Road, Gainesville, FL 32610-0275; Bruce A. Goldberger, PhD, University of Florida, PO Box 100275, Gainesville, FL 32610-0275; Carolyn Hopkins, MD, District 8 Medical Examiner's Office, 606 SW 3rd Avenue, Gainesville, FL 32601

After attending this presentation, attendees will learn about autopsy findings and laboratory diagnosis of anaphylactic reactions and the history and uses of Botox®.

This presentation will impact the forensic community and/or humanity by reporting on the first case of Botox® associated death; describing what kind of conditions Botox® is currently used for, and that it can possibly be a cause for anaphylaxis; and describing how to support the diagnosis of anaphylaxis.

Introduction: adverse drug reactions can occur with any therapeutic drug, with anaphylaxis being the most serious event. Botox (botulinum type A, Allergan Inc, Irvine, CA) is a relatively new drug that is FDA-approved for blepharospasm, strabismus, cervical dystonia and glabellar wrinkles. It is also used 'off label' for a variety of disorders such as chronic pain syndromes, hyperhidrosis, cosmesis, and achalasia. It has been touted as extremely safe and effective. To date, no deaths associated with Botox have been reported. We report the first case of anaphylaxis and death in a woman who received a mixture of Botox and lidocaine injections.

Case History: a 43-year-old woman who had chronic upper back pain presented at a rehabilitation clinic for a repeat set of Botox and lidocaine injections. Fourteen months previously, she had received her first set of Botox injections and obtained relief from her pain for several months. However, over the last few months, her back pain returned. A 5 cc solution of 1% Lidocaine and 100 units of Botox was made and 1 cc was injected into each of the 5 trigger points located in her upper back. Immediately following the last injection, she experienced a vasovagal reaction, lost consciousness and exhibited seizure activity. She was transported to the local hospital emergency room, where despite all efforts, she died.

Autopsy and Toxicologic Findings: the most significant autopsy finding was pulmonary edema and hemorrhage. The hypopharynx, larynx and trachea showed no evidence of edema or hemorrhage. Postmortem blood toxicology demonstrated a lidocaine level of 1.1 ug/mL and a methadone level of 0.12 mg/L. Premortem serum demonstrated a tryptase level of 37.6 ug/ml (reference range 0.4-10.9 ug/ml) and an IgE level of 6.7 IU/mL (reference range 0.0-100.0 IU/mL).

Discussion: anaphylaxis can occur quite suddenly, and is often a clinical diagnosis or a diagnosis of exclusion. It commonly occurs with food allergies and insect stings. An elevated serum tryptase level can support the diagnosis of anaphylaxis. Tryptase is a mast cell specific enzyme that is released in allergic reactions. This patient demonstrated a greatly elevated tryptase level. Although IgE was not significantly ele-

vated, it does not exclude anaphylaxis, since some drugs may trigger mast cell degranulation directly. Because the mixture included lidocaine, the cause of the anaphylaxis cannot be definitively solely attributed to Botox, since rare anaphylactic reactions and death have been associated with lidocaine. The patient's previous injections of Botox may have been the time of sensitization.

Conclusion: both Botox and lidocaine have few reported adverse side effects. This is the first Botox associated anaphylactic reaction and death. Despite reports of safety and few complications, precautions should always be taken for an adverse reaction.

Botox®, Lidocaine, Anaphylaxis

G11 Significant Trends in Work-Related Deaths — United States

Gordon K. Murphy, MD, 814 Hathaway Road, Dayton, OH 45419-3555*

After attending this presentation, attendees will become familiar with work-related deaths and how to investigate them properly.

Both the general public and forensic scientists will realize that there are hazards inherent in every form of work, whether sedentary, or involving physical labor. Prevention of work-related deaths involves recognition of hazards; personal protective equipment; instilling proper work practices; and monitoring the workplace. It will be recognized that most important of all is a persistent commitment to safety by both management and labor. While there has been a significant decrease in work-related deaths over time, many still occur, and many of these are preventable.

In recent years, work-related deaths have ranked second only to motor vehicle accidents as a category of accidental deaths in the USA. It is vital that the forensic scientist be familiar with all aspects of work-related deaths because of their frequency; the often time-consuming and complex nature of a proper investigation; and because these deaths often have implications for the living as well, in the context of prevention. A significant number of these deaths result in litigation - civil, criminal, or both.

Investigation of work-related deaths involves thorough examination and documentation of the scene of death, with expert consultation when indicated; a complete autopsy, including toxicology; and clear statement of conclusions of the investigation as warranted by the evidence.

Four significant trends in work-related deaths in the USA are apparent from experience and review of the literature. 1 - A significant decrease in the number and incidence of work-related deaths particularly since the turn of the 20th century, as well as in the past 20 years 2 - Mining and quarrying; construction; and agriculture in that order were formerly the three industries in which the largest numbers of work-related deaths occurred. Due to significant improvements in safety in mining and quarrying, and in agriculture, the three leading industries are now construction, transportation, and manufacturing. 3 - Work-related deaths due to gunshot were formerly infrequent. Since 1990, however, homicide has been the second-leading cause of work-related deaths in the USA. Homicide is the leading cause for females. 4 - Deaths due to collapses of open-trench excavations in construction, although preventable, continue to rise.

Illustrative cases: Construction - a motor-vehicle accident, the leading cause of work-related death. Deaths at two construction sites, one presenting the coroner with an unusual responsibility Open-trench excavation - a death resulting in both a large fine stemming from OSHA citations, and a civil lawsuit. Homicide - While the great majority of work-related homicides are committed by fellow workers, each of these two cases is a law enforcement officer shot and killed by another because of mistaken identity during a crisis. Manufacturing - death in a chocolate candy factory Death from immersion in a vat at a paper mill Accidental death of a lawyer at work

Conclusions: The investigation of work-related deaths is challenging. It requires broad knowledge of various fields of work, and of the dangers inherent in each. Investigation must be both wide-ranging, yet focused. All findings must be rigorously documented.

Both the general public and forensic scientists will realize that there are hazards inherent in every form of work, whether sedentary, or involving physical labor. Prevention of work-related deaths involves recognition of hazards; personal protective equipment; instilling proper work practices; and monitoring the workplace. It will be recognized that most important of all is a persistent commitment to safety by both management and labor.

While there has been a significant decrease in work-related deaths over time, many still occur, and many of these are preventable.

Work-Related Death, Homicide, Investigation

G12 Over Diagnosis of Low Voltage Electrocution

Ronald K. Wright, BS, MD, JD, 2101 SW 29th Avenue, Fort Lauderdale, FL 33312*

After attending this presentation, attendees will understand the mechanisms of death in electrocution; be provided easily conducted analyses to prevent over diagnosis of electrocution; recognize that over diagnosis of electrocution is relatively common.

This presentation will impact the forensic community and/or humanity by understanding the pitfalls which can occur in investigation of low voltage electrocutions and techniques to employ to reduce over diagnosis.

The fact that electrical burns are the only significant finding in low voltage electrocutions is well known in the forensic pathology community. The fact that electrical burns are seen in only approximately 50% of low voltage electrocutions is also well known. Further, it is generally understood that a high index of suspicion is required if there is a possibility that an electrical circuit may have killed someone, as the autopsy will not identify the cause of death in approximately 50% of cases.

Unfortunately, the above works to create over diagnosis in some cases. The author has encountered eight cases of over diagnosis of low voltage electrocution in the past eight years in his consultative practice of forensic pathology. Of these cases, the author was a consultant to the defense in seven and to the plaintiff in one. The possibility of bias could thus be argued, but then again, the government-hired death investigator also has a bias to determine a cause of death, and in the majority of these cases, if electrocution was not diagnosed, the cause of death was certainly obscure. Invocation of electrocution made a tidy diagnosis in an otherwise puzzling case in the majority of cases.

The eight cases presented show variable circumstances, with varying degrees of certainty that the death could not have been electrocution.

In each case there was a possibility of electrocution because some source of electricity was available to the deceased prior to his or her demise.

In each case, the approach will be to show that for there to be an electrocution, there must be a circuit of more than 16 mamps through the person immediately prior to the death. 16 mamps is used a minimal figure as that is the average "no let go" value for alternating current passing from hand to hand. Further, it is necessary to show that the circuit of more than 16 mamps traversed the body through the chest or the head or both. With low voltage electrocution the mechanism of death is either asphyxia (rarely) or ventricular fibrillation (commonly.) Asphyxia is produced by prolonged exposure (minutes) of the chest causing tetanic contractions of the chest musculature during a through-the-chest circuit or by seizures induced by a through-the-head circuit. Ventricular fibrillation requires a through the chest circuit, of probably

more than 100 mamps of current flow, but of very brief duration, as little as 0.2 seconds.

For there to be a circuit of more than 16 mamps through a person there must be exposure to voltage sufficient to overcome the resistance to current flow which the human body presents. For contact through the skin, requiring the skin to be minimally keratinized, moist and flushed, the resistance is greater than 1000 ohms. Thus to achieve 16 mamps of current flow requires 16 volts as a minimal voltage to achieve "no let-go." As will be shown, one of the cases involved batteries have a voltage below 16 volts, thus making it a case of over diagnosis.

Further, low voltage direct current probably requires much higher current flows than seen with alternating current making the DC current case even more unlikely.

In one of the cases, the conduit through which wires passed caused the insulation to be cut, causing a short circuit which blew the fuse to the transformer. Upon replacement of the fuse, the cut wire arced periodically. As the conduit was grounded, it was never ever to have a voltage, and thus insufficient voltage provided a way to determine over diagnosis.

In another case, the possibility of ground leakage, producing a force field of varying voltages over distance was proposed as the mechanism of electrocution. Demonstration of shoes with high dielectric (resistance to the flow of electricity) made the over diagnosis unlikely.

In four of the eight cases the autopsy demonstrated causes of death from other causes than electricity. These included traumatic asphyxia, ruptured AV malformation of the lung, aortic stenosis with cardiomegaly and buried left anterior-descending coronary artery with ischemic changes new and old in the distribution of the LAD.

In two of the cases the deaths were witnessed. In both of these cases there was no involuntary movement produced by the flow of electricity. A circuit through a person sufficient to cause death causes involuntary contraction of the muscles in the circuit 0.2 seconds after the initiation of the circuit. This results in a scream or shouts if the current passes through the chest. In addition, if the circuit passes through the upper extremity there is involuntary flexion. If the circuit passes through the trunk and lower extremities there is involuntary extension. Both of these phenomena should be described by witnesses who could see and hear the soon to be deceased. In two the presented cases no such movements were heard or seen.

However, the most striking and uniform absence in all of the presented cases is the pathway to ground. In none of the presented cases was there a demonstrable pathway to ground. To have an electrical circuit there must be a source of electrons and something conductive to allow them to flow to a place with fewer electrons. In a low voltage electrocution there must be a circuit of more than 16 mamps from an energized source and the person must be grounded to complete the circuit. In all eight cases there is complete absence of pathway to ground, thus an analysis of pathway to ground which is simple and easy to do, is the most important criteria to employ in the investigation of a possible electrocution.

Autopsy, Electrocution, Cause of Death

G13 Accidental Parachuting Death Due to Equipment Failure

Martha J. Burt, MD and Matthew J. Bowes, MD, Miami-Dade County Medical Examiner Department, Number One on Bob Hope Road, Miami, FL 33136*

After attending this presentation, attendees will understand the importance of an integrated approach to determining cause and manner of death in skydiving related fatalities.

This presentation will impact the forensic community and/or humanity by emphasizing the importance of a multidisciplinary approach to death investigation.

The goals of this research project are to recognize the importance of a multidisciplinary approach to the investigation of parachute deaths, with an emphasis on the importance of scene investigation and equipment analysis.

Skydiving carries a low but significant risk of harm for participants. Between 1992 and 2002, there have been between 27 and 44 skydiving deaths per year in the United States, with an average of approximately 35 deaths per year. As compared with other high risk sports, skydiving has a relatively low mortality rate (25 deaths per 100,000 participants, versus SCUBA diving, 25 per 100,000 and boxing, 50 per 100,000 participants). Human error is the most important cause of mortality in skydiving. Equipment failure is considered rare.

Case Report: A 47-year-old male with no significant medical history began his dive at 13,000 feet. He deployed his main parachute at 5000 feet. The position of his body at the time of deployment of the parachute was head down. Witnesses observed the parachute deploy properly, but the subject did not steer. The subject began to spin, thus tangling his lines. The subject was not observed to make an attempt at cutting the lines and deploying the reserve parachute, which would have been the correct course of action. The subject fell to Earth in a grassy field some distance from his designated drop zone. At the time of his impact, his body was traveling at somewhat less than terminal velocity, since his parachute was deployed, but deployed imperfectly. Fire-rescue was called, but resuscitation was unsuccessful and he was pronounced at the scene.

External examination showed a mildly obese male with several abrasions, lacerations and contusions. In particular, the left neck had a transverse, linear, patterned mixed abrasion and contusion. Internal examination demonstrated scant subarachnoid hemorrhage without skull fractures or cerebral contusions. The organs of the neck underlying the transverse abrasion/contusion had extensive acute hemorrhage. The atlanto-occipital joint was severely dislocated, without transection of the brainstem or proximal spinal cord, but with significant impingement on the brainstem and spinal cord structures. Several ribs were fractured. The heart had a full thickness laceration of the right ventricle with hemopericardium. The coronary arteries did not have any atherosclerosis. The lungs were contused but not lacerated. The liver and spleen were extensively lacerated.

Examination of the parachute harness demonstrated a torn vertical nylon strap on the left side, which connected the horizontal chest strap to the leg straps. The vertical strap doubles over through a metal ring to allow for adjustment to the harness length between the chest strap and the leg strap. The edges of the nylon strap were frayed in close proximity to the metal ring. The company owned several other similar harnesses of the same type, which showed significant wear pattern in the same location.

Integration of data collected from the scene, autopsy and analysis of the harness allowed us to surmise that the nylon strap had snapped when the parachute deployed, thus causing the freely mobile chest strap on the left to be violently pulled caudally by the deploying parachute, forcefully abrading and contusing the left side of the neck while snapping the head backward. This caused the atlanto-occipital dislocation, disabling the subject and making self-rescue impossible. The disturbed flight characteristics of the limp and unbalanced human form caused the parachute to spin and tangle, hastening the subject's descent. The death was ruled an accident.

Equipment failure as a cause of parachute death is rare, but potentially preventable. This case underscores the critical importance of equipment evaluation by a competent analyst.

Skydiving Death, Parachute Equipment, Scene Investigation

G14 The Richard Cory Phenomenon: Suicide and Socioeconomic Status in Kansas City, Missouri

Thomas W. Young, MD*, Jackson County Medical Examiner, 660 East 24th Street, Kansas City, MO 64108; Suzanna Wooden, University of Missouri, Kansas City School of Medicine, 2411 Holmes, Kansas City, MO 64108; Jinwen Cai, MD and Gerald L. Hoff, PhD, Kansas City Missouri Health Department, 2400 Troost, Kansas City, MO 64108; Paul C. Dew, MD, MPH, University of Health Sciences, 1750 Independence Avenue, Kansas City, MO 64106

The goal of this presentation is to present findings from a retrospective study demonstrating a positive association between suicide and socioeconomic status.

This presentation will impact the forensic community and/or humanity by enabling the design of more effective public health interventions for people at risk for suicide. The study also illustrates how data obtained from a coroner or medical examiner agency may be useful for the epidemiologic research of violent death.

Edwin Arlington Robinson's famous poem, "Richard Cory," tells how a man of refinement and wealth goes home "one calm summer night" and inexplicably puts "a bullet through his head." The poem leaves the reader surprised that a wealthy man with all one could seemingly desire in life kills himself. Is a suicide like his unexpected? Results of a retrospective study performed in Kansas City, Missouri, indicate that suicide actually occurs more frequently among those with more of life's finer things.

The Jackson County Medical Examiner receives reports of and investigates all deaths from injury and many natural deaths in Jackson County, Missouri, and maintains a database of information from these investigations. The information includes the home address of each victim. Jackson County Government performs house and personal property appraisals for taxation purposes. Appraisal values for real estate and personal property can be viewed from the Jackson County Government website (www.jacksongov.org) by the parcel address and by the name of each individual owning personal property subject to taxation. These government home and personal property appraisals tend to be lower than actual real market value.

The authors studied all suicides reported to the Medical Examiner from 1998 to 2002. They compared appraisals of houses where suicide victims used to live to appraisals of houses lived in by victims from a control group of non-suicidal deaths. Each non-suicide control victim was randomly selected from the Jackson County Medical Examiner database and matched by age, race, sex, and year of death with each suicide victim. Where available, appraisals for personal property owned by each victim, the victim's spouse, or the victim's parents were also obtained and compared for each group. Additionally, stressors for suicidal intent, such as financial strain, recent loss of a loved one, relationship difficulties, and health, mental or drug problems, were identified for each suicide from investigative reports.

The suicide and control groups each had 426 victims. Significantly more victims in the suicide group lived in houses than victims in the control group (suicide: 70% vs. control: 56.8%, $p < 0.001$ by chi square analysis). Appraisal values for the houses obtained for 277 members of the suicide group had a significantly higher mean and median compared to those of 227 members of the control group (mean: \$70,143 for suicide vs. \$61,513 for control, median: \$62,316 for suicide vs. \$50,580 for control, $p = 0.04$ for two means by two-tailed t-test). Personal property appraisals were available for only 93 members of the suicide group and 90 members of the control group. Although the mean and median appraisals were higher for the suicide group (mean: \$3,666 for suicide vs. \$3,054 for control, median: \$2,750 for suicide vs. \$2,045 for control), the differences were not statistically significant. Analysis of stressors within the suicide group identified mental health and rela-

tionship issues as the predominant stressors, but financial strain, identified in only 8% of victims, was the least frequent stressor. Those suicide victims identified with financial strain had even higher mean and median house values than the suicide or control groups (mean of financial strain group, \$77,126; median, \$74,050).

The data indicate that suicide victims are: 1) more likely to live in houses than other victims rather than in apartments or trailers, 2) more likely to live in more expensive houses than other victims, 3) more likely to kill themselves because of factors other than financial strain, and 4) if financial strain is a factor, more likely to kill themselves after becoming accustomed to a more affluent lifestyle.

Suicide, Socioeconomic Status, Retrospective Study

G15 Suicide: A Ten-Year Retrospective Review of Kentucky Medical Examiner Cases

Lisa B. Shields, MD*, Donna M. Hunsaker, MD, and John M. Hunsaker III, MD, JD, Office of the Associate Chief Medical Examiner, 100 Sower Boulevard, Frankfort, KY 40601

The goal of this presentation is to present a retrospective analysis of information gleaned from postmortem examinations of all suicides from the medical examiners' records in Kentucky between 1993 and 2002; and to correlate this data with national trends regarding suicides.

This comprehensive report aims to dispel the conventional image of the suicide victim as an elderly Caucasian male afflicted by physical disease and demonstrate how suicidal trends have been drastically altered over the years; and to delineate distinguishing characteristics present at the scene and revealed in the medical history that may aid investigators in ascribing the manner of death as suicide.

According to the Center for Disease Control's Monthly Vital Statistics Report in 2000, suicide ranks eleventh in the United States and accounts for approximately 30,000 deaths annually. A host of biological and psychosocial components interplay in the investigation of a suicide. Precipitating factors may include domestic quarrels, loss of employment, financial difficulties, substance abuse, chronic disease, or mental illness. The commonly held belief of the typical suicide victim includes either an elderly Caucasian male with a debilitating disease or a female dying from acute drug intoxication commonly referred to as an overdose. Men are more likely to commit suicide than women. Researchers attribute the lower number of female suicides to a larger number of women who may attempt, but fail to commit, suicide by drug overdose. Furthermore, women may be prone to ventilate emotional problems with others in an attempt to avert suicide whereas men are less likely to admit hardships and are more impulsive in their actions. Although a suicide note may illustrate suicidal intent, it is present in less than one third of cases reported by some authors.

This study presents all 2,866 medical examiner cases of suicide between 1993-2002 in Kentucky. The majority of victims were males (81.8%) and Caucasian (94.8%). Black females comprised the smallest group of decedents, consisting of only 0.59% of suicides. Individuals ranged between 11 and 96 years of age with an average age of 42.0 years. The greatest number of suicides occurred in the fourth decade of life followed by the fifth decade and then the third decade. The preferred mode of death was by gunshot (67.6%), followed by hanging (13.7%), overdose (10.0%), and carbon monoxide poisoning (4.6%). Of the 1,934 gunshot wound fatalities, 79.5% of the wounds involved the head, 18.3% the chest, and 2.6% the abdomen. Both males and females chose a firearm as their primary means of committing suicide, 71.4% and 50.5%, respectively. The head was the most likely target of the gunshot wound in all shooting victims, specifically, 80.4% of the men and 72.7% of the women. 65.5% of black victims utilized a firearm to commit suicide, and 83.8% of these were head wounds. In men, the second and third most common causes of death respectively were hanging (14.5%) and overdose (5.9%). Conversely, this pattern was reversed in women:

the second leading cause of death was overdose (28.1%) and the third, hanging (10.3%).

The review analyzes a myriad of factors that may have prompted an individual to commit suicide: medical and psychiatric history, domestic relationship problems, substance abuse, financial and legal difficulties, and seasonality. The presence of a suicide note, previous suicide attempts, family history of suicide, dyadic murder-suicide, and suicide by cop have also been documented. A discussion of “playing” with a gun known in Russian Roulette and issues related to schizophrenic patients who commit suicide will also be presented. Furthermore, this study inventories and discusses the variety of disease processes and toxicological findings uncovered at autopsy.

Forensic Science, Forensic Pathology, Suicide

G16 Homicidal Cerebral Artery Aneurysm Rupture

Joseph A. Prahlow, MD, c/o South Bend Medical Foundation and Indiana University School of Medicine, 530 North Lafayette Boulevard, South Bend, IN 46601*

After attending this presentation, attendees will understand that, in the correct setting, a natural disease cause/mechanism of death may be considered a homicide, and to learn a set of proposed criteria for such deaths involving ruptured cerebral artery aneurysms.

This presentation will impact the forensic community and/or humanity by addressing the difficult question of whether or not minor head trauma, or even the threat of trauma, can be implicated in a death due to ruptured cerebral artery aneurysm. If trauma (or threats of trauma) can be considered a contributory cause in such deaths, “homicide” may be a reasonable manner of death, given the proper circumstances. The paper proposes a set of criteria to help forensic pathologists determine whether or not a given case represents a “homicide by ruptured berry aneurysm.”

In 1978, Davis published his classic work, “Can sudden cardiac death be murder?”¹ In Davis’ paper, a logical, well-reasoned argument is made for certifying certain cardiac deaths as homicides, so long as a set of specific criteria are met. Using Davis’ criteria, a mugging victim who suddenly collapses and dies from underlying severe coronary artery disease can be appropriately ruled a homicide. While some forensic pathologists may not agree with such a ruling, the phrase “homicide by heart attack” remains well-known to many within the forensic community.

Cardiac disease is not the only natural disease process that can be considered the underlying mechanism of death in homicide. Subarachnoid hemorrhage related to traumatic ruptured cerebral artery berry aneurysm or arteriovenous malformation has received some attention in the medical and forensic literature. In this paper, we present a case of “minor” head trauma causing the rupture of a cerebral artery aneurysm. The MOD was considered “homicide.” The ensuing discussion will address this controversial topic and present a proposed set of criteria useful in making such a determination.

An intoxicated, 46-year-old man, his wife, and their female friend returned to the friend’s home late one night, after having been out for dinner and drinks. The man was reportedly loud and boisterous. Upon hearing the commotion, the friend’s adult daughter, who had been sleeping, got-up, came-out of the bedroom, and asked them to be quiet, since her live-in boyfriend needed to get-up early for work. She then stated that she was going back to bed. The 46-year-old man then proposed to the daughter that he might join her in bed. The daughter’s live-in boyfriend then emerged from the bedroom and confronted the intoxicated man. A short verbal altercation ensued, followed by a single punch, thrown by the boyfriend, that landed on the other man’s face. The man immediately collapsed to the floor, totally unresponsive.

Emergency resuscitation was initiated by the owner of the home. Emergency medical services responded to a 911 call and transported the victim to the hospital, where work-up and imaging studies revealed diffuse basilar subarachnoid hemorrhage and a ruptured berry aneurysm in the basilar artery. He died approximately 36 hours after the initial collapse.

Autopsy confirmed the presence of diffuse, basilar subarachnoid hemorrhage, as well as a ruptured, 9 mm basilar artery aneurysm. Brain examination was consistent with global ischemia. The remainder of the autopsy was significant for cardiomegaly (500 gm), with concentric left ventricular hypertrophy, as well as mild to moderate atherosclerotic cardiovascular disease involving the aorta and coronary arteries. There were no facial injuries identified at autopsy. A blood ethanol level from the time of hospital admission was 153 mg/dL.

Police investigation confirmed the story as presented above. The victim’s wife, the homeowner, her daughter, and the boyfriend all related similar scenarios as they recalled the events. The cause of death was ruled “subarachnoid hemorrhage due to ruptured basilar artery aneurysm following blunt head trauma.” The manner of death was ruled “homicide.”

Whether or not “minor” head trauma may cause the rupture of a cerebral artery aneurysm (or arteriovenous malformation) remains a controversial topic. Some claim that “significant” or “severe” head trauma is necessary, with concomitant skull fractures or brain contusions/lacerations. Others feel that minor head injury is sufficient, in certain instances, to cause aneurysm rupture. A careful review of the literature suggests that minor head trauma may, in fact, contribute to or cause the rupture of an intracerebral aneurysm or arteriovenous malformation. This appears to be true particularly when the traumatic event (or threatened traumatic event) is associated with intense emotion, with a rise in blood pressure. Another factor that increases a person’s risk for cerebral aneurysm rupture (traumatic or spontaneous) is ethanol intoxication, due most probably to the considerable intracranial blood vessel dilatation known to occur in association with ethanol intoxication.

The following represent a proposed set of criteria for ruling a ruptured cerebral artery aneurysm (or arteriovenous malformation) as a homicide: 1) Head trauma (and/or extreme emotional stress) must immediately precede the onset of symptoms related to ruptured aneurysm (or arteriovenous malformation). 2) Autopsy findings must confirm the presence of a ruptured aneurysm (or arteriovenous malformation), with no findings indicating that the rupture occurred prior to the trauma/emotional stress. 3) When head trauma is implicated, autopsy evidence of physical injury of the face/head may or may not be present. 4) Head trauma (and/or extreme emotional stress) must have occurred during or as a result of an event that would normally be considered a form of criminal activity. 5) In order to implicate the emotional stress of an event as a cause or contributing cause of the intracranial hemorrhage, the victim should have realized that the threat to personal safety was implicit, and the circumstances should be of such a nature as to be commonly accepted as highly emotional.

It is important to remember that each case must be evaluated on its own. Death scene investigation and witness statements are often of paramount importance, particularly when attempting to address criteria #1, #4, and #5. If the criteria are not met, it is prudent *not* to rule such a death as a homicide. In such an instance, an “undetermined” ruling is acceptable, with or without a statement suggesting that the case may represent a homicide. As a corollary, a modified form of the criteria may be utilized in an attempt to determine whether accidental trauma can be implicated in deaths related to ruptured cerebral aneurysms or arteriovenous malformations; criteria #4 would not apply in such accidental trauma cases.

Homicide, Natural Disease, Cerebral Aneurysm

G17 Death by Defibrillator: A Unique Homicide by Electrocution

Kendall V. Crowns, MD and Adrienne Segovia, MD, Cook County Medical Examiner's Office, 2121 W. Harrison Street, Chicago, IL 60612*

This presentation will review a case in which an external defibrillator was used as a weapon, discuss the general features of defibrillators, and review the role of defibrillators in accidents and suicides.

This presentation will review a case in which an external defibrillator was used as a weapon, discuss the general features of defibrillators, and review the role of defibrillators in accidents and suicides.

A 49-year-old mentally challenged black male worked as part of a cleaning crew in a suburban dialysis clinic. According to co-workers while he was mopping the floor he had a seizure and collapsed to the floor. Upon their arrival paramedics found the subject in ventricular fibrillation and despite full advanced cardiac life support measures including external defibrillation he was pronounced dead at a local emergency room.

The autopsy examination showed a well developed, well nourished black male weighing 189 pounds and measuring five feet nine inches in height. Externally there were two irregular burn marks: one on the upper left chest measuring 0.9 x 0.6 inches and the other on the upper right chest measuring 0.5 x 0.4 inches. Internal examination was remarkable for a 415 gram heart and 90% atherosclerotic occlusion of the right coronary artery. The remaining coronary arteries were free of atherosclerotic disease. The lungs and brain were remarkable only for the presence of edema. A scene investigation was performed which disclosed no irregularities or the presence of electrical equipment in the room in which the decedent had worked. The cause of death was attributed to coronary atherosclerosis and the manner of death was natural.

One week later a member of the cleaning crew came forward stating that the initial story had been a fabrication. The crew member revealed that an 18-year-old co-worker, who had tormented the mentally challenged decedent on multiple occasions, had turned on one of the clinics external defibrillators which had a preset energy level of 200 joules. The 18-year-old then coaxed the decedent over and discharged the defibrillator into his chest. Following this statement and police investigation, the cause of death was amended to electrocution and the manner of death was changed to homicide.

The first experiments using electricity to stop the heart were conducted in 1775 using chickens. It was not until 1956, however, that the first successful external defibrillation was performed on humans.

A defibrillator delivers 60,000 watts of electricity in four to five millisecond intervals with a resultant energy level of 300 joules. This level of energy is analogous to a bolt of lightning. A properly used defibrillator delivers a current through the chest wall and heart. This causes the heart to stop and allows the pacemaker cells of the heart to repolarize and re-establish a sinus rhythm.

There are two general types of defibrillators, external and internal. These can be further sub-divided into either manual or automatic/semi-automatic types depending on whether an individual or machine recognizes the ventricular fibrillation. Defibrillators can be further subdivided based on charge direction, monophasic or biphasic of the defibrillator. Defibrillator energy levels range from 0 to 360 joules for manual defibrillators and to a preset range of 200 to 350 joules with automatic/semiautomatic defibrillators.

Among paramedics accidents occur at a rate of 1 per 1,700 defibrillator shocks and 1 per 1,000 for EMTs trained in the use of defibrillators. The most commonly reported injuries in these groups are accidental shocks. In patients, the most common accidental injuries are skin burns, and occasionally myocardial muscle damage. Rarely, an automatic defibrillator may shock a patient with a normal rhythm and cause fatal arrhythmias.

Two cases have been reported in which defibrillators were used in suicide attempts. In one a male nurse discharged the defibrillator into his head. He survived and recovered fully. The second case involved a hospital employee who discharged a defibrillator into his chest. He was found in ventricular fibrillation and died despite resuscitative efforts.

No reported cases of the homicidal use of external defibrillators were found in a review of the literature. This case represents a unique and to date unreported form of homicidal electrocution.

Defibrillator, Electrocution, Homicide

G18 The Influence of Violence in the Media on Unusual Methods of Murder and Suicide

Karin A. Margolius, MD, LLB and Gerard A. Cadden, MD, PathCentre, Locked Bag 2009, Nedlands, Perth, WA 6009, Australia*

After attending this presentation, forensic pathologists and crime scene officers will learn about the difficulties in detecting hidden homicides and that knowledge of the latest media releases is vital in crime scene analysis.

This presentation will impact the forensic community and/or humanity by describing to the forensic community the subtleties in signs of murder; addressing the need to be aware of the latest film releases; and addressing the need for an integrated scene analysis team.

There is a wealth of research about the influence of the media on violence, particularly homicides. Most recent reports show little or no correlation between crime and viewing habits. This has not stopped the calls for censorship of the media which may restrict freedom of speech.

The cases to be presented have been linked to a film in which there was an unusual method of causing death. The film showed the perpetrator encasing the victims in a film of plastic wrap causing asphyxiation. He then removed the wrap and the murders remained unsolved for a long period of time. Similarly subsequent concealment of the homicide method occurred in one case so that crime scene analysis would have been difficult if the recent release of the film had noted been identified.

A teenage girl was found lying in an undisturbed bed in the bedroom of a house occupied by her boyfriend. She had two broken fingernails, a small bruise on the thigh and a few petechiae in her eyes. Not far from her head was a roll of unused plastic cling-type wrap while the remainder of the wrap was found in the garbage bin some distance away. At trial the perpetrator confirmed that he copied the method of murdering his victim after viewing the film.

In another case a woman was found with the plastic wrap around her head requiring intense crime investigation into the circumstances surrounding her death. After seeing the film, she used the method to kill herself. In a similar case suicide was thought to be the manner of death in a man who was found with wrap around his head and neck.

Each case will demonstrate the difficulty in scene analysis, the problems in excluding homicide and the need for an awareness of the latest film releases. There are features in each case that suggest that the deaths were due to homicide. Each case died after seeing the same film, utilizing the same method as shown in that film. The media has influenced the deaths in these cases.

Homicide, Media, Concealment

G19 Use of the Impact Baton or So-Called “Rubber Bullet” as Less Lethal Force in Air vs. Water

Darryl J. Garber, MD and Irwin Golden, MD, County of Los Angeles Department of Coroner/Medical Examiner, 1104 N Mission Road, Los Angeles, CA 90033; Lakshmanan Sathyavagiswaran, MD, Chief Medical Examiner-Coroner, Los Angeles County, 1104 N Mission Road, Los Angeles, CA 90033*

After attending this presentation, attendees will be able to recognize and differentiate wounds associated with impact baton, versus gunshot wounds associated with handguns and/or high velocity projectiles. Comparison will be made between impact baton wounds occurring in air as opposed to water.

This is a case of an officer involved shooting with a local law enforcement SWAT Team intervention using “less lethal” force which recently occurred at our office. The decedent is a 34-year-old white Hispanic man measuring 69 inches in height and weighing 283 pounds. The decedent had barricaded himself inside his trailer and was armed with a weapon. He was apparently depressed over his mother’s illness and had a history of drug abuse. Less lethal force was used to subdue the decedent in the form of a police dog as well as the use of the “Impact Baton” or so-called “Rubber Bullet.” The Sage Control Ordnance KO1 ammunition in a 37 mm Arwen 37 Mark III was used. This is known as the Sage Less Lethal Launched Ammunition and Ordnance System (L3A0S). The less lethal means used to subdue this man were unsuccessful and he was ultimately subdued with the use of .223 high velocity rifle wounds. The Arwen round wounds observed in this case will be compared to a second case in which rubber bullets were used to subdue an armed man in the San Gabriel River in Los Angeles County. In the second case the impact batons were fired through water, thus altering the wound characteristics. No fatal bullet wounds were incurred and the man ultimately drowned.

Rubber Bullet, Impact Baton, Less Lethal

G20 Dissection, Preservation and Sexual Abuse of Bodies and Body Parts – An Exceptional Case of Necrophilia

Martin Bauer, MD and Thomas Tatschner, MD, University of Wuerzburg, Institute of Legal Medicine, Versbacher Str. 3, Wuerzburg 97078, Germany; Michael Roesler, MD, Institute of Forensic Psychology and Psychiatry, Saarland University, Kirrberger Straße, Homburg 66421, Germany; Dieter Patzelt, MD, Institute of Legal Medicine, University of Wuerzburg, Versbacher Str. 3, Wuerzburg 97078, Germany*

After attending this presentation, attendees will learn that necrophilia is a rare disorder which can reach extreme dimensions with long-term sexual abuse of dissected and partially preserved body parts. He will retain that cooperation between police, forensic pathology and forensic psychiatry is essential to deal with such cases.

Necrophilia is rare and only few cases have been published in the literature. The cases presented here are unique because the crimes were committed by one individual in a period of 20 years. The stolen bodies were dissected and the organs and body parts partially preserved. The offender abused the corpse and the dissected body parts in a way that is hard to imagine and he documented this abuse on thousands of digital images.

The objective of this presentation is to demonstrate a cases of necrophilia committed by a 40-year-old man with mutilation, dissection and sexual abuse of three bodies and with extensive sexual abuse of dissected body parts which, in the last case, was documented by the offender on thousands of digital images.

The Greek term necrophilia or necrophilism refers to a morbid fondness of being in the presence of dead bodies and, in a stricter sense, to the impulse to have sexual contact or the act of such contact with a dead body, usually of males with female corpses (*Stedman's Medical Dictionary*, 24th ed.). Necrophilia is classified as psychiatric disorder (other disturbance of sexual preference) and the psychopathology of necrophiliacs is an interesting, but largely unknown field of forensic psychiatry based mainly on the work of Krafft-Ebing from 1886 (*Psychopathia sexualis*). However, since this disorder is directly associated with bodies and body parts, forensic pathologists play an important role in the investigation of such cases. The following case series demonstrates that the anatomical and pathological know-how of forensic pathology is indispensable for the police investigations and the psychiatric examination. Furthermore, forensic science is necessary to reunite body parts by morphological and molecular analysis thus ensuring that a dignified funeral finally can take place which is extremely important for the next-of-kin as they try to cope with this traumatizing event.

The chronologically last case of this series, which was the most spectacular, illustrates all features of necrophilia in an extreme dimension which, to our knowledge, never was reached in previous publications and case reports.

In October 1999, the body of a 14-year-old girl, who had been killed by a train accident, disappeared from a morgue at a small cemetery located in a rural area in Northern Bavaria, Germany. Extensive investigations were started but did not provide any results. Regional and national media reported on the case and considerable public pressure was exerted on the investigators.

Three months later, a forester observed a man who was taking photographs of intestines spread out in front of him. Although this observation was not reported to the police until 4 weeks later, the man could be identified and he immediately confessed having taken and sexually abused the body. Because of beginning putrefaction, the 40-year-old engineer had started to dissect the body after a few days, removing organs and body parts such as the intestines, liver, uterus, vagina and breasts. Using these specimens, he continued with sexual activities in his home bathroom and documented every detail with a digital camera. More than 7000 images were found on his computer hard disk showing extreme situations which are difficult to cope with even for experienced forensic pathologists.

The remains of the girl consisting of the trunk, parts of the extremities and the skull were found in a hole filled with mud on the property of the man. Some of the dissected specimens had been treated with an alcoholic solution to stop decomposition and could be recovered in his home. He also admitted having abused 2 other cadavers of young females: in 1985 he had opened a casket and mutilated a body by removing breasts, eyeballs and other body parts and in 1981 he had dismembered the corpse of a 21-year-old woman and further dissected and abused the torso at his home leaving the extremities in the casket. This body-snatching had not been noticed at that time. From this case there were still some specimens kept in his home such as a carefully prepared spine column with the pelvis attached by a Velcro fastening. He was suspected of being involved in more cases of body-snatching or body-stripping that had occurred in the region between 1985 and 2000 but no evidence could be found and he denied those accusations.

According to German criminal law he was convicted to two years and three months of prison because of disturbance of human remains. A psychiatric examination was ordered by the court and the diagnosis “necrophilia” (ICD 10: F65.8, other disorder of sexual preference) was made. According to the forensic psychiatrist, the criminal responsibility of the defendant was diminished and the probability of repeating similar crimes with corpses was high. The risk of committing homicides to satisfy his sexual urges in the future was considered to be significant and he was moved to a criminal mental hospital for an indefinite period of time.

Necrophilia, Sexual Abuse, Body Parts

G21 Too Many Causes of Death: What's the Manner?

Wendy M. Gunther, MD, Office of the Chief Medical Examiner and Department of Legal Medicine, Virginia Commonwealth University, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510*

After attending this presentation, attendees will be able to evaluate the importance of competing causes of death discovered at autopsy. Rank causes of death in a hierarchical order depending on importance to the mechanism of death. Integrate scene information, gross autopsy discoveries, histologic findings, and toxicology results to determine the hierarchy of causes of death. Relate manner of death to the most important cause of death.

This presentation will impact the forensic community and/or humanity by recalling and reviewing the importance of integrating scene information, autopsy findings, histology, and toxicology into the determination of the most important cause of death, in order to determine an accurate manner of death. Understand the likelihood of multiple converging natural diseases in the homeless and alcoholic population. Increase awareness of recognizing significant and even predominating natural disease in persons with worrisome but nonfatal injuries, which may affect determination of manner of death.

A 53-year-old homeless man, familiar to local storeowners for about 15 years, had been living for the last three months beneath the trailer of an abandoned tractor-trailer behind a strip mall. Nearby storeowners said he appeared to be losing weight, and undergoing general health degeneration. He had no regular medical care. He had a history of admission to local hospitals for peptic ulcer disease and for chronic pancreatitis, with a splenic artery aneurysm recognized at one admission. The night before his death, children were observed throwing rocks in his direction. The children ran off when adults approached.

He was found dead beneath the trailer, surrounded by empty beer cans and vodka bottles. The scene investigators saw a bruise behind his left ear. At autopsy, he had numerous bruises of different ages on his shoulders, arms, chest, and legs, although no external bruise was appreciated in the livor behind his left ear. Small abrasions were noted on his elbow and hand; there was no other evidence of external injury.

The following lesions were found on internal examination: a small subgaleal hemorrhage behind the left ear, with a recent left-sided subdural hematoma; fresh injury to the left thoracic wall, without rib fracture; three separate ulcers or tears at the esophago-gastric junction, one of which appeared to have perforated, but might have been post-mortem; an ostium secundum defect of the heart, with right ventricular dilatation; slight coronary atherosclerosis, with a left predominance of the coronary system, and with a remote infarct of the posterior left ventricle, which was surrounded by a faint hyperemic area; micronodular cirrhosis of the liver, with diffuse, prominent fatty change; severe chronic pancreatitis, with a stented splenic artery aneurysm; three peptic ulcers in the first part of the duodenum, without frank bleeding; an intrahepatic aneurysmal dilatation of a large branch of the portal vein, with thrombosis; and moderately severe emphysema with chronic bronchitis. It was not possible to answer police inquiry, at gross autopsy, as to which of these had caused his death; or whether his manner of death was natural, accident, or homicide.

What do you do when you have too many causes of death, without a clear manner? The ramifications of multiple severe illnesses and injuries in a single case are discussed, particularly in a setting of homelessness and chronic alcoholism, with relevance to the manner of death.

Multiple Causes of Death, Manner of Death, Alcoholism

G22 Postmortem Analysis of Anastomotic Suture Line Disruption Following Carotid Endarterectomy

Judy Melinek, MD, New York City Office of Chief Medical Examiner, 520 First Avenue, New York, NY 10016; Patrick Lento, MD, Mount Sinai Hospital Medical Center, 1190 Fifth Avenue, New York, NY 10029; John Moalli, ScD*, Exponent Failure Analysis Associates, 149 Commonwealth Drive, Menlo Park, CA 94025*

The goal of this presentation is to describe a case report of a suture line disruption following surgery and how proper specimen handling and microscopic analysis allowed us to determine the cause of this therapeutic complication.

This presentation will impact the forensic community and/or humanity by providing this first report of its kind in which a postmortem analysis of suture material from a failed suture line implicated improper surgical technique in the death of a patient. In cases where an anastomotic failure is successfully repaired, a broken suture is often discarded along with any clot and blood-soaked gauze. The failure may be reported in the surgical literature or to the suture manufacturer but, without photography or an ultrastructural evaluation of the filament, it cannot be confirmed whether surgical technique or defective manufacturing was at fault.

In the forensic setting there is a singular opportunity to examine the sutures and resolve these issues. The findings can have both medico-legal and public health implications. In this study it was clear that tissue debris and formalin fixation did not significantly hinder such an analysis and we, therefore, recommend that in future death investigations of this nature, the medical examiner should refrain from handling the suture ends with dissecting implements, and preserve the anastomotic suture line with the surrounding tissue en-bloc so that a more detailed analysis can be performed.

The tensile strength of a surgical suture is essential in maintaining the integrity of vascular anastomoses. In the surgical literature, there have been several reports of suture line disruptions due to apparent fracture of polypropylene suture, including failure of an atrial septal defect repair, a proximal anastomosis of a coronary artery bypass, an aortic closure in a patent ductus arteriosus repair, a femoral-popliteal bypass repair, and a carotid endarterectomy. These previous case reports do not present a detailed analysis of the suture tips and there is no photography to document the findings.

While faulty operative technique and the loading strength of individual sutures have been implicated in spontaneous suture line disruptions, there has, to date, never been a published post-mortem analysis of a suture that has known to have failed. We present the case of suture line disruption leading to fatal exsanguination in a 77-year-old man following carotid endarterectomy with a facial vein patch. As part of the public health role performed by the medical examiner's office and in compliance with the requests of family, hospital and the suture manufacturer, we performed a detailed analysis to address the question of whether the suture or the surgical technique were at fault.

A 77-year-old white man with a history of hypertension, coronary artery disease and remote myocardial infarction underwent a carotid endarterectomy for high-grade stenosis of the right carotid artery. Under general anesthesia, the endarterectomy was performed and a right facial vein patch was placed using a double armed, #6-0 Prolene suture. He expired approximately 18 hours after surgery, following a sudden, fatal exsanguination from the surgical site. At autopsy, there was a 1 cm defect of the sutured anastomotic line. At the defect, two suture tips were identified: a straight cranial end and a tightly coiled caudal end. There was no knot on either side, nor were any loose suture fragments identified. The smooth edges of the vein graft and carotid artery confirmed that the tissue itself didn't fray or tear.

The carotid specimen was preserved en-bloc in 10% formalin and photographed using both dissecting and scanning electron microscopy. Examination of the specimen under a dissecting microscope demonstrated that other suture knots from the specimen, some involving vascular ligatures and others involving a distant line of interrupted sutures, were tied in stacked granny or half-hitch configurations. Several of these interrupted sutures were in various stages of untying, with one that had completely untied but had not yet pulled through the tissues.

For scanning electron microscopy, suture tips from the disrupted anastomotic line and from elsewhere on the specimen were carefully removed and oriented. For controls, several #6-0 Prolene control sutures were removed directly from the manufacturing package and were alternately cut with a scalpel blade, surgical scissors, or were manually broken and "popped off" the suture needle. Ultrastructural photography demonstrated that suture tips cut by a scalpel have a squared-off, straight edge while ones that have been cut by scissors are flattened or wedge-shaped with horizontal linear shear marks along the cut surface.

The microscopic shape and contour of the disrupted suture tips, and the complete absence of a knot or additional suture fragments, indicated that surgical technique (an untied knot) was the cause of the suture line disruption. The removal of a broken or untied suture at surgery or at autopsy should not preclude proper analysis of the failed suture, as the results can have both medico-legal and public health implications.

Forensic Science, Forensic Pathology, Anastomosis

G23 Advanced Flow Cytometric DNA Degradation Analysis: Utility in Postmortem Interval Estimation

Erica Williams, MD, Hospital of the University of Pennsylvania, Department of Pathology and Laboratory Medicine, 6 Founder Building, 3400 Spruce Street, Philadelphia, PA 19104; Andrew Bantly, BS, Hospital of the University of Pennsylvania, Abramson Cancer Center Flow Cytometry and Cell Sorting Shared Resource, 3400 Spruce Street, Philadelphia, PA 19104; Jesse Chittams, MS, University of Pennsylvania School of Medicine, Department of Biostatistics and Epidemiology, 3400 Spruce Street, Philadelphia, PA 19104; Jonni Moore, PhD, Hospital of the University of Pennsylvania, Abramson Cancer Center Flow Cytometry and Cell Sorting Shared Resource, 3400 Spruce Street, Philadelphia, PA 19104*

After attending this presentation, attendees will be able to determine if application of a statistical model and objective computer modeling to DNA degradation data will yield reproducible, accurate results, and help in post-mortem interval estimation.

This presentation will impact the forensic community and/or humanity by providing preliminary results which indicate that more advanced analysis, including statistical evaluation and computer modeling, of DNA degradation data is possible. These methodologies could be then be applied to forensic autopsy samples to assess their validity in estimating a post-mortem interval.

This poster will show data used to develop a mathematical model for PMI estimation as well as juxtapose two different flow cytometric computer models in an effort to select the most reliable methods of estimation.

Over the past decade, since the first proposal by Cina that flow cytometry might be useful in post-mortem interval estimation by monitoring DNA degradation, several papers have been published attempting to establish a link. Using flow cytometry, previous studies on splenic and hepatic tissue have suggested that cellular DNA degradation increases with time, and could thus potentially be used as a tool for post-mortem interval estimation. However, much of this previous work has been focused on selecting the best type of sample for analysis, rather than on perfecting the technique and analysis of the data obtained. In an

attempt to delineate the best analytical method, this study involved the collection of easily obtainable blood samples, from normal living donors, which were stored at room temperature, then assayed for DNA content at varying times post collection (0-191.5 hrs) to determine the amount of DNA degradation. This amount of degraded DNA was quantified using two different computer programs: CellQuest™ v. 3.11 (Becton-Dickinson, San Jose, CA) and Modfit™ v. 3.0 (Verity Software, Topsham, ME, U.S.A). The first program allows for subjective analysis of the amount of DNA degradation, while the second program uses a computer model which can objectively assign the amount of DNA degradation, without user input.

After DNA degradation determination by both computer programs, the relationship of DNA degradation and sample age was plotted and further analyzed with a random coefficient statistical model to yield a population regression curve.

The validity of this curve was then tested using blood collected from another group of normal donors and analyzed at varying times in a blind study. In 20 of 28 samples, a correct 24 hour period was able to be assigned (71%). These preliminary results suggest that a mathematical model, combined with objective computer analysis, can be applied to the monitoring of DNA degradation of cellular material, and can potentially become a tool in determining post-mortem interval.

Post Mortem Interval, Flow Cytometry, DNA Degradation

G24 The Impact of Dermatologic Consultation in Autopsy Examination: A Case of Pseudoxanthoma Elasticum

Carrie L. Kovarik, MD, UT Clay J. Cockerell, MD, Sheila D. Spotswood, MD, and Jeffrey J. Barnard, MD, University of Texas Southwestern Medical School - Forensic Science, 5323 Harry Hines Boulevard, Dallas, TX 75390*

After attending this presentation, attendees will understand and realize the usefulness of dermatologic consultation in autopsy examinations through a case presentation of pseudoxanthoma elasticum.

This presentation will impact the forensic community and/or humanity by demonstrating that a dermatology consultation may be a very useful addition to forensic and hospital autopsies. We present an example of how this consultation may lead to the diagnosis of systemic disease and possible cause of death.

Dermatologic consultation in the autopsy examination may be very useful in many cases. We present a case of pseudoxanthoma elasticum, a genetic disease, that was diagnosed by a thorough external examination and histologic evaluation of the skin.

A forty-nine-year old white female was found unresponsive in an apartment fire and was taken to the local area hospital. On arrival, the patient was in asystole and had a carbon monoxide concentration of sixty percent. She was also found to have evidence of smoke inhalation and burns over approximately fourteen percent of the total body surface area. The patient was pronounced dead and was transferred to the Dallas County Medical Examiner's Office.

On skin examination, the patient had a large leathery, firm, dark brown plaque with surrounding erythema on her back and right flank. On the leading edge of the plaque, there were multiple bullae and skin sloughing. The leathery plaque was clinically consistent with the most severe burn site and was likely the area closest to the heat source given the intense drying of the skin. The bullae and skin sloughing was clinically consistent with a third degree, full thickness, burn. On the skin of her neck, antecubital fossa, and inguinal area, the patient had small yellow papules and a wrinkly appearance that resembled "plucked chicken skin." A biopsy was taken of the bullae on the right flank and the skin the inguinal area.

The biopsy of the bullae was consistent with a full thickness burn and showed a necrotic epidermis and polarization of the nuclei around the hair follicles. The biopsy of the skin taken from the inguinal area was characteristic of pseudoxanthoma elasticum and showed degeneration of the elastic fibers in the middle and lower dermis. On hematoxylin and eosin staining, the elastic fibers were basophilic, irregular, and widely dispersed among the collagen bundles. On von Kossa staining, these elastic fibers were highlighted in a dark brown color.

Pseudoxanthoma elasticum is an autosomal recessive disorder due to a mutation in the ABCG6 gene on chromosome 16. The patients have clumped, distorted, calcified elastic fibers which manifest as disease in many organ systems. The patients typically have flat, yellowish papules on the skin of flexural areas that sometimes coalesce to resemble "plucked chicken skin." Most patients also develop angioid streaks in the eye that may lead to blindness, and many develop progressive calcification of the medium sized arteries which leads to hypertension and myocardial infarctions at a much younger age. Patients may also have calcification of the cerebral and gastric vessels.

Upon further investigation into this patient's history, she was found to be blind and have severe hypertension. These findings, along with the characteristic histologic findings on skin biopsy, lead to a definitive diagnosis of pseudoxanthoma elasticum. This disease has tremendous implications for the family given that it is inheritable and may cause significant morbidity and mortality.

Dermatologic consultation was extremely useful in this case, given that the skin findings, combined with the knowledge of the patient's medical history, provided the diagnosis of a rare, genetic, and life threatening disease.

Dermatology, Consultation, Autopsy

G25 Homicidal Injury or Resuscitation Artifact?

Amy P. Hart, MD, Venus J. Azar, MD, and Boyd G. Stephens, MD, Medical Examiner's Office, City and County of San Francisco, 850 Bryant Street, San Francisco, CA 94103*

After attending this presentation, attendees will become aware of resuscitation artifact created by mechanical cardiopulmonary resuscitation systems.

Objectives: to present a case of resuscitation artifact from mechanical cardiopulmonary resuscitation system which could be potentially confused with homicidal injury and two additional cases involving the use of a mechanical cardiopulmonary resuscitation system; and, to discuss the mechanical cardiopulmonary resuscitation system used in the City and County of San Francisco.

Evaluation and correct identification of resuscitative artifact is critical in the diagnosis and determination of cause and manner of death in certain cases. Resuscitative artifact can emulate inflicted injuries and possibly be misinterpreted. Occasionally new technology and/or medical procedures will create original and distinctive artifact. This presentation discusses one new technology and its related artifact.

The decedent is a 69-year-old obese white man with a history of hypertension who is found dead on the floor of the bedroom/office in the home that he shared with his daughter and a downstairs tenant. On the evening of his death, his daughter was out with her fiancée. During the evening, the decedent reportedly engaged in a verbal altercation regarding the use of the oven in the kitchen with the downstairs tenant. The tenant reported that the landlord seemed very agitated, angry, and tense, which was unusual for him. The tenant called the decedent's daughter, who returned with her fiancée to the residence. While the daughter's fiancée was speaking with the tenant he noted an abrasion on the back of the tenant's right hand, which the tenant claimed was from striking a wall after the verbal altercation with the landlord. The daughter went upstairs and found her father lying on the floor, unresponsive.

Hearing the daughter scream, her fiancée went upstairs. The daughter called 911 while the fiancée started cardiopulmonary resuscitation. When the paramedics arrived, they continued resuscitation using a mechanical cardiopulmonary resuscitation system. Despite all efforts, the decedent was pronounced dead at the scene.

External examination showed an abrasion on the top of the head, abrasions on the right side of the forehead, the right cheek, and the right side of the nose, and contusions of the lateral right eyebrow and left temple. There were petechial hemorrhages on skin of the forehead, the upper and lower eyelids, and cheeks. There were petechial and confluent hemorrhages of the conjunctivae and sclerae. There were large abrasions on the lateral left chest and abdomen. There was a contusion of the left knee. The decedent's doctor was contacted and reported that he considered this death sudden and unexpected.

This presentation will discuss the autopsy findings of this case and two additional cases in which a mechanical cardiopulmonary resuscitation system was used. The City and County of San Francisco Medical Examiner's Office participated in the development of prototypes of a mechanical cardiopulmonary resuscitation system (Revivant AutoPulse). Recently, the San Francisco Fire Department emergency personnel began using this mechanical cardiopulmonary resuscitation system in the field. This presentation will discuss the rationale and operation of mechanical cardiopulmonary resuscitation systems and associated findings at postmortem examination.

Forensic Pathology, Resuscitation Artifact, Mechanical Cardiopulmonary Resuscitation

G26 Screening Items of Evidence for the Presence of Body Fluids/DNA in Forensic Biology Casework — A Hypothesis-Driven Approach

Melissa Kell, BSc, Sobia Malik, MSc, Gerry Alderson, MSc, and Andrew Greenfield, MSc, Centre of Forensic Sciences, 25 Grosvenor Street, Toronto, Ontario M7A 2G8, Canada*

After attending this presentation, participants will learn how the implementation of various case screening strategies and initiatives developed in response to case hypotheses has assisted in addressing pertinent forensic questions in a timely and efficient manner.

This presentation will impact the forensic community and/or humanity by adapting processes and undertaking examinations specifically in response to hypotheses formulated by information in case histories has permitted us to work more efficiently while addressing the most pertinent questions in cases. Sharing these successes will assist other laboratories in implementing similar measures.

This poster will present specific examples of case screening strategies and initiatives adopted at the Centre of Forensic Sciences (CFS) designed to facilitate hypothesis-driven examinations. The aim is to promote the examination of relevant items only, in a manner that is timely and efficient.

Many forensic cases require a small number of items to be examined in order to address the pertinent questions at hand. On the other hand, larger and more complex cases require that decisions be made with respect to which items are to be examined, the order in which those items are examined, and, given a particular result, the necessity of additional examinations. Information provided through the case history and case conferencing as well as knowledge gained through experience and training can be used to formulate a hypothesis in accordance with the scientific method to address these decisions.

Recently, CFS case screening procedures were updated and further aligned with the principles of hypothesis testing. An increased emphasis was placed on assessing the relevance of an examination. The following statement from our DNA Case Screening Manual is one example:

"Scientists are required to evaluate the relevance of an examination using the principle of reasonable expectation and to be mindful of the limitations such an examination confers."

The approach is demonstrated through the following examples of classes of cases typically encountered at the CFS:

Sexual Assault Cases

Sex assaults comprise roughly two thirds of the workload of the Biology Section. Examples of initiatives undertaken to screen items more quickly in accordance with the case history provided include:

- The sexual assault examination kit (SAEK) provided to treatment centres throughout the province has been redesigned such that only relevant samples are collected. Furthermore, the design of the kit dovetails with our screening procedures in the laboratory, and provides samples that can be retained for independent testing.
- In sexual assault cases, relevancy of item examination is evaluated and hypothesis-based flowcharts govern the order in which selected items are examined. When vaginal intercourse is the only allegation, oral and rectal samples are not examined. Vaginal samples are examined beginning with the examination of the vaginal smear. If semen is identified, DNA testing of the vaginal swab is immediately initiated and case screening is terminated pending DNA results. In the absence of semen on the vaginal samples, underwear from the complainant is examined for the presence of semen and/or saliva only if vaginal penetration and/or cunnilingus is alleged, and if the underwear were worn shortly after the alleged assault. Clothing is examined for the presence of semen only if the case history indicates that external ejaculation is suspected or if the complainant cannot reliably describe the circumstances of the assault.
- A process was designed to expedite the examination of microscope smears made from internal samples collected during the SAEK. The examination provides a rapid screen in order to expedite the processing of positive sexual assault cases while minimizing the consumption of related samples.
- A Cold Case Program was established through the joint efforts of the CFS and a major metropolitan police service. This initiative involves the examination/re-examination of unsolved cases by targeting only those cases and those items that are most likely, based on case history, to produce a DNA result attributable to the perpetrator. Strict criteria for submission as well as a hypothesis-based flowchart provided to investigators ensure submission of only relevant items, which leads to a timely examination and the highest chance of success.

Property Crime Cases

The CFS has initiated a "Break and Enter" program to accommodate the submission of evidence from break and enter cases where no suspect is known. The focus of this program is to produce DNA profiles, in a timely fashion, for upload to the National DNA Databank in cases where there are no other investigative leads. To control a potentially unmanageable influx of break and enter casework, strict guidelines were established to target the submission of one item per case that is most likely to be attributed to the perpetrator. Items that are accepted as per the guidelines include swabs of blood, cigarette butts, and swabs from drink containers. Items such as swabs of doorknobs, where there is a prior expectation of low levels of DNA having been deposited through innocuous means, are not accepted.

Blood Cases

The principle of hypothesis testing can also be applied in situations where the examination for the presence of blood is required. For example, when processing assault cases where the case history suggests only one bleeding person (complainant), and where a large number of items from the suspect are submitted, the examination of a single item is sufficient if in fact blood is detected. Item selection is based on the circumstances of the event (e.g., a shoe, if there was kicking involved, or the outermost upper garment if there was punching or an assault with a weapon).

Ultimately, the hypothesis-based approach promotes representative sampling over exhaustive sampling and leads to more meaningful results for clients in a timely fashion.

Case Screening, Forensic Biology, Hypothesis Testing

G27 Fatal Kawasaki Disease Associated With Cardiac Rhabdomyomas in an Infant

Erik K. Mont, MD, Miami-Dade County Medical Examiner*

Department, Number One on Bob Hope Road, Miami, FL 33136; Allen P. Burke, MD, Armed Forces Institute of Pathology, Department of Cardiovascular Pathology, 6825 16th Street, NW, Building 54, Room 2005, Washington, DC 20306

The purpose of this report is three-fold: to present a hitherto undescribed association (Kawasaki disease and cardiac rhabdomyoma); to illustrate an extremely rare cause of sudden death in infants (cardiac tamponade due to a ruptured Kawasaki aneurysm); and to demonstrate the co-existence of two coronary complications of Kawasaki disease: proximal coronary aneurysm (common) and non-aneurysmal stenosis (rare).

This presentation will impact the forensic community and/or humanity by presenting a hitherto undescribed association in a rare cause of death (cardiac rhabdomyomas in fatal case of Kawasaki disease due to rupture of a coronary aneurysm in an infant).

The purpose of this report is three-fold: to present a hitherto undescribed association (Kawasaki disease and cardiac rhabdomyoma); to illustrate an extremely rare cause of sudden death in infants (cardiac tamponade due to a ruptured Kawasaki aneurysm); and to demonstrate the co-existence of two coronary complications of Kawasaki disease: proximal coronary aneurysm (common) and non-aneurysmal stenosis (rare).

Introduction: Kawasaki disease (KD), or mucocutaneous lymph node syndrome, is an inflammatory disease of infants and children that is often associated with a systemic vasculitis preferentially involving the coronary arteries. Although the acute illness usually resolves spontaneously, 15-30% of untreated children develop cardiovascular complications, including proximal coronary artery aneurysms and rarely coronary stenosis without aneurysm formation. Fatal complications are uncommon, occurring in an estimated 0.5% of cases. Sudden deaths are usually related to myocardial ischemia secondary to thrombosis of coronary aneurysms or coronary scarring. Among fatal cases of KD, coronary artery rupture has been reported in approximately 5% of those autopsied.

KD usually afflicts children under five years of age, and the diagnosis is based on a constellation of clinical features. The signs include fever unresponsive to antibiotics, cervical lymphadenopathy, bilateral conjunctival injection, labial and oropharyngeal mucosal erythema and fissuring, and cutaneous erythema and exanthema that often involves the palms and soles. Infants under six months of age can present with aggressive coronary vasculitis with aneurysms in the absence of the typical clinical signs.

The etiology of KD is unknown. Although a number of toxins and infectious agents have been implicated, acting as direct pathogens or via superantigen mediated autoimmunity, no constant associations have been identified. Moreover, case reports have described rare cases of KD occurring in association with other medical conditions, including congenital anomalies of the coronary arteries, Beckwith-Wiedemann syndrome, and cystic fibrosis. To our knowledge, KD has not been previously reported in association with cardiac rhabdomyomas.

Cardiac rhabdomyomas are rare congenital hamartomatous tumors usually discovered in infants and children. Most are multiple, occurring anywhere in the myocardium. Rhabdomyomas of the heart are strongly associated with tuberous sclerosis. The clinical presentation and prognosis depend on the size and location of the tumors.

Clinical History: The decedent was a four-month-old white male infant who was the product of a 38 week gestation, delivered via cesarean section for maternal pre-eclampsia. The early neonatal period was marked only by transient hyperbilirubinemia, which resolved spontaneously. The infant was healthy until approximately three months of age, when he developed a cough and intermittent fevers that reportedly responded to treatment with acetaminophen. He was seen by his primary pediatrician several times during the ensuing 2-3 weeks and diagnosed with otitis media. Despite treatment with antibiotics, fevers and cough persisted, prompting an emergency department visit. At the time, his temperature was recorded at 102.1. He had no lymphadenopathy, rash, or oral mucosal abnormalities, although redness of the eyes was noted. He was discharged home with continued antibiotics and symptomatic treatment. Ten days after being examined in the emergency department, the infant became suddenly unresponsive while being dressed by his mother. Resuscitative efforts were unsuccessful.

Autopsy Findings: The body was that of a well-developed, well-nourished white male infant who was large for the age of four months. The skin was pale and free of exanthema. The oral mucosa was free of lesions, and the conjunctivae were clear. There was no lymphadenopathy. The brain was free of tubers, and the kidneys had no masses. The pericardial sac was distended with 400 cubic centimeters of partially clotted, bright red blood. The heart was normally formed. The epicardial coronary arteries were markedly thickened and firm, most with a cord-like appearance. Focally (predominantly in the distal left obtuse marginal branches), the arteries had a beaded appearance, with areas of thickening alternating with thin, grossly normal-appearing segments. The proximal right coronary artery had a 0.8 x 0.8 x 0.7 centimeter thin walled aneurysm with a 0.1-0.2 centimeter rupture in the epicardial surface. Transverse sections of the thickened arterial segments demonstrated firm, yellow-white, circumferentially thickened arterial walls surrounding narrow, focally pinpoint residual lumina. The cardiac valves and chamber dimensions were normal. The myocardium was firm, red-brown, and free of gross abnormalities. A 0.2 x 0.2 x 0.2 centimeter smooth excrescent nodule was on the right ventricular aspect of the septum, just below the right ventricular outflow tract. The endocardial surfaces were otherwise unremarkable. The pulmonary artery, the aorta, and the major systemic arterial branches were free of thickening or other gross abnormalities.

Microscopic examination: Histologic sections of the coronary arteries demonstrated diffuse chronic and mixed inflammatory infiltrates involving the intima, media, and adventitia. Focally, the inflammation was accompanied by intimal hyperplasia and non-occlusive adherent luminal surface thrombi. The media was focally disrupted and obliterated. Both the media and the adventitia had large areas of sclerosis and neovascularization resembling granulation tissue. Sections of the right coronary aneurysm demonstrated attenuation of the arterial wall with destruction of the media and transmural mixed inflammation with eosinophils. The thin wall was focally disrupted, with transmural fibrin deposition at the rupture site. Myocardial histologic sections revealed multiple small subendocardial and intramural rhabdomyomas in the left and right ventricles, characterized by well demarcated foci of large, clear cells, some with spider cell morphology.

Discussion: Coronary artery aneurysm rupture due to KD and cardiac rhabdomyomas are both independently rare. To our knowledge, they have not been previously reported together. In addition, the coexistence of proximal aneurysm with diffuse non-aneurysmal stenosis in the acute phase of KD is described. The relationship, if any, between these entities is not clear, and the rhabdomyomas may represent an incidental finding in this case of fatal KD.

Kawasaki Disease, Rhabdomyoma, Coronary Aneurysm

G28 Hmong Cultural Aversion to Forensic Autopsy: Bridging Communication and Cultural Barrier

Thomas K. Resk, MD*, PO Box 3215, Chico, CA 95927-3215; Thomas A. Rudd, MD, PO Box 332, Highwood, IL 60040-0332

The goal of this presentation is to share with the forensic community practical experience in communication methods, including the use of community public radio broadcasting, to both increase understanding of the autopsy and to lessen cultural resistance to forensic autopsy among the Hmong cultural community in the USA.

This presentation will impact the forensic community and/or humanity by increasing understanding and acceptance of the forensic autopsy by Hmong people as an instrument of "good" for the entire community as well as greater sensitivity by the forensic community to the culture of the Hmong and their desired treatment of the dead.

This poster presents the work of the authors and a dedicated group of Hmong who addressed a series of cultural problems discovered during the course of a routine forensic autopsy performed on an Hmong elderly woman, a member of one of the five Hmong clans living in Butte County, located in northern California. After resolution of the cultural issues of this individual clan member, the scope of our work was expanded to examine cultural objections to autopsy by all eighteen clans which compose the some 300,000 Hmong currently residing in the United States. Over several months a series of meetings to identify Hmong cultural/religious objections to autopsy were held among members of the Hmong community, the Butte County Chief Deputy Coroner, and the county forensic pathologist. Given deeper insight, understanding, and sensitivity to the Hmong cultural aversion to autopsy examination, a number of mitigating steps were initiated by the Butte County Sheriff-Coroner and forensic pathologist which assured surviving Hmong relatives that the spirit of their deceased family member could enter the after-life with minimal negative cultural consequences for the decedent. The risk of the decedent's spirit returning to haunt surviving relatives because of the perceived failure of the relatives to prevent autopsy, a palpable fear among the relatives, was also eliminated. At the same time the requirements of the law necessitating forensic autopsy were also upheld.

Mitigating steps initiated included:

(1) Performing a full autopsy only when absolutely necessary.
(2) When a decedent coming to forensic autopsy was known, or suspected, to be Hmong, the next-of-kin was contacted by the forensic pathologist to inform them that an autopsy would be done and for what purpose. An offer for the family to elect a family member, or family representative, to 'talk' to the spirit of the dead person prior to autopsy in the presence of the body was proffered. Because of the Hmong belief that the spirit resides in the dead body, it is believed possible to communicate to the person's spirit after death. The purpose in talking to the dead body was to relate why an autopsy had to be done for which the family members bore no responsibility. Currently, a native Hmong-speaking liaison between the Hmong community and the Coroner's Office is being sought to replace the time consuming contact role of the forensic pathologist.

(3) Replace all organs back into the body after autopsy.
(4) Allow no metallic foreign items to be left in the body after autopsy.

Delay performing the autopsy until appropriate family ritual arrangements could be made.

Recognizing that the Hmong cultural aversion to autopsy affected not only the local community but also the broader Hmong community throughout the United States, a one hour long radio program titled, "Forensic autopsy and the Hmong" was carefully scripted employing very simple Hmong terms to explain medical terms totally foreign to the Hmong language. The radio program was broadcast over a local

northern California Community Public Radio station, FM 90.1 KZFR – Chico, with an estimated local listening audience of 4,000 Hmong. The radio program was recorded, burned to CD, and redistributed throughout the United States to numerous Hmong Cultural Centers as well as forensic pathologists who expressed an interest through the National Association of Medical Examiners (NAME) internet-based computer listserv.

A conservative estimate is that tens of thousands of Hmong listeners will ultimately be exposed to this radio program.

Hmong Culture, Autopsy Resistance, Radio Broadcast

G29 Postmortem Diagnosis of Genetic Arrhythmia Syndromes

Carolyn H. Revercomb, MD, Northern District Office of the Chief Medical Examiner, Fairfax, Virginia, and Department of Legal Medicine, Virginia Commonwealth University School of Medicine, 9797 Braddock Road, Fairfax, VA 22032*

After attending this presentation, attendees will understand current methods of postmortem diagnosis of genetic arrhythmia syndromes.

Genetic arrhythmia syndromes, which are almost certainly under-diagnosed by medical examiners, have been theorized to cause some deaths from Sudden Infant Death Syndrome and have been implicated in the development of fatal arrhythmias during exercise. A presentation by an M.E. about cases where genetic analysis supported an etiology for fatal arrhythmia may encourage others to increase their index of suspicion for these disorders and to support efforts to develop cost-effective screening methods.

Genetic disorders predisposing to sudden death from arrhythmia in the absence of cardiac anatomic abnormalities account for an unknown number of deaths presenting to the medical examiner. Two cases illustrate the importance of clinical history in such deaths and the methods by which postmortem diagnosis of these conditions can be accomplished.

A 15-year-old girl collapsed in front of witnesses while swimming and died despite immediate medical attention. Autopsy revealed no injuries, anomalies or acute disease process, and electrolyte analysis and toxicology were non-contributory. Medical history was significant for two fainting episodes in the past year under conditions of emotional stress. Review of antemortem EKG's showed mild prolongation of the Q-T interval and increased Q-T with increased heart rate. Molecular studies of frozen myocardium have shown a mutation in a cardiac ryanodine receptor gene associated with catecholaminergic polymorphic ventricular tachycardia. Also present was a polymorphism in the KCNE1 potassium subunit gene; mutations in that gene have been associated with Long Q-T Syndrome. The death has been classified as due to cardiac arrhythmia; further molecular studies are ongoing.

A 43-year-old woman was found dead where she had been shoveling snow. A complete autopsy revealed no cause of death. The information that her previously healthy sister had collapsed and died on hearing of her death prompted molecular analysis of a liver specimen archived for toxicology. A mutation was present in a cardiac potassium channel gene known to be associated with congenital Long Q-T Syndrome.

Genetic sequencing for mutations associated with sudden death from fatal arrhythmia is expensive, time-consuming and not widely available. Review of the circumstances of death, family history and medical records following a negative autopsy facilitates selection of the rare case appropriate for molecular testing. Frozen myocardium is currently the best specimen for analysis, and should be retained in suspected cases.

Simplification of screening for known mutations or abnormal gene products would enhance the ability of the medical examiner to determine that a genetic arrhythmia syndrome caused a death. These conditions are heritable and can often be managed by pharmacotherapy, avoidance of

arrhythmia inducing substances and medications, and/or defibrillator placement. Surviving family members may therefore benefit from counseling and electrophysiologic screening. These interventions have the potential to save lives.

Long Q-T Syndrome, Molecular Diagnosis, Arrhythmia

G30 Is Hypertension a Risk Factor for Fatal Rupture of Intracranial Aneurysms?

Ana Rubio, MD, PhD, Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201; Christopher Cox, PhD, Division of Epidemiology, Statistics and Prevention, National Institute of Child Health and Human Development; DHHS, 6100 Executive Boulevard, Room 7B05, Bethesda, MD 20892; David Fowler, MD, Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD 21201; Juan Troncoso, MD, Neuropathology Unit; Department of Pathology, Johns Hopkins School of Medicine, 720 Rutland Avenue, Baltimore, MD 21205*

After attending this presentation, attendees will be able to describe detail of the characteristics of the subjects dying from ruptured berry aneurysms, including age, gender, and risk factors, detailed location, size, and anatomic extension of the subarachnoid hemorrhage depending on the location; and describe the risk factors for fatal rupture of berry aneurysms.

This presentation will impact the forensic community and/or humanity by demonstrating a better understanding of the epidemiology and risk factors of nontraumatic subarachnoid hemorrhage, specifically ruptured berry aneurysms

Background: Berry (saccular) aneurysms of the circle of Willis arteries are the most common cause of fatal subarachnoid hemorrhage in the absence of pre-existing trauma. The incidence of intracranial berry aneurysms increases with age, with a 1% prevalence in the overall population, 2% in middle age individuals and 5% in older people. The annual risk of rupture is estimated as 0.6%, with a very high fatality rate. Berry aneurysms have a multifactorial etiology. They are most commonly found at points of branching. An underlying defect in the wall of the vessel where the aneurysm subsequently forms is frequently found. They are familial in about 5% of the cases, and multiple in a similar percentage of cases. Besides age, other risk factors for the development and rupture of berry aneurysms are smoking, hypertension, heavy alcohol use or drugs. The role of hypertension in the development and rupture of aneurysms is controversial, and there are no previous studies correlating heart weight (raw or normalized) with the development or rupture of berry aneurysms.

Goals: To better define the population affected by fatal rupture of berry aneurysms and detect and characterize risk factors. A primary hypothesis of the study is that an increased heart weight represents a risk factor for aneurysmal rupture.

Subjects and Methods: We designed and performed a case-control study. Cases were all individuals autopsied at the Office of the Chief Medical Examiner for the State of Maryland in whom subarachnoid hemorrhage secondary to ruptured berry aneurysm was identified.

Two controls were selected per case in order to increase the power of the study. In order to minimize bias, controls were matched for age (within five years) and gender; we only selected individuals who died accidentally, and had an autopsy performed in our office, prior (one of the controls) or subsequent (the other control) to the matching case.

Anthropometric parameters including age, gender, race, height and weight were recorded. We obtained clinical information including history of smoking, alcohol or drug use and hypertension. At autopsy, heart weight, presence and severity of coronary atherosclerosis, brain weight and toxicologic findings were tabulated. Heart weight is normalized for height, weight and body surface, as previously described. In addition, detailed information regarding the ruptured aneurysm was con-

sidered for the cases (side, location, size, distribution of the subarachnoid hemorrhage, presence of additional, unruptured aneurysms). Data was analyzed by multiple logistic regression, with case/control status as dependent variable and heart weight and other predictors as potential risk factors.

Results: A total of 145 cases (65 women [aged 47.5+/-12.7 years] and 80 men [aged 44+/-10.7 years]) and 290 controls (130 women [aged 47.5+/-13.2 years] and 160 men [aged 43.9+/-11.1 years]) were included in the study. Results of the multiple logistic regression analysis include odds ratios and confidence intervals for additional risk factors.

Berry Aneurysm, Hypertension, Fatal Rupture

G31 Fatal Acute Thrombosis of Anomalous Right Coronary Artery Arising From the Left Sinus of Valsalva

Supriya Kuruvilla, MD*, Harris County Medical Examiner Office and University of Texas Health Science Center; J.A. Jachimczyk Forensic Center, 1885 Old Spanish Trail, Houston, TX 77054; Antonio Neto, MD, University of Texas Health Science Center, 6431 Fannin, MSB 2.120, Houston, TX 77030; Dwayne A. Wolf, MD, PhD, Harris County Medical Examiner Office, J.A. Jachimczyk Forensic Center, 1885 Old Spanish Trail, Houston, TX 77054

Anomalous origin of coronary artery(s) may be an isolated cause of sudden death. Many different mechanisms have been suggested. The goal of this presentation is to illustrate a previously undescribed complication of this anomaly, namely fatal acute thrombosis occurring in an anomalous right coronary artery, otherwise free of atherosclerosis.

Previously postulated mechanisms of death in cases of isolated anomalous origin of coronary arteries have focused on functional insufficiency of the coronary vessel because of periodic compression, either between great vessels, or within the aortic wall. The present case suggests that another mechanism of death may be acute thrombosis of the anomalous artery. This mechanism may be related to other postulated mechanisms through intraluminal turbulence.

A 63-year-old Caucasian woman was found dead in her secure residence. She was of average height and weight with no external or internal injuries. The aorta and great veins were normally distributed; moderate atherosclerotic plaques were in the aorta. The 600-gram heart had concentric left ventricular hypertrophy, measuring up to 2.1 cm; the right ventricle was 0.5 cm; hypertensive changes were evident in the kidneys. The myocardium was uniform with no diffuse or discrete zones of fibrosis. The valves had a normal configuration, but the aortic valve cusps were partially calcified with no vegetations.

The left main coronary artery originated normally, from the left sinus of Valsalva; the left main coronary artery bifurcated to give rise to the anterior descending and circumflex branches. The right coronary artery also originated from the same ostium in the left sinus of Valsalva and traveled between the aorta and the pulmonary artery. The proximal 0.2-0.3 cm segment of the right coronary was intramural within the aorta and had an ovoid, narrow lumen. A 0.3 cm occlusive acute thrombus was within the lumen of the right coronary artery, 0.5 cm from its origin, extending for a length of 1 cm. The thrombus was in the portion of the right coronary artery interposed between the aorta and the pulmonary trunk, just distal of the intramural segment. The right coronary artery supplied the posterior apical myocardium. The coronary arteries were free of atherosclerosis.

Several mechanisms of death have been proposed in cases of isolated anomalous coronary origin. Because of the abnormal position with respect to the aorta, these vessels typically follow a course between the great vessels. One possible consequence is compression between the great vessels (a "scissors" mechanism). Since the aorta and pulmonary arteries are distended at different phases of the cardiac cycle, and because the coronaries are filled primarily during diastole, strenuous

exercise, and consequent increased heart rate and shortening of the cardiac cycle, should present an increased risk of death for these patients. Indeed, most such deaths occur during strenuous exercise. Additionally, the proximal segment of the anomalous artery generally follows an intramural course; that is, it is within the aortic root, sharing tunica media with the aortic wall, without an intervening adventitia. This intramural segment typically has an ovoid cross section, and may well be further compromised with intra-aortic pressure. The latter mechanism is supported by clinical *in situ* intravascular ultrasound studies. In most cases the anomalous coronary emerges at an acute angle with the aortic wall, such that blood flow into the vessel would be less direct than in the "typical" arrangement. Other anatomic or functional features have been proposed, such as ostial ridges impeding flow into the vessel lumen. The present case indicates that another mechanism may occur in some patients, thrombosis of the anomalous origin. Turbulence of the intraluminal blood, perhaps caused by any (or a combination) of the other postulated mechanism(s) may lead to focal thrombosis. The absence of atherosclerosis in the thrombosed segment indicates that the anomalous origin was the likely cause of the thrombosis.

Anomalous Coronary Artery, Acute Thrombosis, Sudden Death

G32 Undiagnosed Cardiac Sarcoidosis and Sudden Death: Report of 14 Cases

Carol H. Allan, MD*, Ling Li, MD, Susan Hogan, MD, and Mary G. Ripple, MD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD 21201; Allan Burke, MD, Department of Defense, Armed Forces Institute of Pathology, 14th & Alaska Avenue Northwest, Washington, DC 20306; David Fowler, MD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD 21201

After attending this presentation, attendees will be able to recognize the significance of the postmortem diagnosis of sudden death due to undiagnosed cardiac sarcoidosis in the field of forensic medicine.

Cardiac sarcoidosis is often clinically silent. It has been reported that sudden death is the most common manifestation of myocardial sarcoidosis. Our study has demonstrated that it is important for forensic pathologists to consider cardiac sarcoidosis in sudden unexpected deaths and to perform a complete autopsy including histological examination of the regional lymph nodes in addition to the major organs.

The Office of the Chief Medical Examiner (OCME) for the state of Maryland documented 37 deaths caused by sarcoidosis from 1993 through January 2003. Of the 37 cases, 14 (37%) carried no previous diagnosis of sarcoidosis. Five of the 14 cases (36%) were witnessed to suddenly collapse (including 1 case of collapse after a non-fatal assault). The remaining 9 cases (64%) were found unresponsive at home. All 14 cases had a complete autopsy with histological and toxicological studies. The mean age of the 14 patients at death was 40 years (± 5.9 , range 35-47 years). There was an equal distribution of sexes (7 males, 7 females) with a race distribution of 12 African Americans and 2 Caucasians. The majority of the cases (79%) were clinically silent. Only 3 (21%) of the cases had a prior cardiac history, including one who had biventricular hypertrophy with cardiac pacing, one with congestive heart failure and 1 case with non-specific cardiac complaints. Other known medical conditions included depression (2), obesity (2), diabetes mellitus (2), and asthma (1).

The diagnosis of cardiac sarcoidosis was based on microscopic findings of non-caseating granulomatous inflammation involving the heart and at least one other organ (lungs and/or regional lymph nodes), or with microscopic evidence of cardiac involvement and grossly enlarged regional lymph nodes in the absence of evidence of other infection or other granulomatous processes.

Mean heart weight for all 37 cases was 518 g (± 140 , range 310-830 gm). Of the 14 cases of previously undiagnosed sarcoidosis, 13 (93%)

showed cardiac involvement. Five of the 13 (38%) cases had gross evidence of cardiac sarcoidosis that ranged from pericardial, epicardial or endocardial plaques to fibrosis of the ventricles and septum. However, the majority, 62% (8/13) of the cases showed no significant gross pathological changes in the heart and the diagnosis of cardiac sarcoidosis was made on histological examination. None of the 13 cases showed cardiac involvement alone. Three of the 13 (23%) cases had no gross evidence of disease in any organs. Of the 13 cases, non-caseating granulomatous inflammation was identified in the lung (13/13 cases), lymph nodes (5/5 cases with histological examination), liver (4/13 cases), spleen (3/13 cases), and kidney (2/13 cases). One patient died of extensive pulmonary sarcoidosis without cardiac involvement.

This report emphasizes the significance of the postmortem diagnosis of sudden death due to previously undiagnosed cardiac sarcoidosis. The implications of the medicolegal autopsy including histological examination are addressed.

Sarcoidosis, Sudden Death, Forensic Autopsy

G33 Accidental Insulin Overdose

Nick I. Batalis, MD, Medical University of South Carolina, 1032 Yorktown Drive, Charleston, SC 29412; Joseph A. Prahlow, BS, MD, South Bend Medical Foundation, 530 North Lafayette Boulevard, South Bend, IN 46601*

After attending this presentation, attendees will understand the postmortem laboratory tests required to make a diagnosis of insulin overdose.

This presentation will impact the forensic community and/or humanity by using a case of accidental insulin overdose which occurred in a hospital setting as an example, this paper addresses the difficult task of attempting to diagnose an insulin overdose after death. Guidelines are presented regarding the proper collection, storage, and evaluation of postmortem blood samples in cases of suspected insulin overdose.

Exogenous insulin has been used for many years to treat diabetes mellitus. Over the years there have been numerous accidental overdoses by these patients. However, in other instances insulin has been used as an agent for suicide and homicide in diabetics as well as non-diabetics. Presented here is a fatal case of accidental insulin overdose in a nondiabetic.

An 82-year-old white male, postoperative day 12 from incarcerated hernia repair, was transferred to the hospital's rehabilitation unit for care of continuing medical problems. A week after admission to the unit, the patient's nurse entered his room to check on him and to flush his PICC line. One hour later, the patient was noted to be in distress and a "Code Blue" was called. During the code a rapid blood sugar was found to be low and the physician ordered one ampule of D50 to be given. Blood glucose was 13 mg/dl initially and 33 mg/dl (normal range 64-105 mg/dl) eighty minutes later. During the code, it was noted that the PICC line was not usable, as it had "clotted-off." The patient's clinical course became substantially worse following this event and he died two days later.

Autopsy, limited by previous embalming, revealed severe hypertensive and atherosclerotic cardiovascular disease. Laboratory testing on a blood sample stored from the night of the hypoglycemic event included a C-peptide level of 0.9 ng/ml (normal range 1.1-4.6 ng/ml) and an insulin level of 297.5 (normal range 0-22.7 mIU). The cause of death was determined to be insulin overdose. Investigations were conducted to detect the cause of this incident. It was deemed that the patient mistakenly received from 100 units to 500 units of insulin. No reason or evidence of malicious administration could be found during investigation. Investigation concluded that nursing personnel accidentally flushed the PICC line with insulin, instead of heparinized saline. The containers for heparinized saline and insulin are of similar size and appearance.

Insulin is a major regulatory hormone that serves to lower the serum concentration of glucose. A proinsulin molecule, consisting of a two peptide chain molecule (insulin) linked by a connecting peptide (C-peptide), is synthesized in the beta cells of the pancreas. Rising serum glucose causes cleavage of the proinsulin molecule and yields the active insulin molecule and the inactive C-peptide in a 1:1 ratio. A major difference between commercial insulin and endogenous insulin is the absence of C-peptide in commercial preparations. With a large dose of exogenous insulin, the expected laboratory values include an elevated insulin level and a low C-peptide level.

Considering the difficulty of making a diagnosis of hypoglycemia postmortem, the interpretation of insulin and C-peptide levels becomes a crucial aspect of making a diagnosis of insulin overdose. In the case of a diabetic individual, postmortem anti-insulin antibody levels and free and total insulin levels also are appropriate tests. Peripheral blood is preferred as blood samples from the right heart have much higher insulin levels than peripheral blood. All samples should be placed in red-top serum separator tubes, spun down, and frozen as soon as possible. Samples for insulin and C-peptide levels are also valid in green-top plasma tubes, when spun down and frozen as above. Samples in purple-top EDTA tubes are not valid for analysis, nor are hemolyzed specimens. Anatomic autopsy findings in cases of insulin overdose are often unremarkable.

In any case of insulin overdose a comprehensive scene investigation to document the amount and type of insulin used, along with information revealing the source of the insulin is crucial. In addition, a complete autopsy, including appropriate laboratory studies, is needed to make a firm diagnosis in these cases. Special attention should be given to properly collecting and storing blood samples, as these specimens often yield the strongest evidence of insulin overdose.

Insulin Overdose, Accident, Complication of Therapy

G34 Unexplained Sudden Death and the Likelihood of Drug Abuse

Amy C. Gruszecki, MSFS, DO and Gregory G. Davis, MD, MSPH, Jefferson County Coroner/Medical Examiner Office, 1515 Sixth Avenue South, Room 611, Birmingham, AL 35233-1601*

After attending this presentation, attendees will be able to define the relationship between drug abuse and deaths where neither anatomical nor toxicological cause for death is found.

This presentation will impact the forensic community and/or humanity by recognizing that a history of drug abuse may be sufficient to explain death in appropriate circumstances, just as chronic alcoholism can be accepted as a cause of death even in the absence of acute ethanol intoxication.

Rationale: Our office regularly receives cases of young adults with a history of drug abuse who have died suddenly and unexpectedly in whom neither anatomical nor toxicological cause for death is found at autopsy. In forensic pathology, these deaths are likely to be classified as undetermined in cause and manner. The common presence of a history of drug abuse, however, has led us to hypothesize that drug abuse induces some change that increases the risk of sudden death and that this change persists after the drug is no longer detectable in the body.

Methods: We conducted a retrospective case-control study of deaths investigated by the Jefferson County Coroner/Medical Examiner Office, Alabama between 1986 and 2002. The study group consisted of decedents between 10 and 70 years of age whose cause and manner of death remained undetermined following an autopsy and toxicological analysis for ethanol and drugs of abuse. The control group was chosen to most closely represent a random sampling of the population of Jefferson County, Alabama. The decedents chosen for the control group were either pedestrians or passengers in motor vehicle accidents, people

who died suddenly and unexpectedly while engaged in ordinary pursuits. Every decedent in the control group received an autopsy and toxicology analysis for ethanol and drugs of abuse. The control group was age matched to the study population within 5 years of the age of the study decedent and within 2 calendar years of the date of death of the study decedent (to keep social trends similar). The charts of all cases and controls were reviewed for the circumstances surrounding death, a documented history of drug abuse, and any compelling physical signs at autopsy that indicated drug use, i.e. needle track marks, nasal septum perforation, or polarizing particles in foreign body giant cells within the lungs. All toxicology results were noted including the presence of cocaine, any other drugs or medications, and ethanol. Decomposed remains were included in the study.

Results: The study group of undetermined deaths consisted of 62 decedents, 24 of whom had some evidence of drug abuse (history, physical signs, positive toxicology for cocaine or its metabolites in urine or bile, opiates, or methamphetamine). In the matched control population 9 decedents had a positive drug history or a drug of abuse detected by toxicology or both. These results are shown below.

	Evidence of drug abuse	No evidence of drug abuse	Total
Case study group (undetermined cause)	24	38	62
Control group (pedestrian or wreck)	9	53	62
Total	33	91	124

Analysis of these data shows that a decedent with a history of drug abuse has a risk odds ratio of 3.7 (95% confidence interval 1.59-8.69). In other words, an individual with an undetermined cause and manner of death is 3.7 times more likely to have evidence of drug abuse as is an individual who dies in a motor vehicle collision as either a pedestrian or passenger. For this study $p = 0.0015$, so chance is an unlikely explanation for these results. Nor is simple intoxication alone the explanation for death in the study group. Analysis revealed no statistically significant difference between the study group and the control group for the presence or absence of ethanol in the blood at the time of death.

Conclusion: A history of drug abuse is far more common in sudden, unexplained deaths than it is in a control group chosen to represent a random sample of the population, even in the absence of a level of drug sufficient to account for death at the time of death. Research suggests that cocaine use in particular induces chronic biochemical and physiological changes that persist beyond the presence of circulating cocaine in the blood, just as the induction of hepatic enzymes by alcohol persists beyond the presence of ethanol in the blood. These findings imply that a history of drug abuse may be sufficient to explain death in appropriate circumstances, just as chronic alcoholism can be accepted as a cause of death even in the absence of acute ethanol intoxication.

Sudden Death, Drug Abuse, Cocaine

G35 Acute Bacterial Meningitis With Predominance of Immature Granulocytes

Reade A. Quinton, MD*, University of Texas Southwestern Medical Center, Department of Pathology, 5323 Harry Hines Boulevard, Dallas, TX 75390-9073; Loren Clarke, MD and Javad Towfighi, MD, Penn State Milton S. Hershey Medical Center, Department of Anatomic Pathology - H179, 500 University Drive, PO Box 850, Hershey, PA 17033-0850; Jeffrey J. Barnard, MD, Southwestern Institute of

Forensic Sciences, 5230 Medical Center Drive, Dallas, TX 75390; Rene L. Galindo, MD, PhD and Philip J. Boyer, MD, PhD, University of Texas Southwestern Medical Center, Department of Neuropathology, 5323 Harry Hines Boulevard, Dallas, TX 75390

This presentation highlights three cases of acute meningitis with a predominance of immature granulocytes and compares these cases to a retrospective evaluation of cases diagnosed as "acute meningitis."

While a rare phenomenon, knowledge of the fact that immature granulocytes may constitute the principle cell type in the CSF and subarachnoid space of acute bacterial meningitis may prevent misclassification of these cells at the time of evaluation of CSF in the hematology and cytopathology laboratories and during surgical and autopsy pathology examinations.

Background: Bacterial meningitis, in its acute stage, is typically characterized by a "purulent" inflammatory cell infiltrate of abundant polymorphonuclear cells and necrotic debris. Intracellular or extracellular bacteria can be observed in some cases. The neutrophils seen are typically mature, or degenerating. As the process gains chronicity, neutrophils are eventually replaced by mononuclear cells. Recognition of neutrophils in the cerebrospinal fluid (CSF), as opposed to mononuclear cells (macrophages and lymphocytes), is a key clinical finding that guides therapy.

Case Reports: During a period of a year, at two institutions, a total of three fatal cases of acute bacterial meningitis were evaluated at autopsy in which the predominant cell type was immature granulocytes with only rare polymorphonuclear cells recognized.

Case 1: The first case involved a 12-year-old female with a history of morbid obesity and systemic lupus erythematosus, treated with corticosteroids. She was reported to have collapsed suddenly after a two day history of fever, diarrhea, and dark urine. Despite resuscitation efforts, the patient could not be revived and she was pronounced brain-dead the following day. Peripheral blood evaluation had demonstrated a marked left shift. CSF was not evaluated. She had been treated for 1.5 days with antibiotics prior to her demise. An autopsy revealed an inflammatory infiltrate composed of predominantly immature and mature granulocytes within the meninges, lungs, gastric mucosa, and adrenal glands. The bone marrow was normal, suggesting that these cells were the result of a left shift. Organisms were not initially identified by histology, histochemistry, or culture, but subsequent immunohistochemical testing performed at the Center for Disease Control was positive for *Neisseria meningitidis*.

Case 2: The second case involved a one day old female infant, born at 36 weeks estimated gestational age. At birth the infant was unresponsive with Apgar scores of 0, 1, and 5, requiring aggressive resuscitation. Blood cultures identified a *Listeria monocytogenes* bacteremia, and the patient died the following day. Development of a marked left shift occurred during a 20 hour period on a series of three peripheral blood smears. CSF was not evaluated. Antibiotics had been administered prior to death. An autopsy demonstrated miliary microabscesses involving the trachea, lungs, esophagus, stomach, intestine, liver, spleen, and adrenal glands. In addition, an inflammatory infiltrate within the leptomeninges showed a predominance of immature granulocytes rather than mature neutrophils. *Listeria monocytogenes* was cultured from lung and meningeal samples.

Case 3: The third case involved a 44-year-old male with a history of paranoid schizophrenia. He had no known history of immunosuppression and did not drink alcohol or abuse drugs. He had been in his usual state of health until one day prior to his demise when he had complained that he "felt bad." The next morning he was found unresponsive on the floor next to his bed. He was not taking antibiotics prior to his demise. At autopsy, histologic examination of the meninges revealed a dense inflammatory infiltrate of immature granulocytes. Postmortem cultures of cerebrospinal fluid were positive for *Neisseria meningitidis*.

Materials and Methods: Histologic sections were evaluated by hematoxylin and eosin and Gram stains and immunohistochemically for

CD68, CD20, CD3, and myeloperoxidase. Findings from these cases were compared to and contrasted with, by retrospective evaluation, all routinely diagnosed acute bacterial meningitis cases in our database.

Results: Myeloperoxidase positive immature granulocytes constituted the predominant cell type in each of the three cases; only very rare segmented forms were identified. Scattered admixed CD68 positive macrophages and CD3 positive T lymphocytes were identified; only rare CD20 positive B lymphocytes were identified. Gram stain failed to identify bacterial clusters in any of the three index cases.

Discussion: While a rare phenomenon, knowledge of the fact that immature granulocytes may constitute the principle cell type in the CSF and subarachnoid space of acute bacterial meningitis may prevent misclassification of these cells at the time of evaluation of CSF in the hematology and cytopathology laboratories and during surgical and autopsy pathology examinations. The organism, treatment, and host factors that may predispose toward manifestation of immature granulocytes in these patients remains unclear.

Acute Bacterial Meningitis, Autopsy, Forensic Science

G36 Coronary Artery Anomalies and Sudden Death: Two Case Reports in Young People

Margherita Neri, MD*, Department of Forensic Pathology, University of Foggia, Viale Pinto 1, Foggia 71100, Italy; M. Di Pudua, MD, Institute of Forensic Medicine, University of Foggia, Ospedali Riuniti Via Luigi Pinto n. 1, Foggia 71100, Italy

The goal of this presentation is to present to the forensic community two cases of sudden death due to coronary artery anomalies by autopsic and clinicopathologic findings and histological studies.

This presentation will impact the forensic community and/or humanity by presenting to the forensic community two cases of sudden cardiac death due to rare coronary artery anomalies in young people. These two cases have been studied by means of autopsic and histological examinations. It would be an important contribute to the scientific community for the diagnosis of one of the possible causes of sudden death in infant and young people.

Coronary artery anomalies may cause sudden death. This presentation discusses the clinicopathologic features, the autopsic findings and microscopic features in two cases with different coronary anomalies.

Case 1: A 13-month-old infant, white male, was found unresponsive in his crib. The infant was transported to the hospital, where resuscitative efforts were unsuccessful, and the infant was pronounced dead. Previous clinical history: at the age of 6 months numerous episodes of apnea's crisis, cyanosis and convulsion and at the age of 7 months, the infant was diagnosed as epileptic. Cardiologic examinations (ECG, echocardiogram, Holter monitor evaluation) and chest X-Ray were normal.

The autopsy revealed a well developed and well nourished 13-month-old white male. All internal organs were in their normal anatomic relationship. The heart, in the fresh state, weighed 45 grams. Upon sectioning, the myocardium was reddish. Atrio-ventricular and semilunar valves were normal. The right coronary artery arose from the left sinus of Valsalva associated to a tunneled passage of the posterior interventricular coronary artery. The first section of this artery presented a take-off and a passage between the aortic and pulmonary root. The coronary circuit was dominant to the right.

The histological examination of the cardiac tissues revealed diffused and biventricular myocytolysis in contractile subendocardial bands characterized by altered, eosinophilic, hypercontracted myofiber. In many areas the myofiber appeared fragmented into irregular, partially acidophilic transverse bands. The immunohistochemical exams, effected on cardiac fragments, resulted positive to the anti - desmin and anti-actin antibodies, and negative to the anti C5 antibodies. Examination of the other organs were unremarkable except for pulmonary edema and polyvisceral stasis.

Case 2: A 22-year-old white male collapsed and died while exercising in a swimming pool; prompt medical assistance and attempted resuscitation were unsuccessful. At the age of 21, he was hospitalized in a Neurological Clinic, where instrumental and clinical data suggested the diagnosis of Friedreich's ataxia. The subject underwent molecular genetic analysis for the FA gene that revealed neither expansion nor point mutation of the FA gene. One year later, he was hospitalized at another Neurological Clinic where a general examination showed kyphoscoliosis, pes cavus, and a neurologic examination showed nystagmus, hypotonus, distal hypotrophy of the arms and legs, ataxia, areflexia, abnormalities in superficial and deep sensations. Ncv and EMG examinations were compatible with a severe axonal-myelinic sensory-motor neuropathy, while vitamin E, B12, folic acid, antigliadin antibodies, hexosaminidase, transferring isoforms, lactate and pyruvate were all normal. The diagnosis was spinocerebellar heredodegeneration, Friedreich's type. A treatment with idebenone, CoQ100 and Vitamin E associated with physiotherapy was suggested.

At autopsy the body was that of a well-developed young adult. Skin, ostia, oral and scleral mucosae were normal. On evisceration the heart had a normal intrathoracic position with the following diameters: longitudinal 11 cm, transversal 13 cm and antero-posterior 7 cm; the weight was 475 gr. On opening, the ventricular chamber was 30 mm wide, the wall and the inter-ventricular septum measured 28 mm each. The endocardium was white, smooth and bright, no trombi or vegetations were detected. Atrio-ventricular and semilunar valves were normal. The right coronary artery normally arose from the right ostium. In the left sinus of Valsalva two distinct ostia were detected instead of the left coronary artery ostium. The diameters of the two ostia measured 1,5 and 2,5 mm respectively and were separated by a septum that divided the stem determining a separate origin of the two left coronaries. Incannulation and a careful dissection demonstrated that the larger ostium was one of the circumflex branch, the smaller one the ostium of the anterior branch.

The histological examination of the sections revealed diffuse interstitial fibrosis due to the presence of thin fibrous septa dividing the muscle cells. Miocytes showed fragmentation of the fibers, nuclear enlargement, sometimes pyknosis and cytoplasmatic vacuolization. A section taken from the interventricular septum showed hemorrhagic infiltration of the wall with single erythrocytes between the single myocytes and small blood extravasations. Examination of the other organs were unremarkable except for pulmonary edema and polyvisceral stasis.

The autopsic findings and the histological studies effected lead us to conclude that these are both cases of sudden cardiac death in subjects affected by coronary anomalies.

In the first case death was caused by cardiac arrhythmia sustained by myocardial hypoxia induced by an anomalous origin of the right coronary artery from the left Valsalva sinus.

In the second case death was caused by cardiac arrhythmia, sustained by myocardial hypoxia induced by an anomaly of the left Valsalva sinus, divided into two distinct ostium: one in the anterior interventricular coronary and one in the circumflex associated with myocardial hypertrophy, in subjects affected by Friedreich's ataxia.

Congenital coronary anomalies constitute a statistical incidence of 0,3-0,8% and represent 0,1-2% of all congenital cardiac conditions worldwide. If we consider the anomaly originating of the right coronary artery from the left Valsalva sinus, as revealed in one of the two cases examined, the prevalence from autopsic studies is reduced to 0,026%.

Congenital anomalies of the coronary arteries present great difficulties in diagnosis because these diseases can be absolutely asymptomatic and, although rarely, can manifest themselves with syncopal episodes or with a fading symptomatology leading to heart failure. However, the prognosis is influenced by the seriously of coronary anomaly.

The anomalous origin of the right coronary artery from the left Valsalva sinus has long been considered a mostly benign disease and only in 1982 three cases of sudden death are described whose cause depends on this type of congenital alteration.

In literature, the stenosis or coronary take-off in the initial tract are interpreted as causing ischemia and sudden death.

The origin of the right coronary artery from the left sinus may be an incidental observation during autopsy. Ischemia is usually precipitated by strenuous, prolonged effort, and this explains why a basal ECG or even a stress test ECG may be negative. Syncopal episodes are the only prodromal symptoms. Repetitive ischemic episodes may cause patchy myocardial necrosis and fibrosis as well as ventricular hypertrophy, which eventually can elicit arrhythmias because of the malignant combination of acute and chronic substrates. This may explain why sudden death, associated with an anomalous origin of a coronary artery from the wrong sinus, may occur in adults even though the anomaly has been present since birth.

An anomalous origin of the left circumflex artery from the left coronary sinus itself with a separate ostium, has also been described in victims of unexpected arrhythmic sudden death. This anomaly was considered a benign condition until cases were reported, both clinically and pathologically, with evidence of myocardial ischemia in the absence of obstructive coronary atherosclerosis or causes other than the malformation itself.

It should be noted that in cases of coronary anomalies sudden death, in children and young adults, often occurs during or following physical exertion. In the second case reported death occurred during physical activity and the anomaly of the left Valsalva sinus, divided into two distinct ostium: one for the anterior interventricular coronary and one for the circumflexed, was associated with cardiac hypertrophy, a pathology present very frequently in subjects affected with Friedreich's ataxia.

Sudden Death, Anomalous Origin Coronary Artery, Contraction Band Necrosis

G37 Neurofibromatosis Type 1 Associated With Hydrocephalus and Acute Cardiac Failure: A Fatal Case

Sabina Di Donato, MD, Arcangela Marucci, MD, and Francesco M. Morreale, MD, Department of Forensic Pathology University of Foggia, Viale Pinto n.1, Foggia, Puglia 71100, Italy*

The goal of this presentation is to contribute to the diagnosis of the cause of death in a case of intracranial hypertension due to hydrocephalus and associated acute cardiac failure.

This presentation will impact the forensic community and/or humanity by providing a rare case of tetraventricular hydrocephalus associated with intracranial hypertension and acute cardiac failure in a young boy affected by neurofibromatosis type 1. Disturbance in central sympathetic control resulting in sympathetic hyperactivity has been suggested to be the most likely mechanism responsible for the cardiovascular complications during acute ICH. It would be an important contribute to the scientific community for the diagnosis of the cause of death in ICH.

Test: Neurofibromatosis type 1, also known as von Recklinghausen's disease, is an autosomal dominant genetic disorder, with an extremely wide range of manifestations, and a multisystemic involvement; its incidence is of 1 in 3,500 newborns, and its prevalence of 1 in 4,500 newborns, this makes it one of the most common inherited diseases. It is caused by a mutation of the NF1 gene, located on the chromosome 17, whose product, the neurofibromin, is a GAP-protein which functions as a negative growth regulator, and is thought to be a tumor suppressor. NF1 is clinically characterized by its cutaneous manifestations, café au lait spots, axillary and inguinal freckling, Lish nodules, and multiple neurofibromas with a variable clinical expression,

even in the affected members of the same family. The complications of this disease are numerous and can often be fatal. One severe complication is represented by the development of malignant tumors. The less known vascular lesions, in particular in the arterial tree, may also represent a potentially important complication of NF1, in fact they may be the cause, for example, of hypertension, aortic coarctation, cerebral and visceral infarcts, haemorrhage resulting from aneurysms rupture, etc. Moreover, also cardiovascular abnormalities may occur in NF1, in particular cardiovascular malformations (2.3% of patients) such as pulmonary stenosis, aortic coarctation, etc., hypertrophic cardiomyopathy, and other miscellaneous cardiac abnormalities (such as intracardiac tumors, mitral valve prolapse, aortic dilatation, etc.). Other severe complications are hydrocephalus, and osseous dysplasia, which causes severe scoliosis.

We have seen that patients with NF1 have an increased risk for a variety of cardiovascular disorders (vasculopathy, hypertension, congenital heart defect, etc.), but we want to underline that, in some cases, they are the direct complications of NF1 itself that may induce fatal cardiac disorders.

Case Report: A 12-year-old white male, affected by neurofibromatosis type 1 was admitted to our University Hospital with the suspected diagnosis of meningitis. He was diagnosed as having NF1 at the age of 4-years-old, on the basis of the clinical manifestations. His mother was also affected by NF1. The family history was negative for cardiovascular disease. On physical examination upon admission he measured 155 cm in height, and 48 Kg in weight. He presented dysmorphic features including coarse face with frontal bossing, flat nasal bridge, large nose with anteverted nostrils, large lips, prominent mid-face, numerous café au lait spots (> 1.5 cm) over the body, axillary and inguinal freckling, and multiple dermal and nodular neurofibromas over the trunk and limbs. Moreover he presented macrocephalia (head circumference 58,5 cm), neck stiffness, headache, and he had a temperature of 38°C with vomit for three days. On neurological examination the patient appeared conscious, but sleepy. The remaining physical examination was otherwise unremarkable. The laboratory analysis excluded signs of inflammation.

An urgent CT cranium revealed a tetraventricular hydrocephalus. In the meantime the clinical conditions got worse: the child presented a violent headache, agitation, cyanosis. So he underwent surgery for an emergency ventriculo-peritoneal shunt, 20 cc of clear fluid were drained, but during the operation he had a bradycardia, which progressed to cardiac arrest, and then he died for a cardiocirculatory arrest. Death was attributed to acute cardiac arrest during intracranial hypertension resulting from tetraventricular hydrocephalus.

A complete autopsy was performed. External examination confirmed the clinically noted features of NF1. Internal examination of the cranium revealed an edematous brain, which measured gm 1900 (normal 1400 gm) in weight, with tetraventricular hydrocephalus, a glioma of the left optic nerve, and vasal congestion. Both lungs were heavy and reddish (right 350 g, normal 210, left 300 g, normal 190). The heart weighed 140 g (124 norm), and was in appearance normal in all respects. The epicardial coronary arteries arose normally in a right dominance manner. The autopsy examination was otherwise normal. Microscopic sections of the brain showed a marked edema, cribriosis, little intraparenchymatous haemorrhages, vasal congestion. In the lung it was found edema, acute emphysema, acute stasis, endoalveolar haemorrhages, areas of fibrosis, while in the heart numerous foci of contraction band necrosis, acute stasis, and areas of disarray were found.

The cardiac histological findings require a careful investigation and an adequate interpretation. Contraction band necrosis is a specific morpho-functional entity. Histologically, this form of necrosis is characterised by irreversible hypercontraction of the myocell, extremely short sarcomeres, with markedly thickened Z-lines, paradiscal lesion which progresses to a breakdown of the whole contractile apparatus. This breakdown varies from irregular, pathological and eosinophilic cross-bands, consisting of segments hypercontracted or coagulated

sarcomeres, to a total disruption of myofibrils, the hole cell assuming a granular aspect without visible clear-cut pathological bands. CBN is observed in many human pathologies, it is not an ischemic change, but the expression of catecholamine toxicity, as confirmed by experimental intravenous catecholamine infusion, and by the equivalent human cases with pheochromocytoma. The excess of catecholamines produces cardiotoxicity through two mechanisms: a) a direct cardiotoxicity, due to the binding of catecholamines to adrenoceptors; b) an indirect cardiotoxicity, due to the formation, during the metabolism of the catecholamines, of highly toxic substances such as aminochromes (adrenochrome) and free radicals, which damage different types of heart membranes, causing intracellular Ca^{2+} overload and myocardial cell damage. The finding of CBN, even if microfocal, could be an important histological signal for interpreting the cause of death and the natural history of a disease in any single patient. It may represent a sign of adrenergic stress linked with malignant arrhythmia/ventricular fibrillation.

Now it only remains to clarify which has been the cause of such catecholamine surge. The obstructive hydrocephalus related to NF1, generally results from a periaqueductal gliosis which may cause the stenosis of Sylvius's aqueduct, or the blockage of the IV ventricle, resulting in the block of the draining of the cerebro-spinal fluid, the hyperdistension of the upper ventricular cavities, and the increase of the intracranial pressure. In literature there is evidence of myocardial injury following acute intracranial hypertension. It is well established that traumatic head injury with intracranial hypertension (ICH) initiates a cascade of physiological but deleterious events that result in haemodynamic perturbations, electrocardiographic abnormalities. Recent clinical and experimental studies have demonstrated that the pressor and dynamic response of the heart to head injury with acute ICH is mediated by catecholamine surge, which represents a stress response, mediated by medullary vasomotor centers, triggered by the increased circulatory needs consequent to the decreased cerebral perfusion that follows the sudden ICH. The transient hyperdynamic response of the heart following the excessive sympathetic nervous activation is short-lived and gives way to cardiovascular collapse. In failed hearts, there is histologic evidence of focal myocardial damage that is characteristic of catecholamine-mediated cardiac necrosis.

The patients affected by NF1 have a reduced lifetime expectancy, because of an increased risk for a variety of fatal disorders, which may be the direct complications related to NF1, but also diseases due to the complications themselves. In the case we report, the obstructive hydrocephalus related to NF1 causes an acute ICH resulting in central sympathetic hyperactivity, that is responsible for the cardiovascular complications during acute ICH.

Neurofibromatosis 1, Hydrocephalus, Sympathetic Hyperactivity

G38 A Cluster of Child Deaths: A Medical Examiner System Participates in an Epidemiologic Investigation in Virginia

Mary Jo Martin, MD, Office of the Chief Medical Examiner, 400 East Jackson Street, Richmond, VA 23219; Wendy M. Gunther, MD*, Office of the Chief Medical Examiner, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510; Lisa A. Weymouth, PhD*, Virginia Division of Consolidated Laboratory Services, 600 North 5th Street, Richmond, VA 23219; Elizabeth L. Kinnison, MD, Office of the Chief Medical Examiner, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510; Deborah Kay, MD, Office of the Chief Medical Examiner, 400 East Jackson Street, Richmond, VA 23219; William T. Gormley, MD and Marcella F. Fierro, MD, Office of the Chief Medical Examiner, 400 East Jackson Street, Richmond, VA 23219*

After attending this presentation, attendees will learn how to recognize a developing cluster of deaths in children; how to cooperate with

the Centers for Disease Control, local and national laboratories, and public health departments in analyzing the deaths of individuals involved in a cluster, allaying public fears, and meeting media demands; and to avoid mistakes previously made.

This presentation will impact the forensic community and/or humanity by increasing the ability to recognize a developing epidemiological cluster, and how to optimally communicate with all parties involved, including colleagues at a local and national level, parents and relatives of the decedents, the "worried well," and the media.

A two-year-old girl with a history of multiple upper respiratory infections, and a prodrome of a week of ear pain and fever, presented to an emergency room at 0300 in the morning with a fever of 102 degrees F. She was diagnosed with otitis media, and prescribed antibiotics. Five hours later, she was found dead in bed. Autopsy showed no evidence of bacterial infection; a viral infection was suspected. On the day of her autopsy, a three-year-old boy was diagnosed at a local military hospital clinic with a viral upper respiratory infection. He died in his sleep at home the next morning, after lying on the living room floor watching cartoons, with his mother asleep nearby on the couch. Within three days, two more children in the same geographic area had died at home after short febrile illnesses. When the four deaths were reported, media attention and public concern became intense.

The medical examiner system of the Commonwealth of Virginia was put on alert, and invited the Center for Disease Control to participate in analyzing the developing cluster, utilizing fluids and tissues obtained at autopsy. Two more children died in the following week, and three more in the next ten days. Early results were conflicting and noncontributory. Several weeks passed before it could be determined that this was a temporal cluster of unrelated childhood deaths, that there was no single pathogen responsible, and that the public had been protected.

This half hour discussion follows the experience of multiple medical examiners within a single statewide system coping with an unexplained cluster of child deaths. We review the recognition of the development of the cluster. We re-examine how we dealt with the issues of cooperation with public health colleagues, the CDC, and the laboratory, as well as communicating optimally with each other, the bereaved parents, the media, and the public. We revisit how we learned to utilize the CDC's expertise and resources, while performing optimal post mortem examinations within our medical examiner system. It was necessary to implement new methodologies that were foreign to our system, if well known to the CDC, and to develop new networks of communication as we relied upon colleagues in different states and many different institutions. The goal was to find answers for grieving families, bewildered colleagues, a hysterical public, and the voracious media. Special attention will be paid to the mistakes that were made, and how they could have been handled differently.

Child Death, Epidemiologic Cluster, Infectious Etiology

G39 Police Custody Deaths in the State of Maryland: Passing the Torch

Pamela E. Southall, MD, Ling Li, MD, and David Fowler, MD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD 21201*

The goal of this presentation is to highlight and briefly discuss the major autopsy findings of deaths that occurred during police custody in the state of Maryland.

Medicolegal Investigation of police custody deaths has been a great challenge to our forensic investigators. It may be argued that much more information is needed on this subject. The establishment of a national database has been discussed. It should combine national statistics as well as grouping the information by state. It is hoped that recognizing more trends will perhaps establish criteria that may ease the difficulty of investigating and thus rendering a decision in these cases. Most impor-

tantly, established criteria may assuage the public's perception of police misconduct and ultimately save more lives.

This retrospective study was undertaken to enhance the academic examination of these potentially volatile cases. The Office of the Chief Medical Examiner (OCME) has jurisdiction over all municipalities in the state of Maryland, including twenty-three counties and the city of Baltimore. A total of twenty-five deaths that occurred during police custody were investigated by the OCME from 1993 through 2003. Examination of each case included the autopsy report, the police report, the investigative report and photographs. Highlighted characteristics included race, age and sex distribution, jurisdiction, nature of incident, type of restraint used, autopsy findings, toxicological findings and the cause and manner of death.

Nineteen of the cases involved African-American men, most of whom were in their thirties. Twenty-one of the incidents occurred in the major urban areas of Baltimore City (16) and Prince George's County (5). Cocaine use was found in twelve of the cases.

The reasons for police involvement and the use of restraints included physical assault against another person, irrational behavior and other aggressive actions. The primary methods of restraint involved handcuffing. Eight cases involved the use of handcuffs in the prone position. Four of the eight handcuffed cases had leg irons also. One subject was hog-tied and placed on his side.

Common autopsy findings included abrasions and contusions of the face and extremities. Petechial hemorrhages were found in three cases. Subgaleal hemorrhage was the most commonly documented internal injury. Cocaine intoxication contributed to the cause of death in twelve cases. The manner of death was concluded as undetermined in fourteen cases.

Literary review has recognized some common variables involved in these cases. Most notably, the risk of the prone restraint position and understanding the increased risk of death in individuals experiencing excited delirium caused by either illicit drug usage or psychiatric disorders.

Given the intense public scrutiny that surrounds these cases, it is the manner of death that requires the greatest objectivity when investigating these deaths. The circumstances of each case should stand independently of prior, similar incidents. A primary reason for the difficulty of custody death investigation is the paucity of evident, lethal physical injury. These cases exhaust the importance of the combined major facets of post-mortem examination, specifically the autopsy, the toxicology report and scene investigation. More than usual, heightened cooperation between law enforcement personnel and the medical examiner investigating the case is required.

Police Custody, Death Investigation, Autopsy

G40 Characterization of Recent Cocaine and Methadone-Related Death Trends in Caddo Parish, Louisiana, With Comparison to National Trends

Elizabeth J. Miller, MD, Caddo Parish Coroner's Office, 1704 Market Street, Shreveport, LA 71101; Sharon Brooks, Jacksonville State University, Jacksonville, AL 36265; Patricia Dooley-Netherland, and George M. McCormick III, MD, PHD, Caddo Parish Coroner's Office, 1704 Market Street, Shreveport, LA 71101*

After attending this presentation, attendees will recognize recent trends in drug-related deaths, specifically cocaine and methadone-related.

Cocaine has dominated the picture in drug-related deaths presenting to the forensic pathologist. Recently, there has been a trend toward decreased cocaine-related deaths and increased methadone-related deaths. Unlike cocaine, methadone is not ordinarily considered

an illicit drug, as it is regularly prescribed to heroin users (methadone maintenance programs) and to those with chronic pain. The forensic pathologist will become aware of the increase in methadone-related deaths in general, and the community-specific demographics with respect to each drug.

This study explored a local trend in cocaine and methadone-related deaths for years 2000 through 2002, with comparison to those seen in the major U.S. metropolitan areas. The general local trend in decreased cocaine-related deaths with concurrent increased methadone-related deaths paralleled that in many of the major metropolitan areas in which drug data was available. Discrete local trends were noted with respect to age, race, sex and marital status.

A recent increase in methadone-related deaths has been documented in medical and forensic literature, as well as in the mortality data from the Drug Abuse Warning Network (DAWN). A preliminary assessment of drug-related deaths presenting to the Caddo Parish Coroner's Office in Shreveport, LA, revealed a similar trend, therefore a comparison of local and national demographic data was performed to further characterize this trend.

We conducted a search of cases presenting to the Caddo Parish Coroner's Office between 2000 and 2002 in which death was attributed to drug use. Drugs found on toxicological analysis, as well as demographic information were documented. Finally, we compared our local demographic data with that provided in the most recent available (2000 and 2001) DAWN mortality analyses.

The search of local records yielded 22 cases, all listing either cocaine (13) or methadone (9) as contributing to death. Polypharmacy was documented in 2 of the cocaine-related deaths and in 5 of the methadone-related deaths; however, this was not pursued further as the cocaine/methadone-related mortality trend was the focus of this study. The results are listed in the table below.

Drug	Year	No. Cases	Mean Age (yrs)	Race		Sex		Marital Status	
				B	W	M	F	M	S
Cocaine	2000	7	34	5	2	5	2	0	7
	2001	4	57	3	1	3	1	2	1
	2002	2	51	1	1	1	1	1	unk
Methadone	2000	1	32	0	1	1	0	1	0
	2001	2	37	0	2	1	1	1	1
	2002	6	37	1	5	3	3	4	2

M=married S=single (never married, divorced, widowed)

These results show a gradual transition from greater cocaine-related deaths to greater methadone-related deaths in the years 2000 to 2002. Cocaine-related deaths were seen more often in a younger population of black males (mean 34 years) in 2000, with an increased age seen in subsequent years (mean age 57 and 51 years in 2001 and 2002, respectively). Methadone-related deaths were seen more often in a younger age group (mean age 35 years) and whites in all years. Another demographic trend that emerged and perhaps warrants further investigation was that of marital status. Eight (61%) of the cocaine-related deaths were single (never married, divorced, widowed), while 3 (23%) were married. Marital status of 2 decedents was not known. Three (33%), of the methadone-related deaths were single, while 6 (67%) were married.

A review of the most recent available DAWN mortality data (2000 and 2001) revealed that methadone was one of the top ten drugs reported in 25 of the 33 major metropolitan areas studied and cocaine was one of the top ten drugs reported in all areas. A comparison of the 2000-2001 data revealed an increase in methadone-related deaths by 7 to 72% (median 36.5%) in 17 of the 25 areas. Ten of the 17 experienced a concurrent decrease in cocaine-related deaths, similar to that observed in Caddo Parish, LA. Additionally, 9 of the 10 areas were located within the regions traditionally described as southern (4), midwestern (1), and western (4) United States.

These results indicate a recent trend toward fewer cocaine-related deaths, with concurrent increase in methadone-related deaths in both the region of study and in specific national regions. While local demographic trends were noted with respect to age, race, sex, and marital status, comparison of local trends to national trends was not possible, as the data provided by DAWN does not include specific drug-related demographic information. Additionally, since our study area has less population density than those included in the DAWN analyses, it would be desirable to compare our local data with that of similarly populated areas.

Cocaine, Methadone, Mortality

G41 Positional Asphyxia and Alcoholism: Review of Three Cases

Elizabeth L. Kinnison, MD and Wendy M. Gunther, MD, Office of the Chief Medical Examiner, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510*

After attending this presentation, attendees will recall and consider the role of positional asphyxia in alcoholic deaths. Raise the index of suspicion of alcoholism in positional asphyxia deaths. Using case histories, consider the role of acute intoxication with ethanol, versus no intoxication, versus other agents. Be aware of issues in certification of manner of death in positional asphyxia deaths in alcoholics.

This presentation will impact the forensic community and/or humanity by creating awareness of possible role of alcoholism in positional asphyxia deaths, which has not received deserved consideration previously. Open the dialogue on how chronic alcoholism or acute intoxication in alcoholism is likely to affect positional asphyxia. Remind the forensic community that the manner of death deserves careful attention, as it may still be homicide, even in a person with scene evidence of positional asphyxia, and multiple intoxicants on board.

We report three cases in which positional asphyxia caused death, but was abetted or affected by alcoholism. In one of the cases, acute alcohol intoxication was present; in another, despite fatty liver, no alcohol was found on toxicology; in a third, homicidal assault may have been the instigating factor.

A 46-year-old woman, who had a history of a seizure disorder, was found dead at home. She had consumed a large quantity of beer and a half pint of Jack Daniels whiskey the evening before. She was found lying prone, with her neck hyperextended against the fabric of the foot of a couch. Scene photographs and autopsy findings both indicated that positional asphyxia was the cause of death. A faint bitemark on the tongue, and the absence of any seizure medication in the blood on toxicologic study, suggested that a seizure might have caused her to collapse in that position. However, the blood alcohol level was 0.43% weight per volume.

A 41-year-old man, with a history of probable chronic alcohol abuse and a known seizure disorder, was found dead at home, collapsed across the metal frame of a coffee table, which had had its glass top removed. Prominent pressure marks across his anterior neck and lower abdomen corresponded to the rails of the coffee table frame. The right cornu of the thyroid cartilage had fractured beneath the pressure mark, suggestive of a direct collapse onto the frame, possibly during a seizure; a probable tongue bitemark was present. Although fatty liver and micronodular cirrhosis were found at autopsy, the blood alcohol level was 0.0%. Toxicology did not reveal any anti-seizure medications.

The final case is more problematic. A 54-year-old woman, with a history of both chronic alcoholism and prescription drug abuse, was known to be unsteady on her feet; neighbors said she often had bruises. She was found dead at home, collapsed in her cluttered bedroom, with the head and neck extended into an awkward position. Autopsy showed a linear perimortem neck abrasion, with bruising over the anterior neck, and focal hemorrhage into the strap muscles. She had multiple bruises on

the face, torso, and extremities, but no petechiae, and no fracture of the hyoid bone or thyroid cartilage. Postmortem toxicology showed an elevated amount of mirtazapine (0.6 mg/L), with no alcohol, street drugs, or anti-seizure medications. Death was attributed to asphyxia due to neck compression, due to positional asphyxia, with mirtazapine toxicity contributing. It was unclear whether some of the bruising or the linear abrasion might have been inflicted by an assailant.

These three deaths concern positional asphyxia in a setting of alcoholism. Although it is intuitively obvious that alcoholism should lend itself to deaths by positional asphyxia, there is a dearth of reports in the literature evaluating both. Reports in the popular media anecdotally mention alcoholism in a rare positional asphyxia death with homicidal intent, but the forensic literature has not addressed it. This report aims to open the forensic pathologic discussion on the effect of acute or chronic alcoholism on deaths by positional asphyxia

Positional Asphyxia, Alcoholism, Manner of Death

G42 Causes of Death in Chronic Alcoholics: A Comprehensive Retrospective Analysis of Medical Examiner Cases

Martha J. Burt, MD, Matthew J. Bowes, MD, and Mark J. Shuman, MA, MD, Miami-Dade County Medical Examiner Department, Number One on Bob Hope Road, Miami, FL 33136*

After attending this presentation, attendees will understand the necessity for complete autopsy examination, scene investigation and toxicology in the evaluation of individuals with chronic alcoholism. The spectrum of causes of death in individuals with chronic alcoholism.

This presentation will impact the forensic community and/or humanity by illustrating the spectrum of causes of death in chronic alcoholics and the need for complete death investigation in such deaths.

Acute and chronic alcohol abuse is a common issue faced by medical examiners and death investigators. The morbidity and mortality of chronic alcoholism is well-documented in the hospital population, but little data is available describing those who die outside of the hospital or without medical care. The teaching/dogma in the forensic pathology community is that chronic alcoholics suffer certain injuries, such as subdural hematoma, much more frequently than the general population, though little is published in the scientific literature to support these claims. This study was undertaken to assess the causes of death in chronic alcoholics in a large urban area over a seven year period.

The Miami-Dade County Medical Examiner Department case file computerized database was retrospectively searched, using the keywords "alcohol" and "heavy," and "alcohol" and "abuse" in the history field, and "alcohol" or "ethanol" in the cause of death fields, for the years 1996 to 2002, inclusive. Inclusion criteria were: performance of a complete autopsy; a history of chronic alcohol abuse or scene evidence suggesting the same; acute alcohol use prior to death; and/or alcohol caused or contributed to the death after complete autopsy and toxicology examination. Case files were reviewed to ensure the cases met the inclusion criteria.

During this seven year period, 17,463 autopsies were performed at the Miami-Dade County Medical Examiner Department. 1,457 cases were identified that met the above inclusion criteria, and were broadly grouped into two categories, those with a history of chronic alcohol abuse and/or circumstances of chronic alcohol abuse or acute use (1297 cases, 89%), and those with no history of chronic alcohol abuse or circumstances to suggest alcohol abuse or acute use (160 cases, 11%). The cases were also categorized by the cause of death: blunt injuries (159, 11%), drowning (65, 4%), polydrug intoxication with alcohol present (149, 10%), polydrug intoxication without alcohol present (48, 3%), other single drug intoxication (58, 4%), other alcohol related causes, such as pancreatitis, bleeding varices, and liver failure (501, 34%), and

natural diseases with chronic alcohol abuse as a contributory condition (104, 7%). Gunshot wounds, stabblings and hangings each accounted for 1% or less of the cases. The most common cause of death in both those with and without history of alcoholism fell into the “other alcohol related deaths” category (438/1297, 34% in those with history; and 63/160, 39% in those with no history). Twenty-one percent of those with a history of chronic alcohol abuse died as a result of a natural disease unrelated to alcohol abuse. A total of 19 cases were identified where the cause of death was related to a subdural hematoma (3 in the group without a history of alcohol abuse and 16 in the group with a history of alcohol abuse), for an overall incidence of roughly 1% in our study population. Within the chronic alcohol abuse group, pedestrians struck by vehicles accounted for more than those killed in a motor vehicle crashes (23 versus 18).

This retrospective study of medical examiner cases shows that those who suffer from chronic alcohol abuse are more likely to die from a non-natural process, such as trauma, drug intoxication or drowning, than they are to die from a natural complication of abusing alcohol. A thorough death investigation, including scene investigation, autopsy and toxicology is necessary to clearly establish the cause and manner of death in individuals with a history of chronic alcohol abuse.

Cause of Death, Alcohol Abuse, Autopsy

G43 FluiDDB.com: A Model Database for Unidentified Bodies

Michael C. Britt, BS and Marta U. Coburn, MD, District Twenty Medical Examiner, 3838 Domestic Avenue, Naples, FL 34104*

The goal of this presentation is to highlight the importance for medical examiners to have a database where information about unidentified decedents can be kept and ultimately used as a central clearing-house for interested parties searching for information about missing persons.

It is our hope that FLUIDDB.com will serve as a model for medical examiner's offices in all states and that it will be instrumental in identifying at least a portion of the unidentified bodies that previously established criminal databases have not been able to successfully identify. It is also our goal to encourage newfound interest in medical examiners and their staff to re-examine the case files that lay dormant in their offices of these “forgotten” bodies.

This presentation will highlight the reasons why there should exist an easily accessible website where information about unidentified bodies found may be readily accessed by family members, police, and any other interested party. Dr. Marta Coburn, Chief Medical Examiner of Collier County, Florida realized the need to create such a website and designed a simple, yet comprehensive, database. FLUIDDB.com, an acronym for Florida Unidentified Decedents Database, employs existing computer technology in a user-friendly format that engages the interested party in the search process, while maintaining the integrity of sensitive criminal data. This fact is instrumental in the success of the identification process because current criminal databases are not available for public use.

Identification of a body is often hampered for many reasons and the longer a body remains unidentified, the less likely it is that their identity will be discovered. To compound the problem, the majority of medical examiner's offices do not have the means to readily access all of their cases of unidentified bodies. Therefore, even the most cursory search cannot be executed when medical examiners receive requests for information from family members searching for missing loved ones. The database will serve to organize these cases into a format that permits medical examiner staff immediate retrieval of information. A complete list with information about all of the unidentified deaths is obtainable given the participation of each medical examiner's office in a given state. The searcher may then streamline their focus and pursue only

those published cases that match the information about the missing person they seek. The website was also designed to allow each office to easily update or delete information as needed. The discussion will include insight about entering information into the various data fields from the medical examiner's perspective and how to retrieve information from the searcher's viewpoint.

This presentation also discusses future plans to link FLUIDDB.com to other websites that may contain purely scientific information such as dental records or anthropological data. Recommendations for medical examiners and their staff of the most effective methods for establishing identification of unidentified bodies will also be provided. These guidelines will hopefully serve as a checklist of steps that should be taken during the early part of an investigation in an effort to exhaust all means of conventional identification procedures.

The office of the District Twenty Medical Examiner is confident that this database will eliminate the need for families or police to write, call or fax each individual medical examiner's office or law enforcement agency and will instead utilize the website as a means to narrow their search.

Unidentified Bodies, Identification, Missing Persons

G44 Compressional Asphyxia Due to a Crowd Stampede: The E2 Nightclub Disaster

Adrienne Segovia, MD, Mitra B. Kalelkar, MD, Aldo J. Fusaro, DO, Scott Denton, MD, Edmund R. Donoghue, MD, Kendall V. Crowns, MD, Eupil Choi, MD, J. Lawrence Cogan, MD, Ronald Knoblock, MD, Cyndi D. Gardner, MD, and Barry D. Lifschultz, MD, Cook County Medical Examiners Office, 2121 West Harrison Street, Chicago, IL 60612*

After attending this presentation, attendees will be able to recognize the findings in cases of compressional asphyxia, understand the proposed pathophysiologic mechanism for their development, and become acquainted with models of crowd panic behavior.

This presentation will impact the forensic community and/or humanity by recognizing the findings in cases of compressional asphyxia in your daily forensic pathology practice, understand the proposed pathophysiologic mechanism for asphyxial deaths, and become acquainted with models of crowd panic behavior.

We present 21 deaths due to compressional asphyxia that occurred in a Chicago nightclub stairwell in February, 2003. For reasons that remain unclear approximately 500 persons fled down a long narrow 28 step stairwell. The alleged trigger for the event was an altercation between two women on the dance floor, and the use of pepper spray to control the situation.

The victims ranged in age from 19 to 43 years. Nine were male and twelve were female. At autopsy external evidence of injury, when present, consisted of abrasions and contusions. Petechial hemorrhages of the sclera and conjunctiva, face and neck region were present in 17 of the 21 victims. The remaining five showed scleral and conjunctival congestion without petechiae. Petechiae were also present on the shoulders and the mid back. Petechial hemorrhages of the larynx, oral mucosa, pleura, epicardium, epiglottis and scalp were also present in the majority of the victims. One victim had bite marks of the lips and two had bite marks of the tongue. When present, muscle hemorrhage involved the temporalis and sternocleidomastoid muscles. Hemorrhage was also present in the soft tissues overlaying the thyroid. The only bony injury present was a fracture the right second rib anteriorly. Petechial hemorrhages were not identified in the lower extremities of any of the victims. Hyperaeration of the lungs was present in four of the 21 victims. Toxicology studies revealed the presence of alcohol and the presence of an antidepressant in one victim.

Asphyxia due to crowd compression was first described by Ollivier d'Angers in 1837. Ollivier reported that twenty-three persons died when they were compressed by a crowd of approximately 300,000 exiting the

Champ de Mars in Paris following a re-enactment of the storming of the citadel of Antwerp. Ollivier used the term ‘masque echymotique’ to describe the physical findings consisting of subconjunctival hemorrhage, craniocervical cyanosis and cerebral vascular congestion. In 1900, Perthes described the clinical syndrome and included mental dullness, hyperpyrexia, tachypnea, hemoptysis and “contusion pneumonia” to the complex of findings. Since then the syndrome has been further defined and can include neurological complications, ophthalmic complications, petechiae of the mucosal membranes, epistaxis, hematemesis, microscopic hematuria and albuminuria. Associated traumatic injuries have been described. Of these, thoracic injuries are most common and include rib fractures, hemothorax, pneumothorax, pulmonary contusions, cardiac contusion, and clavicle fractures. Fractures of the upper extremities, pelvis, lower extremities and spine are the second most commonly associated traumatic injury. More severe, crushing injuries may produce lacerations of the liver, rupture of the diaphragm, as well as injury to the small bowel and colon.

The majority of the victims demonstrated the classic findings of asphyxia by compression - petechial hemorrhages in the absence of associated fatal internal traumatic injuries. The etiology for the development of the classical findings is unclear. A “fear response” leading to closure of the glottis and contraction of the abdominal muscles was proposed in 1905 by Lejars. The work of Williams et. al., in 1968 supported this. Their study monitored blood flow and intrathoracic pressure in anesthetized dogs. They reported that blood flow through the jugular vein and carotid artery decreased with thoracic compression. To simulate closure of the glottis, Williams and co-workers occluded the endotracheal tubes of the dogs, which resulted in an increase in pressure of the jugular vein and the development of the classic findings. The classic findings, however, have been documented in situations when the glottis was not closed; for example, in entrapped victims who were screaming. Nontraumatic/compressional mechanisms can produce the classic findings such as paroxysmal coughing, which can only occur when the glottis is open. Closure of the glottis may be responsible for the hyper-aeration of the lungs seen in some of the victims, but not necessarily in the development of subconjunctival, scleral or facial petechiae. The absence of petechial hemorrhages in the lower extremities has been shown to be the result of collapse of the inferior vena cava, which occurs with increasing levels of thoracoabdominal pressure. This protects the veins of the lower extremities.

The twenty-one deaths described above occurred when the crowd panicked and rushed into one of two available stairwells. The term panic will be used here to describe flight from a perceived danger. For panic to develop a specific threat to physical survival having immediate effects must exist. The behavior of panicking individuals in a crowd has been studied. Panicked flight is directed towards escaping imminent danger. The convergence of fleeing persons in a collective panic frequently occurs because individuals flee in one direction assuming that escape is possible in that direction while ignoring other exits. This behavior is called “herding.” Herding behavior occurs when the crowd moves in the same direction and other exits are not efficiently used. Models show that this behavior pattern frustrates escape. Individual behavior occurs when each person finds an exit only by accident and is similarly ineffective in effecting escape. Models show that escape is best accomplished when there is a mixture of individual and herding behavior. Individual behavior allows some to detect the exit, while herding allows successful solutions to be imitated by others.

A review of the literature found few case reports which described compressional asphyxia caused by crowds, and also lacked traumatic injuries and presented the autopsy findings. Several articles emphasized the management of patients, discussed the implications for disaster planning, and emphasized that morbidity and mortality were the result of associated internal injuries. Little mention has been given to the duration of the compression, which we believe contributes significantly to mortality.

In summary, we describe twenty-one deaths from compressional asphyxia due to a crowd stampede. The majority demonstrated the classic findings first described in 1837 by Ollivier. Mortality resulted from chest compression inhibiting respiratory movement and was related to the duration and the amount of weight rather than internal or related traumatic injuries.

Compressional Asphyxia, Crowd Stampede, Petechiae

G45 Perspectives on the Variety of Mass Identification Projects

Charles H. Brenner, PhD, Consultant in Forensic Mathematics, 6568 Sobrante Road, Oakland, CA 94611-1123*

The goal of this presentation is to relate considerations and strategies for identifying a large collection of corpses.

The incidence of mass identification efforts looks to increase in the future as it has in the past. The aim of this presentation is to encourage the use of experience from past identification efforts in solving new ones.

Experience with previous mass identification projects establishes a general framework to apply to such problems, but also teaches the lesson to expect novel challenges each time.

Airplane crashes (SwissAir 111 near Halifax in 1997, American 587 in Queens shortly after 9/11/2001), wars (Bosnian mass graves, Kuwaiti POWs), and the destruction of the World Trade Towers have in common a large number of deaths with most of the corpses damaged beyond recognition. Given the condition of the bodies, DNA is the most reliable modality for identification. Given the large numbers, sorting out the identities requires efficient and carefully-designed routines. A few general ideas seem to be always applicable; other kinds of ideas, the list of which grows with each new experience, are important for one disaster or another.

The first category, the generalities, includes: DNA profiles are obtained from the victims, and from references – family members and/or personal effects. Tentative or candidate identities are determined by a screening step in which every victim is rapidly compared with every reference sample, highlighting related-seeming pairs. The screening list should be prioritized by degree of similarity. Each candidate identity is then tested beginning with the easiest. The DNA part of the test consists in making appropriate kinship and/or DNA matching calculations taking into account all typing information. The result of the calculation is a number, a likelihood ratio that is usually either very large or very small – virtually ensuring or else contradicting the tentative match – but sometimes inconclusive. Common sense dictates that even when the likelihood ratio is very large, all available information must be carefully checked for any inconsistencies that might suggest a human error occurred. If all is well, the identity will be assumed.

Other ideas are sometimes critical but not universal. The DNA of victims from old graves or the smoldering ruins of the WTC (unlike that from plane crashes) is often of poor quality; analysis must cater to allelic dropout. Related victims are a salient feature of some tragedies, which needs to be appreciated lest a war victim be mistaken for his son or his brother. Moreover, in the airplane crashes, the relationships among victims were even an essential component of some of the identifications. For the WTC alone bodies are generally so fragmented that association of victim parts is an important preliminary to screening. One site or several? Where the victims are distributed among multiple graves, as in Bosnia and Kuwait, the criterion for a “very large” likelihood ratio varies with site and circumstances. One grave found in Iraq had about 150 bodies and there was a list, of unknown reliability, of mostly Kuwaitis claimed to be there. It turns out that tentative identifications reinforce each other as the pattern emerges that the list is largely accurate though it has some omissions. Large disasters of course magnify difficulties.

culties, but also create a new problem in kind: For a plane crash a seeming parent-child or even sibling-sibling relationship between a victim and a reference person usually proves to be a correct relationship, but in the case of WTC or Bosnia it usually does not. When the number of victims is very large, the screening process needs to emphasize combinations of at least two family members both of whom match the same victim. Otherwise false leads in the candidate list swamp the good ones. If a project is ever mounted to identify a hundred thousand or more dead, such as the Kurds or Shiites killed in Iraq, it is a safe bet that previously unnoticed difficulties will come to light requiring some new ideas to solve.

The process of identifying a large number of victims using DNA is rapidly gaining maturity. Many mass identification projects have been attacked in isolation, as if each were a new problem. But now there is a sizeable body of experience. The ideas from past work provide useful lessons and tools for approaching new identification projects. One of these lessons is to keep an open mind. There is always something new.

Mass Disaster, DNA Identification, War Victims

G46 Investigation, Identification, and Repatriation of Contaminated Fatalities

Craig T. Mallak, MD JD, Office of the Armed Forces Medical Examiner, Armed Forces Institute of Pathology, 1413 Research Boulevard, Rockville, MD 20850; Elspeth C. Ritchie, MD*, USUHS, Department of Psychiatry, Room B3068, 4301 Jones Bridge Road, Bethesda, MD 20814*

After attending this presentation, attendees will understand the complications involved in the investigation and identification of infectious remains and have a raised level of awareness of the potential complications involved with the transportation of contaminated remains from overseas into theater.

The presentation should alert and inform medical examiners, policymakers, investigators and others as to the complexities involved in investigation, identification and repatriation of contaminated fatalities.

The recent war in Iraq raised the specter that chemical, biological or radioactive agents would kill soldiers. Although most remains contaminated with most chemical or nuclear agents could be decontaminated, remains contaminated with smallpox, anthrax or other agents such as Ebola virus would remain hazardous and present a potential threat to if returned to the United States.

Current DoD policy and commitment is to return remains the remains of all fallen service members to the United States as expeditiously as possible. Cremation prior to return renders biological and chemically contaminated remains safe, but is contraindicated for radioactive remains. Unfortunately, involuntary cremation is specifically prohibited by U.S. military regulations. To date, the United States military did not have a good strategy to return of radioactive or potentially infectious remains to the United States.

For the occasional civilian case of contaminated remains being returned to the United States, the Centers for Disease Control (CDC) issues a permit allowing importation. To obtain this permit, the remains must be a hermetically sealed and remain sealed until buried. Such a hermetic seal would be adequate for transportation of biological, chemical and radioactive remains except for gamma emitters.

As this issue was addressed, there were two guiding principles. Paramount of these was protecting the health of mortuary affairs teams, medical personnel, other service members, and the American public. Protection of the living must take precedence over rapid repatriation of remains. There was also a commitment to fully and scientifically account for those who died in service to this country, even if the remains could not be returned.

A system was designed consisting of a commercially available "Zeigler casket" enclosing a "Ziegler case" that the manufacturer

claimed to produce a hermetic seal. Inside the case the remains were to be contained within a "Bioseal" pouch. This triple seal containment system failed several tests conducted in early March 2003 in an altitude chamber. The Zeigler case leaked, even at sea level. The Batesville casket and Zeigler case warped and lost integrity under a drop of only four feet. The Bioseal system was hard to seal properly, even while testers were wearing normal clothes and in clean controlled conditions. It did maintain a seal to 67,000 feet when sealed properly. Small amounts of sand in the seam ruined the seal. Thus, we currently do not have a system that maintains a hermetic seal under testing.

Temporary interment was chosen as the next best option at that time (March, 2003), but was not deemed as a desirable. It would be done only when decontamination attempts were not successful. A tissue sample would be obtained prior to interment and shipped to Armed Forces DNA Identification Laboratory (AFDIL) for identification of the decedent and for possible identification of the pathogen.

Three other options are currently under study: a better containment system; irradiation in place; and voluntary cremation in theater. A better containment system is being developed. Irradiation in place requires that a mobile irradiator be developed. Mandatory cremation would also require a crematorium in theater. Although the end of the war meant that those options were not needed immediately, it is anticipated that future conflicts will produce the same issues.

Contamination, Identification, Repatriation

G47 When is SIDS Over-Laying?

W.P. Ryan, MBBS, PO Box 267, Nowra, NSW 2541, Australia*

The goal of this presentation is to acknowledge the powers of observation as perhaps the most important factor at a crime scene is vital.

This presentation will impact the forensic community and/or humanity by encouraging practitioners to be observant.

When called to a dwelling on the eastern aspect of our town, I was advised by the police officer in charge that "It looks like a SIDS." Observation at the scene, not only of the victim but of the domestic surrounds within the dwelling, made an indelible impression on my mind.

From the evidence gleaned from family members and, basing my opinion on my personal experience in such cases, I formed an opinion that the case was rather one of over-laying.

I will demonstrate by way of slides, the total scene.

SIDS, Over-Laying, Crime Scene

G48 Unexpected Death From Ureterocele in an Infant

Joyce L. de Jong, DO, Sparrow Hospital, Forensic Pathology, 1215 East Michigan Avenue, Lansing, MI 48909*

After attending this presentation, attendees will recognize ureteroceles as a possible cause of unexpected death in infants.

This presentation will impact the forensic community and/or humanity by creating awareness of a possible cause of unexpected death in infancy.

An infant died suddenly of an ectopic ureterocele which was undiagnosed in life. Ureteroceles are cystic dilatations of the submucosal portion of the terminal intravesical ureter. They are generally classified as intravesical (entirely within the bladder) or ectopic (some portion is situated permanently at the bladder neck or in the urethra). The incidence of this abnormality is about 1 in 5,000 to 12,000 births. In infants, the most common presentation is a urinary tract infection within the first few months of life. Other common presentations include a palpable abdominal mass from an obstructed renal unit or detection during an

antenatal maternal ultrasound. In the case presented, a 4-month-old white male died within minutes after his arrival at an emergency department. The parents reported the child had "not felt well" for about a week prior to his death. The autopsy revealed a right ectopic ureterocele with bilateral ureteral obstruction, urethral obstruction, and a urinary tract infection due to Escherichia coli. Sudden death in an infant caused by a previously undiagnosed ureterocele has not previously been reported.

Ureterocele, Infant Death, Genitourinary

G49 An Unusual Motorized Vehicle Fatality

Russell T. Alexander, MD, John Turner, MD, and Louis Dibernardo, MD, Duke University Medical Center, Department of Pathology, DUMC Box 3712, Durham, NC 27710*

After attending this presentation, attendees will understand the clinical features, classification, and pathogenesis of Osteogenesis Imperfecta. The high risk that these patients have for fatal intracranial injury after relatively minor trauma. The common causes of death of these patients. The possible diagnostic confusion of this disease with child abuse

This presentation will impact the forensic community and/or humanity by making the forensic community become aware of the disease Osteogenesis Imperfecta, its clinical features, and the likelihood of these patients to die after what would normally be considered minor trauma. The forensic community will also become aware of the typical causes of death of these patients and the possible confusion of this disease with child abuse in young patients. The typical external features and radiographic appearance of the disease will be shown so that the forensic community will be able to recognize patients with Osteogenesis Imperfecta in the future.

The goals of this presentation are to present a case that summarizes the typical clinical features of osteogenesis imperfecta (OI) and that highlight the high risk that these patients have for fatal cranial injury following relatively minor trauma.

The decedent was a 20-year-old female with a past medical history of OI who was living independently at a local college. She was riding in her motorized wheelchair on a level concrete path at an unknown speed when it came to a sudden unexpected stop. She was unrestrained and was thrown forward out of the wheelchair. The left side of her head impacted the ground. There was no loss of consciousness or altered mental status at the time of the accident. She was transported to a local hospital where physical examination revealed a small scalp laceration and blood in her left external ear canal. Extreme body dysmorphism consistent with the history of OI was noted, but no new trauma to the extremities was identified. A computerized tomography (CT) scan of the brain revealed a large epidural hematoma and multiple fractures through the left side of the calvarium. Approximately 5 hours after the accident, her level of consciousness decreased. A repeat head CT confirmed a left sided epidural hematoma now with significant midline shift and subfalcine herniation. An emergent craniotomy was performed for evacuation of the epidural hematoma. She died soon after surgery.

Postmortem examination revealed the head to be disproportionately large for the body. Reflection of the scalp revealed a complex comminuted left temporal bone fracture status post repair. The bones of the skull were "egg shell" thin. A 10 x 6 cm temporal-parietal epidural blood clot compressed the underlying brain. A thin layer of subarachnoid hemorrhage overlay the cerebral convexities. Marked cerebral edema was associated with bilateral herniation of the parahippocampal gyri and cerebellar tonsils. Sectioning of the brain disclosed left to right midline shift and subfalcine herniation. Additionally, the sclera were blue and soft. The teeth were opalescent, brownish, and chipped. Both upper extremities were dysmorphic and tortuous. The lower extremities exhibited marked bowing and deformity. Radiographs revealed severe

scoliosis of the spine with placement of a fixation rod. The legs contained internal fixation rods in both femurs and tibias. Representative samples of bone from the ribs and spine were soft and friable. Microscopic examination showed decreased amounts of bone that were disorganized and only focally calcified.

OI ("brittle bone disease") is a heterogeneous genetic disorder of type I collagen. Affected individuals have fragile bones and abnormalities in other tissues rich in type I collagen including teeth, sclera, and ligaments. The disease is due to mutations in the COL1A1 or COL1A2 genes that encode type I procollagen. The disease is divided into types 1 – 4 based on skeletal abnormalities, the extra-skeletal tissue affected, and the genetic defect present. Type I OI is a mild form of the disease characterized by less severe bone involvement, blue sclera, deafness, and variable involvement of teeth (dentinogenesis imperfecta). The most severe form of OI, type II, presents with extreme bone fragility, intrauterine fractures, crumpled long bones and ribs, severe deformity, blue sclera, and is usually fatal in the perinatal period. Type III OI is characterized by progressive bone deformities, frequent fractures, short stature, scoliosis, deafness, dentinogenesis imperfecta, variably hued sclera, and survival often into adolescence and young adulthood. Type IV OI is intermediate in severity between types I and III, and it is characterized by moderate bone fragility and deformity, deafness, variable dentinogenesis imperfecta, and normal sclera.

McAllion and Colin (1996) have reviewed the causes of death for non-type II OI patients. Patients with types I and IV OI had increased numbers of deaths due to respiratory complications of their disease, as well as compression of the brain due to basilar invagination of the skull. However, many type I and IV OI patients had a normal lifespan and died due to diseases that affect the community at large. The type III OI patients often died of respiratory complications of their disease. Five percent of the type III OI patients died due to cranial injury after falling out of a wheelchair.

A concern for the forensic community is the possible confusion of child abuse with OI since both can present with unexplained fractures. It has been estimated that up to 1% of infants presenting with fractures in the first year of life have OI (Byers, 2000). This highlights the need for accurate recognition of OI. The usual other signs of abuse including lacerations, burns, retinal and intracranial hemorrhages, and signs of sexual trauma should be sought. Laboratory evaluation of collagen, imaging studies of bone, and genetic analysis may provide support for a diagnosis of OI.

This case presentation highlights the increased risk that OI patients have for fatal intracranial trauma after relatively mild traumatic injury. Because of this risk, OI patients should always wear a seat belt when riding in a wheelchair.

Osteogenesis Imperfecta, Epidural Hematoma, Trauma

G50 Three Unusual Cases of Sudden Unexpected Death in Pregnancy Occurring in One Week in the State of Maryland

Tasha L. Zemrus, MD and David R. Fowler, MD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD 21201-1020*

After attending this presentation, attendees will become aware of relatively uncommon causes of death in the pregnant woman.

This presentation will impact the forensic community and/or humanity providing the opportunity for the forensic community to learn about relatively uncommon causes of sudden unexpected maternal death that they may see in their practice.

From June 24 through June 30, 2003, three cases of sudden unexpected death in pregnant women presented to the Office of the Chief Medical Examiner for the State of Maryland.

The first was a 40-year-old, previously healthy G7P6 female, carrying triplets as a surrogate mother for another couple. Her pregnancy history was significant for anemia during pregnancy, a previous large for gestation baby with shoulder dystocia and postpartum hemorrhage, and there was less than one year between the last delivery and the current in vitro fertilization and conception. She was being evaluated for possible pregnancy-induced hypertension (PIH) and it was recommended that she be admitted to the hospital for further care, but she refused. On the day of her death, she complained of shortness of breath, collapsed and was unable to be resuscitated. Emergency cesarean section delivered a stillborn male fetus. The other two fetuses were left inside her uterus. Autopsy was significant for focal 50% atherosclerotic narrowing of the left anterior descending coronary artery, left ventricular hypertrophy, and features of Hashimoto's thyroiditis, previously undiagnosed. The presumptive cause of death was a cardiac arrhythmia, most likely due to hypothyroidism. The second was a 39-year-old, previously healthy G2P1 female, who complained of abdominal fullness and cramping, then passed out while shopping. She was unable to be resuscitated and a stillborn male fetus was delivered by emergency cesarean section. Autopsy findings included diffuse hemorrhage into the retroperitoneal and peritoneal soft tissue originating from a lateral rupture of the spleen. There was no history of illness or trauma. Microscopy failed to indicate an infectious or malignant process underlying the rupture, and also identified prominent lymphocytic infiltration of the pituitary gland. The cause of death was determined to be spontaneous rupture of the spleen in pregnancy, with lymphocytic hypophysitis considered a contributory condition. The third case was a 28-year-old, previously healthy G1P0 female, who had a two week history of sporadic palpitations, occasional dizziness and shortness of breath. On the day of her death, she was diagnosed at the hospital with supraventricular tachycardia (SVT), became unresponsive, and was unable to be resuscitated. Autopsy findings were negative. The presumed cause of death was determined to be SVT.

These cases represent three relatively rare causes of death in pregnant women and are conditions of which the forensic community should be aware.

Spontaneous Rupture of Spleen, Hashimoto's Thyroiditis, Supraventricular Tachycardia

G51 Compressed Gas Cylinder Related Injuries: Case Report of a Fatality Associated With a Recreational Paintball Gun, Review of the Literature and Safety Recommendations

Nabila A. Haikal, MD, and Richard C. Harruff, MD, PhD, King County Medical Examiner's Office, 325 9th Avenue, HMC Box 359792, Seattle, WA 98104*

By describing a fatality involving the pressurized canister of a paintball gun, this case report highlights the potentially serious hazards associated with these devices and reviews relevant safety guidelines in handling pressurized gas cylinders.

This presentation will impact the forensic community and/or humanity by underscoring the serious injury potential of gas powered paintball guns, the authors hope to: i) dispel the misconception that paintball markers are mere toys, ii) promote the safe use of compressed gas cylinder-powered devices, like paintball guns, by encouraging a

healthy respect for their injury potential and emphasizing the need for adherence to age restrictions, game rules, and use of protection gear, and iii) prevent potentially avoidable paintball gun injuries by contributing to accident reporting and statistics and increasing public awareness.

The purpose of this paper is to draw attention to the potentially significant morbidity and mortality that may result from the recreational use of compressed gas cylinder-powered equipment, illustrated by a fatality involving a paintball marker/gun. Because such injuries are more common in a non-commercial setting lacking rigorous enforcement or consistent operator implementation of established paintball game rules, it is important to recognize the need for adherence to safety recommendations common to all devices employing pressurized gas cylinders, irrespective of the application involved.

Compressed gas cylinders, used in a variety of industrial, occupational and recreational devices and settings, present a substantial accident hazard due to the large amount of energy stored in the pressurized gas cylinder, which is released upon sudden decompression. Property damage and serious, or even fatal bodily injury may result from the careless or improper handling of gas cylinders, modification of equipment, or device malfunction.

This report describes a case of severe, fatal blunt force injury of the head sustained when a compressed carbon dioxide gas cylinder decompressed suddenly upon disconnection from a paintball gun. The gas cylinder was propelled from the gun, striking the head of the 15-year-old who was holding the gun. The impact resulted in craniocerebral injuries including depressed, comminuted skull fractures and cerebral contusions leading to death. Subsequent inspection of the device found that the gas cannister separated from its own coupling rather than from the connector attached to the device. The operator was apparently oblivious to the dangers inherent in handling pressurized cylinders when he unscrewed the cannister from the gun.

Although there have been numerous anecdotal and well documented reports of paintball equipment-related injuries, this appears to be the first report of a fatality involving a paintball gun. Previously, the most commonly reported injuries have involved ocular trauma resulting from paint pellets striking the eyes. Considering the current case report and previous reports of non-fatal injuries, it is apparent that failure to adhere to established safety standards accounts for the vast majority of serious injuries involving paintball guns.

Initially designed for the purpose of marking trees in the setting of forestry, the use of gas powered paintball markers/guns has gained increasing popularity over the last decade as a 'toy weapon' used in combat simulation or 'war games,' whether for sport or military training. As gas cylinder-powered devices, paintball guns are subject to the standard safety recommendations addressing the physical, chemical, mechanical, and inhalation hazards of compressed gas cylinders, tailored to the specific purposes of recreational combat simulation maneuvers. Users of compressed gas cylinders are strongly advised to follow the manufacturers' and suppliers' safety instructions with regard to proper storage, labeling, hazard designation, transport, inspection, handling, and maintenance of cylinders and their connections as well as operator age restrictions and recommended personal protective gear.

High pressure gas cylinders present a multitude of hazards including sudden decompression, flammability, inhalation toxicity, cryohazard, heavy object hazard, risk of explosion, and asphyxiation. For these reasons, pressurized gas powered devices are essentially accidents waiting to happen with potentially lethal outcome. The fatality reported herein illustrates the serious accident hazard of gas cylinders, particularly in a non-commercial recreational setting and emphasizes the need for awareness and strict adherence to relevant safety practices.

Paintball Marker/Gun, Compressed Gas Cylinder, Fatality

G52 Cerebral Air Embolism: An Uncommon Complication of a Common Procedure

Bret M. Wehrli, MD*, London Health Sciences Centre, 339 Windermere Road, Department of Pathology, Room A3-147, London, Ontario N6A 5A5, Canada; Sidney Siu, MD, 827 Richmond Street, London, Ontario N6A 3H7, Canada; Edward Tweedie, MD and Michael J. Shkrum, MD, London Health Sciences Centre, 339 Windermere Road, London, Ontario N6A 5A5, Canada

The goal of this presentation is to describe air embolism which is an uncommon but potentially fatal complication of esophagogastroscopy.

Forensic pathologists should be made aware of this uncommon complication as endoscopy is a commonly performed procedure. Cerebral air embolism can occur in the absence of an obvious right-to-left shunt. Careful review of imaging studies may be helpful in confirming the diagnosis and cause of death.

Esophagogastroscopy is routinely performed at most hospitals and is considered a very safe procedure. The two most common major and potentially life-threatening complications are perforation and bleeding. Another rare and potentially fatal complication of this procedure is cerebral air embolism. We present an example of cerebral air embolism following esophagogastroscopy eventuating in patient death.

The patient, a 71-year-old female, presented to hospital with a history of chronic abdominal and back pain. Investigations revealed a decreased hemoglobin level and her stool tested positive for occult blood. She underwent esophagogastroscopy to try to identify a bleeding source. Several abnormalities were identified including three small linear ulcers at the distal esophagus, a prepyloric ulcer, and an abnormal inflamed area within the duodenal cap. Biopsies of the stomach and duodenum revealed chronic active gastritis and duodenitis. Fragments of hepatic parenchyma were also present in the duodenal biopsy.

Immediately following the procedure, the patient developed an acute decline in her level of consciousness. She did not respond to verbal or painful stimuli. Her pupils were equal and pinpoint. She had a bilateral positive Babinski sign.

An emergency CT scan of her head demonstrated air within the arterial and venous cerebral vasculature. The cranial bones were normal. Bifrontal cortical infarcts involving the middle cerebral and the anterior cerebral artery territory were identified on a repeat CT scan performed 3 days later.

The patient's condition did not improve and she expired 6 days after endoscopy. Autopsy confirmed the presence of a 3 cm duodenal ulcer with penetration into the liver and associated peritonitis. Bilateral, hemorrhagic, frontal, recent infarcts were evident grossly and confirmed microscopically. Examination of the heart did not reveal a right-to-left shunt. Bilateral bronchopneumonia, involving all lung lobes, was identified in the lung tissue sections.

Given her large duodenal ulcer that penetrated into her liver, we suspect that air, introduced at endoscopy under insufflation pressure, entered into the venous circulation, either through an exposed vein or through dissection into the hepatic sinusoids. The air then likely ascended to the right atrium, followed by the right ventricle, the lungs, through an unidentifiable pulmonary shunt, the left atrium, the left ventricle, the cerebral arterial circulation with resultant infarcts in the territories of the middle and anterior cerebral arteries.

Only a few cases of cerebral artery air embolism following esophagogastroscopy have been previously documented. In the absence of an intracardiac shunt, proposed alternative mechanisms for paradoxical air embolism include intrapulmonary shunts and transcapillary routes, both of which will likely be unidentifiable at autopsy. As intravascular air is rapidly absorbed, the obtainment of emergency head CT images is critical to the diagnosis and, in this case, the determination of the proximate cause of death. Delays in imaging would likely result in a failure of diagnosis and possibly a wrong or undetermined cause of death.

Cerebral arterial air embolism is a rare, potentially fatal complication of esophagogastroscopy and can occur in the absence of intracardiac shunts. Keys to diagnosis are awareness of this complication and the early obtainment of good quality head CT images following symptom development.

Embolism, Esophagogastroscopy, Fatality

G53 Legal Outcome of Sexual Assault Cases, The County of Aarhus, Denmark

Marianne C. Rohde, MD*, Jytte Banner, MD, PhD, and Annie Vesterby, MD, MDSc, Department of Forensic Medicine, University of Aarhus, Peter Sabroes Gade 15, Aarhus 8000 C, Denmark

After attending this presentation, attendees will become aware of medical findings and legal outcome of sexual assault cases examined by forensic pathologists.

Forensic pathologists are qualified to do clinical forensic examinations of victims experiencing sexual assault, due to their great experience in describing traumatic lesions during autopsies. Objectivity is easier maintained since the Forensic Pathologist does not take part in the following treatment of the victims. In this study the victims testimonies seemed to have had greater influence on the legal outcome than the findings at the clinical forensic examination.

Introduction: The medical examination of victims of sexual assault is in Aarhus, Denmark performed by forensic pathologists at the Rape Crisis Center, the County of Aarhus. This center has existed since the first of November 1999 and is open to all victims of sexual assault irrespective of police reporting or not. It is located in a hospital setting close to the Department of Forensic Medicine. The Rape Crisis Center covers an area with about 645,000 inhabitants.

Material and Methods: This is a study of all cases reported at the Rape Crisis Center or to the police in a fourteen-month period (Nov. 1, 2000 – Dec 31, 2001) from the County of Aarhus which has about 285,000 inhabitants. Police and court files were studied in the reported cases.

Results: 87 cases, all women, were included of which 73 reported to the police and 48 of these had a clinical forensic examination performed.

- 37 (77 %) had the examination performed within 24 hours of the assault, 30(62.5%) had injuries mostly caused by minor blunt trauma and 7 (14,6%) had minor injuries to the genitals.
- 39 (53.4%) women reported vaginal penetration and semen was found in six of these women.
- 18 (24.7%) of the reported sexual assault cases were “stranger rapes”, 45 (61.6%) were “date rapes” and 10 (13.7%) “partner rapes.”

Legal outcome: 11 were convicted and one acquitted in court, the charges were dropped in 25 cases because of lack of evidence. Eight were false allegations (seven date rapes and one stranger rape). No charges were made in 24 cases, in 12 of these no perpetrator was found, of which 11 were stranger rapes. Partner rape had the highest conviction rate (three (30%)), compared to date rape (seven (15.6%)) and stranger rape (one (5.6%)).

Injuries to the body were found in four convicted cases and to the genitals in one. In six of the convicted cases vaginal penetration was reported. Semen was not a finding in any of the convicted cases.

Conclusion: The presence of injuries, vaginal penetration or the findings of semen had, in this study, no influence on the legal outcome. Partner rape had the highest conviction rate compared to date rapes and stranger rapes. Reservations however have to be taken due to the small number of persons.

Sexual Assault, Legal Outcome, Clinical Forensic Medicine

G54 Boating People Pathology

Francesco Introna, MD*, Alberto Tortorella, MD, Roberto Vaglio, MD, and Antonio De Donno, MD, Sezione di Medicina Legale-DIMIMP, Pzza Giulio Cesare, 11, Bari, 70100, Italy

This presentation will impact the forensic community and/or humanity by describing unusual injuries and manner of death in forensic pathology about boating people.

The Authors describes the autopsy findings observed in foreign people died during the attempts of crossing the Adriatic sea to get Italy illegally. The crossings usually took place at night on board a rubber dinghy (8-10 mt long) with powerful outboard engines, driven by affiliate of criminal organization, full up to 40 illegal immigrants.

In the last five years we performed autopsy 57 bodies victims of these accidents.

The autopsy performed on corpses showed two kinds of injuries: some victims ha extensive amputations, produced by violent impact during collision between boats or caused by outboard-motor propeller on victims falling overboard; some others non injuries at all. Survivors, providing information about boating, told that someone of them, before to fall in water, already lost consciousness. In these cases we find blunt injuries on the head associated with focal or multifocal subaracnoid haemorrhages, consistent with trauma to the head. Although the above findings the cause of death in those victims was determined as drowning based on additional evidence (lungs large and bulky, white foam from trachea and bronchi, water in stomach, swollen brain and chemical finds of drowning in sea-water).

These findings are unusual in forensic pathology. The Authors were supposed that subaracnoid haemorrhages, following of trauma to the head, were responsible of lost consciousness and then made easier drowning when people fell in water-sea.

We found often traumatic head injuries made in people boating on rubber dinghy driven speedy and forced to make abrupt maneuvers to escape the guard boats; these injuries were produced accidentally against stiff parts of the boat (many people boating lying or with head rested on the side) or intentionally by others on the ship.

Sometimes victims presented wounds, localized especially on trunk and lower limbs, chemical burns, produced on the skin by oil flowing from breaking. The water-sea, in fact, compromise permeability of skin, allowing contact of derma with oil, so that it produced injuries seem to burns.

The cause and manner of these uncommon deaths and injuries will be also discussed.

Boating People, Subaracnoid Haemorrhages, Chemical Burns

G55 Do Centenarians Die Healthy? – An Autopsy Study

Andrea M. Berzlanovich, MD*, Department of Forensic Medicine, University of Vienna, Sensengasse 2, Vienna, Austria A - 1090 Austria; Thomas Waldhoer, PhD, Department of Epidemiology, Institute of Cancer Research, University of Vienna, Borschkegasse 8a, Vienna, Austria A - 1090, Austria; Ernst Sim, MD, Meidling Traumatology Center, Kundratstraße 37, Vienna, Austria A - 1120, Austria; Peter Fasching, MD, Geriatric Center Baumgarten, Baumgartner Höhe 1, Vienna, Austria A - 1140, Austria

The goal of this presentation is to assess the prevalence of common causes of death and demographic variables in a selected population of centenarians.

This presentation will impact the forensic community and/or humanity by underlining the need for more baseline data of the elderly which can be obtained only by more and well-performed autopsies.

There is a common conception that the very old die of old age, but the prevalent cause of death in this age group remains poorly studied.

Only few necropsies have been performed in patients dying after age 100 years and, little attention has been made on the clinical and morphologic features observed in these oldest old. For that reason we reviewed 34,858 consecutive autopsies done during a 15- year- period (1988 to 2002) at the Institute of Forensic Medicine, Vienna, Austria.

We focused on cases who met our working definition of sudden natural death in very old people: Unexpected or unexplained deaths of non-hospitalized persons over the age of 100 years, which are apparently due to natural causes". In particular, all persons who had not consulted a physician within 10 days before death were included and autopsied.

Of the 30 study corpses, 9 were men and 21 were women; all were Caucasian. The age of these out-of-hospital patients ranged from 100 to 108 years.

Nine persons lived alone in their homes without periodical care from relatives or welfare centers. Another 11 persons also lived alone, but were regularly cared for by neighbors, relatives or welfare workers, 10 lived with at least one family member.

Sudden natural death occurred in all cases in private homes, and in 35% of these cases while sleeping. Resuscitation was attempted in 53% of the cases. More than 63% (n = 19) of those who died were described as having been previously healthy.

About 30% had cardiac antecedents such as stable angina pectoris. Three persons had a history of myocardial infarction. Other pre-existing conditions were hypertension (16%), diabetes mellitus (10%), respiratory (10%) and gastrointestinal disorders (5%).

A total of 22% of the men and 29% of the women had a body mass index exceeding normal range.

Cardiovascular diseases accounted for almost three quarters of the deaths (n = 21); 23% (n = 7) of the centenarians died of respiratory illnesses, and 7% (n = 2) of gastrointestinal disorders.

Myocardial scars or focal myocardial fibrosis were detectable in 2/9 men and in 4/21 women, who died due to cardiac disorders; 3 men and 10 women had acute myocardial infarcts. Calcification of the mitral annulus and of the aortic valves were present in 80%; 15% of the calcified valves were anatomically stenotic.

All deceased had extensive aortic sclerosis, mainly focused in the abdominal part. In all 30 corpses the aorta was dilated in its transverse and longitudinal planes, with aneurysm formation in 5 cases, 2 resulted in fatal rupture.

Four cases of sudden death were caused by pulmonary embolism emerging from the left femoral veins, 3 patients died of bacterial pneumonia.

A gastric ulcer caused perforation with acute diffuse peritonitis in one 100- year old man, and in one 100- year old woman.

Centenarians succumb to disease, they do not die of old age. Undiagnosed conditions in the oldest old present a clinical challenge that increases with the patient's age. However, despite progress in diagnostic technology, confirmation rates of death causes have not changed much. Therefore, as the age of death rises, it is important to preserve and foster postmortem examinations, the most reliable source of medical evidence.

Centenarians, Autopsy, Cause of Death

G56 Degenerative Changes of the Conduction Tissue in Drug Addicts

Michaud Katarzyna, MD*, Béat Horisberger, MD, and Patrice Mangin, PhD, Institut Universitaire de Médecine Légale, Rue du Bugnon 21, Lausanne, Vaud 1005, Switzerland

After attending this presentation, attendees will possibility of the influence of the degenerative findings in the cardiac conduction system in the pathophysiology of the death in chronic drug abusers.

This presentation will impact the forensic community and/or humanity by showing that degenerative changes of the cardiac con-

duction system are more often observed in drug addicts than in the control group.

The destructive effects of some drugs and especially of cocaine on the cardiovascular system are well known. The aim of this study was to evaluate if the degenerative changes concern also the cardiac conduction system and if these changes are more frequently observed in drug addicts.

The material included fatalities studied at the University Institute of Forensic Medicine in Lausanne for the period 1998-2001. The age of the patient ranged from 21 to 47 years (mean 32.4) for the drug addicts and from 21 to 50 in the control group (mean 32.5). In the group of the drug addicts we included 51 cases, all of them known by the police as drug users. Complete autopsy with histological examination were available for each case, and toxicological analyses in 50 cases. The toxicological analyses demonstrated the presence of one or more drugs in the blood in 43 cases, from which in 20 cases 3 or more drugs; cocaine or its metabolites were present in 18 cases. In the control group were included 52 cases not known as drug abuser. Complete autopsy with histological examination were available for each case and toxicological analyses in 40 cases. From 7 cases of intoxication which were included in this group, 4 were suicides by psychotropic drugs, one suicide by cyanide ingestion and 2 were consecutive to accidental monoxide intoxication. In 22 cases the toxicological analyses were negative. In 11 cases the therapeutic levels of different antidepressants were found. Cocaine or its metabolites were found in no case.

The degree of fibrosis and fatty infiltrations has been analysed using the semi-quantitative score evaluation. The changes were analysed in the following structures: the atrioventricular node (NAV), the penetrating part of the node (PB), the branching bundle (BB), the left and right branches (LBB and RBB) as well as the left and right part of the septum superior.

The mean scores for the degenerative changes were higher in the addicts group. The statistical analyses showed significant differences ($p<0.01$) for fibrosis in the atrioventricular node, in the penetrating part, in the left bundle branch, and in the septum superior as well as for fatty infiltration in the branching bundle and in the left bundle branch. No significant differences were found between the results in the group of cocaine-positive drug users and the results in the drug users without cocaine found in toxicological analyses.

The more frequent apparition of degenerative changes in the group of drug addicts, which are often cocaine users, can be explained by cardiotoxic effect of a chronic drug administration. On the other hand, it is evident that the pathomechanism of deaths in drug intoxication is multi-factor, and that interpretation of deaths by overdose can be difficult because the range of drug concentration in fatal cases can be very large. Therefore, the possibility of the influence of the degenerative findings in the conduction system and in the septum superior in the pathophysiology of the death in chronic drug abusers should also be considered. Moreover, in some deaths pathological changes may be associated with the electrical instability of the heart and even contribute to the death, in particular in some unexplained cases of sudden death.

Drug Addiction, Heart, Conduction System

G57 Systemic Amyloidosis in an Intravenous Drug Abuser

Jennifer J. Prutsman-Pfeiffer, MA*, Strong Memorial Hospital, Neuropathology and Postmortem Medicine, Box 626, 601 Elmowwd Avenue, Rochester, NY 14642

The goal of this presentation is present to the forensic community a case of systemic primary amyloidosis in an intravenous drug abuser.

Recognition of systemic amyloidosis and the subsequent microscopic examination of tissues is important during autopsy. Autopsy pathologists, residents, and pathologists' assistants should be aware of

the correlation between systemic secondary amyloidosis and people with a history of illicit drug use/abuse, as well as the possibility of a chronic drug abuser having the primary form of amyloidosis. The type of amyloidosis can be further characterized through immunohistochemical staining of selected amyloid containing tissues.

This poster will present the incidental finding at autopsy of systemic amyloidosis in a 46-year-old African American male that was a former intravenous heroin abuser. Healed track marks were identified on the arms. The patient had cirrhosis and was Hepatitis B and C positive, underwent bimonthly serial paracentesis for refractory ascites, and had congestive heart failure, renal insufficiency, and dyslipidemia. The patient was noncompliant with treatment for his heart condition until 2000, which roughly correlates with the diagnosis of Hepatitis and his last illicit drug use. The patient's social history also includes a 15 pack/year smoking history, six 40-ounce beers per day for 6 years, and cocaine smoking. The patient was admitted to the hospital after paramedics arrived to a complaint at the patient's home of severe testicular edema, the last ascites tap having been performed two days prior. The patient's ascites did not resolve by the administration of albumin, and four litres of ascites fluid were drained three days after admission. The patient had a "seizure" the following early morning, witnessed by his roommate prior to the two attempting to sneak outside for a cigarette. The patient had no recollection of the event. An MRI revealed nothing of significance. Two days later, the patient was found to have a heart rate in the 60s, respirations of 8, and had no detectable blood pressure. Resuscitative efforts were continued for 35 minutes to no avail, and the patient was pronounced dead.

At autopsy, the cut surfaces of the heart and spleen had the typical heavy, waxy, glistening appearance of amyloid deposition. Microscopic sections of the heart, lung, spleen, liver, kidney, gastrointestinal tract, pancreas, thyroid, and prostate revealed amyloidosis, and were positive with Crystal Violet sensitivity and Congo Red specificity staining.

Amyloid is a pathologic proteinaceous deposit that collects in the tissues of persons having an immunologic dysfunction. Amyloid has a distinct gross appearance and under the light microscope appears as an amorphous eosinophilic extracellular substance. It is unique that in staining with Congo Red and viewed under polarized light an apple-green birefringence is visible, and the stain has a dramatic appearance with fluorescent microscopy. There are three major biochemically distinct forms of amyloid; the AL (amyloid light chain) type that is derived from immunocyte dyscrasia and is termed primary amyloidosis, AA (amyloid-associated) type that is often associated with people who have chronic inflammatory conditions and is known as secondary amyloidosis, and A beta amyloid, found in the brain and associated with Alzheimer's disease.

Amyloidosis has been cited in the literature to be a major cause of nephropathy in living heroin abusers. A technique used to inject the drug, called "skin popping," is resorted to when there has been such overuse of the vasculature to cause venous thrombosis and scarring of venous access. Skin-popping leads to skin ulcerations from reaction to the injected drug as well as non-sterile technique. Secondary amyloidosis occurs as a complication of this underlying chronic inflammatory process. An extensive search of the literature contains abundant discussion of heroin abuser renal amyloidosis, but few cases discussing autopsy findings of widespread systemic amyloidosis. This patient has extensive manifestation of the disease in virtually every organ in his body. Is this a case of secondary amyloidosis, or rare primary disease in a drug abuser? Either way, the ultimate cause of this patient's death is most likely an arrhythmia due to cardiac amyloidosis.

The widespread distribution of amyloid in the organs did not quite fit with the diagnosis of secondary amyloidosis as seen in other chronic intravenous drug abusers. The amyloid was further characterized as the AL-type through immunohistochemical staining of selected tissues with a negative result for the Amyloid A stain. The classification of an AL-type amyloid diagnose this patient's disease as primary amyloidosis.

Careful consideration in the differentiation of either primary or secondary amyloidosis is important in this case, since secondary amyloidosis is the type most commonly associated with chronic drug abusers.

Systemic Amyloidosis, Illicit Drug Abuse, Autopsy Pathology

G58 Photographic Imaging of Handgun Gas Clouds Compared to Gunshot Residue Swabs

D'Michelle P. DuPre, BA, MD*, Miami-Dade County Medical Examiner's Office, Number One Bob Hope Road, Miami, FL 33136-1133; Joe Castorenga, Bexar County Forensic Science Center, 7337 Louis Pasteur Drive, San Antonio, TX

After attending this presentation, the attendee will understand that a false negative result may be reported from gunshot residue analysis when ammunition with lead free primers are used.

This presentation will impact the forensic community and/or humanity by demonstrating why gunshot residue analysis is so non-specific when different ammunition is fired, even from the same weapon, and the possibility of a false negative result when lead free primer ammunition is used.

High speed photography is used to capture images of the gas/particle cloud emitted when firing full metal jacketed ammunition, hollow point ammunition and lead free primer ammunition from the same weapon, showing that similar gas clouds are emitted. Gunshot residue analysis is performed by Scanning Electron Microscope and Induction Coupled Plasma screening (ICP).

Lead is typically one of three components reported in a GSR analysis, using ICP. When the type of ammunition primer is not known and lead free primer ammunition was used to fire the weapon, the results may represent a false negative.

This study calls attention to the fact that GSR analysis has many variables. The results may be skewed when lead free primer ammunition and full metal jacketed ammunition are used and false positives may result.

Handgun Gas Clouds, Gun Shot Residue Analysis, Lead Free Primers

G59 Who was Driving: A Case Report

Ersi Abaci-Kalfoglou, PhD*, Hulya Yukseloglu, PhD, Tanıl Baskan, PhD, and Sevil Atasoy, PhD, Istanbul University, Institute of Forensic Sciences, Cerrahpasa, Istanbul 34303, Turkey

After attending this presentation the attendee will learn the power of DNA technology in solving problems concerning traffic accidents.

The forensic community will realize the importance of the application of DNA technology to traffic accidents.

The traffic accidents form one of the major sources of socio-economic loss for almost all the countries. This loss figures as material as well as personal loss. One of the most important strategic approaches is the certainty with which the cause of the accident can be established together with the responsible. The possibility of the determination of the responsible can be considered as the best method of prevention.

In case where the responsible is the driver the question is to identify him. The denial of driving is a very common phenomenon in traffic accidents. However the development in DNA technology the last decade made possible the personal identification in a very high accuracy.

Using this technology we have identified the driver of an accident with two deaths. Following the accident that took place in Izmir, a city in Aegean cost of Turkey, the Institute of Forensic Sciences of The University of Istanbul was asked to determine the driver performing a

detailed crime scene investigation. There were two deaths and two survivors from whom the one had amnesia and the second accused the first to be the driver.

The car examination revealed biological material from the front seat and from the windshield that matched the DNA profile of the second survivor.

The success of the identification was not only because of the power of the technology used but also because of the careful and detailed car examination that was performed. It is true that to end up with a satisfactory result requires a correct crime scene investigation at first part.

Traffic Accidents, DNA Technology, Crime Scene Investigation

G60 The Contribution of Researching DNA Breaks to the Evaluation of Postmortem Delay

Anne Dorandeu, MD*, Eric Baccino, MD, and Maguy Ursule, MD, Lapeyronie University Hospital, 371 Avenue du Doyen Gaston Giraud, Montpellier, Herault 34295, France

After attending this presentation, attendees will understand the results of a study on intranuclear DNA breaks on skin in an animal model.

This presentation will impact the forensic community and/or humanity by demonstrating an initial approach to be followed by further study on human skin, in order to improve evaluation of PMD.

Introduction: Postmortem delay (PMD) evaluation remains a problem for the forensic pathologist. Although Professor KNIGHT recently resumed all the methods used in his last book, it still seemed worthwhile to test a pathological method as a first stage on an animal pattern.

Material and Methods: 2.1) Material: 30 adult male rats, sacrificed according to protocol.

Cutaneous samples 2 mm by 2 mm from the inner thigh every 3 hours up the 24th hour, then every 6 hours until the 48th hour.

2.2) Methods: TUNEL technique: a commercially available DNA end labelling kit, the TUNEL method was standardised, validated and used for this purpose. This TUNEL technique (apoptag oncor) has shown itself to be the most reliable (reference) in a previous work.

2.3) Statistical analysis: For each PMD the average and the standard variation in the number of marked cells was calculated. The comparisons between the different PMDs were analysed with the Fischer test. The estimated PMD from the number of marked cells was based on linear regression. All the statistics were treated with the SAS software and the threshold of 5% significance was retained.

Results: The statistic analysis allowed the establishment of the following regression based on the number of marked cutaneous cells and according to their topography:

$$\text{Delay} = 32.648 - 1.114 \times \text{basal} - 6.886 \times \text{intensity} + 0.209 \times \text{superficial} + 0.434 \times \text{intermediate}.$$

Interpretation of Results: From the statistical results it appears that before the 18th hour there is an intranuclear break in the DNA fragments particularly in the superficial layers mainly constituted of mature keratinocytes, that after the 18th hour whatever the layer these apoptotic phenomena diminish. This reduction in breaks thus presents an interest in the evaluation of post mortem delay since all the layers behave practically in the same way with almost parallel kinetics, up to about the 48th hour.

Conclusion: In the next stage of this work true apoptotic variations will be verified by immuno-histochemistry (detecting the expression of bcl2, P53, caspases 3/9) or simple post mortem DNA breaks related to apoptosis. But having said this the TUNEL technique retains all its relevance in the evaluation of post-mortem delay. If it is really a case of

apoptotic mechanisms, its evaluation in certain organs, taking into account an agonic phase such as brain death but with a heartbeat, the mechanisms leading to apoptosis, blocking some of the factors leading to it could be of interest in organ transplants. A second objective would be to study a human model by taking a sample from a skin fragment at the site where the corpse has been discovered, in order to study it very quickly.

PMD, DNA Breaks, Skin

G61 From VIRTopsy to VIRTObOT: Photogrammetry Based Optical Surface Scanning and Radiological Virtual Autopsy

Michael J. Thali, MD and Marcel Braun, University of Berne, Buehlstrasse 20, Berne 3012, Switzerland; Buck Ursula, Emin Aghayev, MD, and Christian Jackowski, MD, University of Berne, Buehlstrasse 20, Berne 3012; Martin Sonnenschein, MD, University of Berne, Inselspital, Berne 3012, Switzerland; Peter Vock, MD and Richard Dirnhofer, MD, University of Berne, Buehlstrasse 20, Bern 3012, Switzerland*

After attending this presentation, attendees will learn the newest cutting-edge technologies of 3D forensic documentation.

This presentation will impact the forensic community and/or humanity by demonstrating an upgrade of the newest techniques using 3D body surface documentation merged with radiological data sets.

Goal: 3D body-surface documentation and minimal-invasive, image-guided virtual autopsy utilizing optical and radiological scanning: Pushing low-tech documentation and autopsy procedures in a world of high-tech medicine to improve scientific value, to increase significance and quality.

Background: A main goal of forensic medicine is to document and to translate medical findings to a language and / or visualization, which is readable and understandable for judicial persons and for medical laymen. Therefore, in addition to classical methods, scientific cutting-edge technologies can and should be used.

The Institute of Forensic Medicine, University of Bern is, in collaboration with an internationally well selected research team, evaluating and validating several cutting- edge technologies such as 3D optical and photogrammetric surface scanning, Computed Tomography (CT), Magnetic Resonance Imaging (MRI), Magnetic Resonance (MR) Spectroscopy, Micro-CT, Micro-MR and synthetic body models (www.virtopsy.com).

Methods and Results: Through the use of the forensic, 3-D/CAD-supported photogrammetric and 3D body surface scanning method the documentation of so-called 'morphologic fingerprints' has been realized. Forensic, 3-D/CAD-supported photogrammetry and 3D body surface scanning create morphologic data models of the injury and of the suspected injury-causing instrument allowing the evaluation of a match between the injury and the instrument. In addition to the photogrammetric body surface registration and 3D body surface scanning, the radiological documentation provided by a volume scan (i.e., spiral, multi-detector CT, or MRI) registers the sub-surface injury, which is not visible to Photogrammetry and 3D body surface scanning. The new, combined method of merging photogrammetry/3D body surface scanning and radiology data sets creates the potential to perform many kinds of reconstructions and postprocessing of (patterned) injuries in the realm of forensic medical case work. Using this merging method of colored photogrammetric surface and gray-scale radiological internal documentation, a great step towards a new kind of reality based, high-tech wound documentation and visualization in forensic medicine is made. The combination of these methods has the advantage of being observer-independent, non-subjective, non-invasive, digitally storable over years or decades and even transferable over the web for second

opinion.

Results: Body surface and radiological imaging techniques are particularly beneficial for reconstruction and visualization of forensic cases, allowing the opportunity to use the data for expert witness reports, teaching, quality control and telemedical consultation. The preliminary results based on the concept of 'Virtopsy' are promising enough to introduce and evaluate these techniques in forensic medicine. Documentation by these methods is observer-independent, objective and non-invasive. Digitally stored data may be recalled at will and provide fresh, intact topographical and anatomico-clinical reconstruction. Quality control and expert supervision becomes possible in a new manner, as well as image transmission and forensic "telemedicine" consultation. Image and data processing allows two- and three-dimensional views of forensic and anatomical findings. MR Spectroscopy has the possibility of metabolic-chemical analysis. In certain cultural circles where conventional autopsy is stigmatised or even forbidden, virtual autopsy would allow sound medico-legal practice and support for the judicial system without violating religious prohibitions or personal reservations. Also, in the post-mortem examination of highly infectious cadavers this technique could be of particular use (bio-terrorism). Minimally invasive autopsy would reduce the number of conventional autopsies, which are often difficult to bear for relatives. This development could be similar to that observed with the advent of minimally invasive percutaneous or laparoscopic surgery. Our results showed that we strive to lead forensic medicine to new horizons by utilizing the newest technologies.

Discussion and Perspectives: Based on our results, we hope that the combination of forensic-pathologic "know-how" (experience) with high-tech imaging will open new horizons in forensic medicine and other forensic sciences, leading towards a minimally-invasive virtual forensic autopsy (www.virtopsy.com). The automatisation of this process will lead to the development of a "Virtobot."

Forensic Radiology, Photogrammetry, 3D Body Surface Imaging

G62 Comparative Study of DNA Yield and STR Profile Quality Obtained From Various Tissue Types of a Decomposed Body

Shelly A. Steadman, MS, Sedgwick County Regional Forensic Science Center, 1109 North Minneapolis, Wichita, KS 67214; Jaime L. Oeberst, MD, Sedgwick County Regional Forensic Science Center, 1109 North Minneapolis, Wichita, KS 67214; Daniel J. Fahnestock, MS, Sedgwick County Regional Forensic Science Center, 1109 North Minneapolis, Wichita, KS 67214*

The goal of this presentation is to present the forensic community with comparative DNA quantification and STR profiling results obtained following routine extraction of DNA from a variety of tissue types obtained during the autopsy of a decomposed body.

When DNA testing is necessary on bodies that have undergone decomposition, the pathologist may wish to focus collections on bone and nails prior to collection of hair or muscle for downstream typing purposes. Collection of the most appropriate samples for DNA typing will eliminate the need to repeat the extraction and profiling process and will ultimately expedite the identification process.

STR DNA profiling of decedents, either for identification purposes or for casework applications, is commonly used in the forensic setting. Obtaining DNA profiles from decedents where substantial decomposition has occurred presents a challenge to the DNA analyst due to the compromised nature of the cellular material housing nuclear DNA. The forensic pathologist is tasked with collecting tissue from the decomposed body that will most likely yield DNA of high quality and quantity such that nuclear DNA profiling will be possible. This presentation will describe the results of DNA quantification assays and STR DNA pro-

filling results obtained following the DNA extraction of a variety of tissue types collected from a decomposed body at autopsy. The results presented here are useful for predicting the most appropriate tissue types to collect during autopsy when subsequent DNA analysis will be required.

The study involved collecting a variety of tissue types from various areas of the body. Scalp hair, pubic hair, deep muscle tissue (psoas), nail material (toenails), and cross-sectioned vertebral bone were harvested from a body exhibiting moderate decomposition. According to investigative reports, the body was initially placed in a grassy field for two days. Suspects then returned to the scene and buried the body in a shallow grave, where it remained until exhumation eight days later. Temperatures during this period ranged from 48-88° F, with a mean temperature of 67.5° F and a total rainfall of 1.84 inches. The body exhibited mild to moderate postmortem insect larvae activity.

A general description of each tissue type was made prior to further processing for DNA extraction. The scalp hair was matted and evaluation of individual hairs and/or roots was not possible; approximately 36.7 mg of this material was collected for DNA extraction. Pubic hairs were separable, therefore root ends were identified macroscopically; approximately 7 mm of the root ends of ten hairs were collected for DNA extraction. The muscle obtained at autopsy was further sectioned prior to DNA extraction, yielding two visually different tissue samples. One was central to the mass submitted for testing and was pink in color (referred to as "deep" hereafter), while the second sampling was more superficial and gray in appearance (referred to as "superficial" hereafter). The muscle tissues collected for DNA extraction from these two visually distinct samples had a mass of 159.6 mg, and 147.9 mg, respectively. Toenails were selected as nail material that would least likely bear DNA from a foreign source (as compared to fingernails); 190.4 mg of nail material was cut for DNA extraction. Finally, 190.5 mg of bone matrix was shaved from the wedged aspect of the cross-sectioned vertebra for subsequent DNA extraction.

Resulting tissue cuttings were each extracted using organic extraction methods and by Microconâ (Millipore, Corp., Bedford, MA) concentration and purification of the DNA. Extracted DNA from all samples was quantified using 1% agarose yield gel analysis in conjunction with the QuantiBlot® (Applied Biosystems, Foster City, CA) human DNA quantification kit. The quantity of DNA detected for each tissue type using the agarose product gel and human specific quantification systems, as well as estimated overall human DNA yield, was calculated in terms of nanograms of DNA per milligram of tissue extracted.

Quantification results indicated that high molecular weight DNA was detected all tissue types, with the exception of the hairs. Also with the exception of the hair samples, human DNA was detected from all DNA samples using the QuantiBlot® system; the bone sample yielded the highest overall quantity (ng DNA/mg tissue). Although the superficial muscle appears to exhibit a slightly higher overall yield than the deep muscle sample, the slight difference may be due to the subjective nature of visual comparative determination employed when determining quantifications from slot blot. Nevertheless, it can be concluded that resulting muscle tissue yields were similar regardless of sample stratification.

Samples were then amplified using the PowerPlex™16 BIO System (Promega Corp., Madison WI) and amplified products were detected using the Hitachi FMBIO® II Fluorescent Imaging Device (MiraiBio Inc., Alameda, CA). A target template amount of 0.5 ng was incorporated into each amplification reaction based on the QuantiBlot® quantifications; since no DNA was detected for the hair samples, the sample retentates were consumed during amplification.

The DNA profiles obtained from the pubic hair and both muscle tissue samples were partial in nature, while the nail material and bone yielded complete DNA profiles. No profile was obtained from the scalp hair sample. Although high molecular weight DNA of human origin could be harvested from deep muscle tissue of various strata, nail

material, and bone, the extracted DNA did not type with equal efficiency using common nuclear DNA typing techniques. While moderate results were obtained from pubic hairs that were separable upon extraction preparation, hairs submitted in bulky masses were not useful for typing using conventional methods. Deeper muscle tissue yielded a more complete profile than did the more superficial sample collected from the same muscle group. Although all were partial in nature, a more complete profile was generated from the pubic hair sampling than from either of the muscle cuttings. Nail material and bone both generated full DNA profiles and are therefore determined most useful for nuclear DNA typing following decedent body decomposition.

It can be concluded that although the agarose product gel indicates the presence of quality DNA from these samples, the DNA may have undergone damage not explicitly detectable by this method. Furthermore, the presence of microbial DNA complicates the analyst's ability to accurately determine the quantity of amplifiable human DNA present. As expected, due to the relatively short nature of the probe primarily responsible for recognition of human DNA in the blotting quantification system, the presence of adequate quantities of human DNA using these conventional blotting techniques is not necessarily indicative of the quantity of amplifiable DNA. However, data from both the agarose gel and blotting system can be used to predict the amount of human DNA within the total observed high molecular weight DNA, which can be useful for predicting which sample will most likely generate a well-balanced DNA profile across all 16 loci. In summary, this study indicates that nail material and bone tissue collected from decomposed bodies are more likely to yield full DNA profiles than are hairs or muscle tissue when straightforward processing and DNA extraction techniques are employed. When DNA testing is necessary on bodies that have undergone decomposition, the pathologist may wish to focus collections on bone and nails prior to collection of hair or muscle for downstream typing purposes.

Decomposition, PCR DNA Profiling, DNA Extraction

G63 Experimental Evaluation of Rigor Mortis Nysten's Law: Does it Apply to Rats?

Thomas Krompecher, MD*, Andre Gilles, MD, Conxita Brandt-Casadevall, MD, and Patrice Mangin, MD, Institut Universitaire de Médecine Légale, Rue du Bugnon 21, Lausanne, Vaud 1005, Switzerland

The learning objective consists in presenting the development of the intensity of rigor mortis in the different parts of the body of rats.

In 1811, the French physician and chemist P.H. Nysten published the first scientific description of rigor mortis. The law named after him states that "Cadaveric rigidity affects successively the masticatory muscles, those of the face and the neck, those of the trunk and arms and finally those of the lower limbs." It is often added that resolution occurs in the same order. The development of rigor mortis is thus descending, a finding thought to be related to the varying distances between the different muscles and the central nervous system. However, Nysten himself noticed that the destruction of the CNS did not affect the order of the development of rigidity.

In 1917, Naumann confirmed the descending development of rigor mortis, but he also noticed that in some special cases (e.g., in weak individuals, or those diminished by illness), rigidity may show an ascending pattern.

However, in 1950 Shapiro contested Nysten's statement: "it is difficult to understand why a physico-chemical process which takes place in recently dead tissues should follow the sequence usually described. It appears more likely that, because we are dealing with a physico-chemical process in what is virtually a lump of clay, this will take place simultaneously in all the recently dead muscles."

Some years ago, we developed a method to increase our understanding of rigor mortis through the objective measurement of the intensity of cadaveric rigidity in rats. The principle of the method is to determine the force required to cause a movement of small amplitude (4 mm) in the limb under examination. Since the movement doesn't break rigor mortis, serial measurements can be conducted. Our apparatus measures the resistance caused by rigor mortis in the knee and hip joints of rats. This method has been used in the past to evaluate the influence of several pre-mortem and post-mortem factors (i.e., body weight, muscular mass, age, physical exercise, ambient temperature, various causes of death, electrocution) on the development of rigor mortis.

In our present investigation, we tried to determine the validity of Nysten's law in the case of rats. For this purpose, we adapted our method to perform parallel measurements in the masticatory muscles, the neck, the front limbs and the hind limbs in rats, respecting the same principles of measurements.

Experimentation:

Animals: male albino rats, weighing approx. 300 g.

Measurement time points: 10 min, 1h, 2h, 3h, 4h, 5h, 6h, 8h, 12h, 16h and 24 post-mortem.

Results:

Group No 1: hind limbs.

The maximal values of the intensity of rigor mortis were reached at 5 hours post-mortem with a plateau of the intensity between 5 and 8 hours post-mortem, followed by the resolution of rigor mortis.

Group No 2: front limbs.

The time course of the intensity of rigor mortis was practically the same as in the hind limbs in spite of the fact that the muscular mass of the hind limbs was 2.89 times greater than that of the front limbs.

Group No 3: neck.

The maximal values of the intensity of rigor mortis were reached at 3 hours post-mortem in the muscles of the neck. The resolution began at 6 hours postmortem.

Group No 4: masticatory muscles

In the masticatory muscles the maximal values were reached at 2 hours post-mortem. The resolution began at 8 hours postmortem.

Conclusion: The intensity of rigor mortis reaches maximal values significantly earlier in the masticatory muscles and in the muscles of the neck as compared to the front and hind limbs in rats. Consequently, Nysten's law seems to apply to rats as far the onset of rigor mortis is concerned.

Rigor Mortis, Nysten Law, Rats

G64 Microbial Processes in Soils Associated With Skeletal Muscle Tissue and Cadaver Decomposition at Different Temperatures

David O. Carter, MSc*, James Cook University, School of Pharmacy & Molecular Sciences, Douglas, Queensland 4814, Australia; Mark Tibbett, PhD, University of Western Australia, Soil Science and Plant Nutrition, School of Earth and Geographical Sciences, Crawley, Western Australia 6907, Australia; David Yellowlees, PhD, James Cook University, School of Pharmacy and Molecular Sciences, Douglas, Queensland 4811, Australia

After attending this presentation, attendees will understand that the examination of soil microbiological and biochemical processes can provide insight into how temperature can affect the decomposition of cadavers and cadaver components in soil.

This presentation will impact the forensic community and/or humanity by demonstrating the soil microbial community has the potential to provide a basis for the estimation of postmortem and/or post burial interval.

Forensic taphonomy, and forensic science in general, has benefited greatly from the application of biological sciences. For example, the use of entomological principles and practices has led to an increased understanding of cadaver decomposition while providing an efficient and effective means to estimate postmortem and/or postburial interval. Considering that the decomposition of most resources in terrestrial ecosystems is due to the activity of soil microorganisms (often acting in conjunction with a variety of invertebrates) microbial processes in soils have been given little consideration. The microbiota are responsible for the regulation of nutrient transformation and storage in soils. As a result, all organic matter placed in the soil is acted upon (eventually) by soil microorganisms prior to being recycled into the wider ecosystem. The soil microbial biomass is a dynamic population, which can respond rapidly to environmental conditions (e.g., temperature, moisture) and the introduction of fresh substrates. These stimuli may result in a population adapted for specific circumstances.

There are a number of well established microbiological and biochemical methods for studying structural and functional characteristics of soil microbial communities. For example, substrate-induced respiration (SIR) and chloroform-fumigation incubation can be used to estimate the soil microbial biomass while fatty acid methyl ester and DNA analysis can be used to identify the taxa that make up the soil microbial community. Functional processes may be examined through measurements of CO₂ respiration, enzyme activity and nitrogen mineralization, among others. In this study we have applied a number of these methods (mass loss, microbial CO₂ respiration, SIR, enzyme assays) to determine whether temperature affects microbially mediated decomposition of skeletal muscle tissue (*Ovis aries*) and cadavers (*Rattus rattus*) in soils.

In experiment 1, skeletal muscle tissue (*Ovis aries*: 1.5 g) was incubated in soil microcosms at 2 °C, 12 °C and 22 °C in a sandy loam soil (100 g) from Dorset, England. Tissue mass loss was measured gravimetrically at seven day intervals over a period of 42 days. Microbial CO₂ respiration was measured every 24-48 hours using the alkali (0.3M NaOH) absorption method. Soil microbial biomass was estimated on day 21 using the SIR technique. Mass loss and SIR samples were collected using a destructive, sequential harvesting program.

In experiment 2, juvenile cadavers (*Rattus rattus*: ~20 g) were buried in a sandy loam soil (500 g) from tropical Queensland, Australia and incubated at 15 °C, 22 °C and 29 °C. Soil enzyme activities (arylsulphatase, dehydrogenase, phosphodiesterase, protease) were assayed on day 21 using standard soil enzymological techniques.

Experiment 1 demonstrated that each 10 °C increase resulted in an increase in the rate of tissue mass loss. These differences were maintained until day 42, when tissue incubated at 12 °C and 22 °C displayed similar levels of mass loss ($P = 0.266$). This may be due to the loss of readily available substrate (tissue) whereby the remaining tissue represents a more recalcitrant form of organic matter. The rapid utilisation of readily available nutrients was suggested by a flush of CO₂ following burial at 12 °C and 22 °C. Microbial CO₂ respiration gradually decreased following this flush. Test samples (soil with tissue) always demonstrated greater respiration rates than control samples (soil without tissue). Test samples incubated at 22 °C demonstrated greater levels of CO₂ respiration than samples incubated at 12 °C until day 23 ($P = 0.267$). Microbial CO₂ respiration at 2 °C was less than the other temperatures until day 42 ($P = 0.052$). A direct relationship was demonstrated between tissue mass loss and microbial CO₂ respiration (22 °C: $r = 0.690***$, 12 °C: $r = 0.810***$, 02 °C: $r = 0.836***$). Thus, the measurement of microbially respiration CO₂ can provide a basis on which to accurately predict soft tissue decomposition in soil. This can be achieved by calculating the amount of CO₂-C respiration. Microbial biomass estimations demonstrated no differences between test and control samples incubated at 2 °C ($P = 0.139$) or 12 °C ($P = 0.088$). Test samples incubated at 22 °C demonstrated a greater microbial biomass than control samples incubated at the same temperature ($P = 0.002$). This suggests

that temperature is able to control growth of the soil microbial biomass even in the presence of a highly utilizable substrate.

In experiment 2 test samples always displayed greater protease and phosphodiesterase activity than control samples. Protease activity in test samples incubated at 15 °C were less than in test samples incubated at 22 °C ($P = 0.013$). Phosphodiesterase activity in test samples incubated at 15 °C was greater than in test samples incubated at 22 °C ($P = 0.010$). These results demonstrate that cadaver burial can bring about an increase in the activity of some enzymes commonly associated with soil microbial communities. The activity of these enzymes seems to be influenced by temperature. Arylsulphatase and dehydrogenase results did not respond to the presence of the cadaver.

The decomposition of the organic matter used in these experiments may be attributed to increased microbial biomass and/or enzyme activity. These decomposition processes can be greatly influenced by temperature. Soil microorganisms can play a rapid and substantial role in the decomposition of skeletal muscle tissue buried in soil. The decomposition of this relatively simple substrate can be accurately predicted through the estimation of C mineralization (CO₂-C) and assimilation. This method may also assist in the study of the decomposition of amorphous materials such as blood and hair. The decomposition processes examined in the current work were most likely carried out by a diverse community of microorganisms. One particular feature of the taxa that comprise soil microbial communities is that they commonly exhibit a succession whereby a change in the composition of the community takes place over time as a result of change in environmental conditions or substrate. We believe that continued research into soil microbial succession in grave soils may possibly provide a basis for the estimation of post-mortem and/or postburial interval.

Forensic Taphonomy, Temperature, Soil Microbial Community

G65 Does Carcass Enrichment Alter Community Structure of Predaceous and Parasitic Arthropods? A Second Test of the Arthropod Saturation Hypothesis at the Anthropology Research Facility in Knoxville, Tennessee

Kenneth G. Schoenly, PhD, Department of Biological Sciences, California State University, Stanislaus, Turlock, CA 95382; Adam Shahid, MS, University of Missouri, Department of Entomology, 320 Connaway Hall, Columbia, MO 65211; Neal H. Haskell, PhD, Department of Biology, Saint Joseph's College, Rensselaer, IN 47978; Robert D. Hall, PhD, JD, University of Missouri, Department of Entomology, 1-87 Agriculture Building, Columbia, MO 65211*

The goal of this presentation is to present to the forensic sciences community the latest findings on the scientific usefulness of the Anthropology Research Facility (University of Tennessee, Knoxville) as a research and training site for forensic entomology.

This presentation will impact the forensic community and/or humanity by describing an application of probability and power testing of several key variables of arthropod community structure to test the scientific usefulness of the Anthropology Research Facility (University of Tennessee, Knoxville) as a research and training site for forensic entomology.

The on-campus Anthropology Research Facility (ARF) at the University of Tennessee, Knoxville, established by Professor William Bass in 1972, is an outdoor scientific laboratory devoted to the study of human decomposition. In a previous study, probability and power testing of several independent variables of decomposition rate and community structure showed that porcine remains in the ARF do not decompose faster, nor are they saturated with forensically-important (sarcos-

aphagous) arthropods of reduced diversity, compared to remains in three non-enriched sites various distances away. In a second test of this 'arthropod saturation hypothesis,' we ask if the 30-yr history of carcass enrichment at the ARF has altered the community structure of predatory and parasitic arthropods that prey upon the sarcosaprophagous fauna. Over a 12-day period in 1998, using pitfall traps and sweep nets, we sampled over 81,000 invertebrates from freshly euthanized pigs (*Sus scrofa* L.) placed in the four sites: ARF: S2 (700 m away from ARF), S3 (6 km away), and S4 (40 km away). From these counts, we sorted 8,836 and 342 enemies of the sarcosaprophagous community (predators, parasitoids, and parasites) from pitfall and sweep-net counts, respectively, for a total enemy fauna of 9,178 individuals. The community structure of these organisms, measured by species and individuals' accumulation curves, rarefaction, and nonparametric correlation, was comparable in most paired-site tests with respect to colonization rates, ranked abundances, and colonization sequences of predatory/parasitic taxa on a per carcass basis. In the few exceptional cases, ARF differed from each of the three non-enriched sites in rarefaction-adjusted species richness (ARF pitfalls had more species). Spearman rank tests showed that correlations, although significantly positive between all site pairs, were stronger for sarcosaprophagous arthropods than for their natural enemies, confirming the tighter and more predictable relationship between carrion feeders and their carrion than between carrion feeders and their natural enemies. Overall, these findings parallel our earlier results on the sarcosaprophagous community, and except for species richness, bolster the conclusion that ARF is representative of surrounding sites with respect to the carrion-arthropod fauna.

Anthropology Research Facility (ARF), Forensic Entomology, Predatory and Parasitic Arthropods

G66 Trends in Forensic Entomology in the United States and Abroad

Jeffery K. Tomberlin, PhD, Department of Entomology, Texas A&M University, 1229 North U.S. Highway 281, Stephenville, TX 76401; Jason Byrd, PhD, Office of the Medical Examiner, 1360 Indian Lake Road, Daytona Beach, FL 32164; John Wallace, PhD*, Department of Biology, Millersville University, Fredrick Street, Science and Technology Building, Millersville, PA 17551*

The goal of this presentation is to provide those attending with an update on research trends in forensic entomology.

Due to the amount of forensic research conducted in general, it can be difficult for forensic specialists to remain up to date on research trends in their own field much less the countless other disciplines in the forensic sciences. We will provide those attending our presentation with a "snapshot" of current trends in forensic entomology research from around the world with an emphasis on research being conducted in the United States.

Initially, research on insects colonizing carrion was viewed as an attempt to better understand succession and nutrient recycling in terms of general ecology (Payne 1967). However, over the course of the past 20+ years, the aim and direction of such research has been largely focused on the use of insects as evidence in criminal investigations resulting in the development of the discipline of forensic entomology. Today, forensic entomology receives considerable attention from entomology and biology departments in universities throughout the United States and world.

The goal of this presentation is to provide those attending with an update on trends in forensic entomology. Published information on forensic entomology research was gathered through a search of the CAB database via Texas A&M University. Additional information on current research was gathered by contacting individuals from around the world who are known to have active forensic entomology programs. Articles located through the search were broken down into several categories;

research topic, locality of research, year published, and journal. Participants will be provided this information with special reference to states in the U.S. with ongoing programs in forensic entomology. Additional information will also be given on events occurring at the first North American Forensic Entomology Conference, which took place August 7-9, 2003, in Las Vegas, Nevada.

Articles with forensic entomology in the title or as a key word were located as far back as 1983. The number published gradually increased from 3 that year to 50 in 2001. A total of 22 countries published 101 articles on forensic entomology from 1999 through 2003. The top five countries during this period that produced articles in English according the CAB database search are the United States, France, Italy, Germany, and Australia. Other countries with significant contributions have been Thailand, Canada, and India.

Articles from 1999 through 2003 were grouped in one of seven research areas; insect biology (26%), review articles (16%), succession studies (15%), DNA (14%), case study (12%), entomotoxicology (10%), and morphology/taxonomy (7%). These articles were primarily published in three locations; *Forensic Science International* (31%), *Journal of Forensic Sciences* (14%), and the *Journal of Medical Entomology* (9%). Additionally, it was determined that forensic entomology research had been conducted in 18 states during this period: TX, AL, SC WV, CA, VA, NY, OH, GA, HI, MD, CO, LA, TN, MI, FL, MO, PA, and the District of Columbia. A summary of this survey and bibliography is located at: <http://stephenville.tamu.edu/~jktomberlin/forensic.html>

Entomology, Literature, Research

G67 Temperature-Dependent Development of the Blow Fly *Calliphora Vicina* (Diptera: Calliphoridae) and the Effects on the Estimation of the Postmortem Interval

Timothy E. Huntington, BS; Leon G. Higley, PhD, and Frederick P. Baxendale, PhD, University of Nebraska, Department of Entomology, 202 Plant Industry, Lincoln, NE 68583

After attending this presentation, attendees will understand the importance of temperature on the development of the forensically important blow fly *Calliphora vicina* and present new research on the same.

This presentation will impact the forensic community and/or humanity by attempting to improve the quality, accuracy, and reliability of scientific data upon which estimates of the postmortem interval using insects are based. This will help strengthen the science of forensic entomology, but more importantly, serve to help investigators come closer to the truth when investigating the circumstances surrounding a death.

Forensic entomology deals largely with the estimation of the postmortem interval, or PMI, of the victim of a violent crime. There are several ways that entomological evidence may be used to calculate the PMI, but the most commonly used method involves using the developmental rates of blow fly (Diptera: Calliphoridae) and flesh fly (Diptera: Sarcophagidae) larvae. One forensically important blow fly is *Calliphora vicina* Robineau-Desvoidy, commonly known as the blue bottle fly. This species is nearly worldwide in distribution, and is commonly recovered on human remains through the course of forensic investigations.

Because insects are poikilothermic (cold-blooded), blow flies develop at rates which are largely dependant on the temperature of their surroundings. In general, development slows with cooler temperatures and accelerates with warmer temperatures. These developmental rates are of prime importance when calculating the PMI estimate. The temperatures experienced by the developing larvae must be taken into consideration when estimating the time it has taken for them to reach a given stage of development.

There have been a number of studies published on the developmental rates of blow flies at different temperatures. Because of variations in the experimental design, equipment, and sampling regime, there are some discrepancies in the literature regarding the accumulated degree-hours (ADH) and accumulated degree-days (ADD) needed for completion of the life cycle in these flies, as well as their developmental thresholds (those temperatures at which the larvae cease development). These discrepancies, when used to analyze evidence in a capital murder case, for example, can cause an exaggerated estimate of the PMI and cost an innocent person their freedom or help free a guilty person.

Our research has attempted to correct these problems and provides reliable data which forensic entomologists may use when estimating PMIs. Temperature trials over seven constant temperatures were conducted to determine developmental rates. Flies were reared on beef liver within plastic containers in environmental chambers. Thermocouples were placed within each container to accurately record the temperatures experienced by the developing larvae. Development times recorded to the nearest half-day were used to construct a degree-day model for each larval stage. The minimum temperature required for egg hatching within a five-day period was determined and ADH were calculated.

Forensic Entomology, Postmortem Interval, Calliphoridae

G68 Evidence for Neglect of Children and Elderly Persons by Use of Forensic Entomology

Mark Benecke, PhD, MSc*, International Forensic Research & Consulting, Postfach 250411 Cologne, NRW 50520, Germany

After attending this presentation, attendees will recognize and collect evidence in severe cases of neglect, understand how to interpret the evidence, and the importance of the actual scene where the body was found, not only the state at the Institute of Legal Medicine.

This presentation will impact the forensic community and/or humanity by demonstrating forensic entomology in difficult cases: Insects on living persons — investigation however after death of persons.

Wounds of living persons are a potential target for the same flies that live, or feed early on corpses. This can lead both to complications in estimation of PMI (post mortem interval), or to additional information that might be valuable in a trial, or during the investigations. With forensic entomology, and forensic entomologists being more and more present, even lower profile cases like the neglect of elderly people (without violence being used against them (i.e., natural death), and neglect of children comes to our attention. Furthermore, much more people grow older than in the past years which leads to increased awareness of malpractice of caregivers in the professional, and personal environment.

Case 1: Elderly women found dead in October 2002 in her 3rd floor apartment in urban Cologne, Germany. Apartment was very clean except of the bathroom in which a bathtub had been filled with water, and clothing. Exclusively dead adult flies of the species *Muscina stabulans* FALLÉN were found spread on the floor; no blow flies in the zoological sense of the meaning were present in any live stage. Calculation of PMI led to an interval of around three weeks. This would have been a misconduct of the paid professional care giver who was supposed to check for the women every week.

The caregiver claimed that she had called the women ca. two weeks ago to check on her; the now dead women allegedly rejected a visit. This possibility could not be ruled out since the old woman was known to be healthy, yet mentally unstable and behaving "difficult" against everybody.

In clear contrast to the entomological findings, it was assumed that the caregiver tried her best; no prosecution followed.

Case 2: In September 2002, an old woman was found dead in her apartment in an urbanized town in western Germany. Her foot was wrapped in a plastic bag; inside, numerous larvae of *Lucilia sericata* were found. The caregiver openly stated that "it was well possible that the foot of the person was wrapped in a plastic bag, and that maggots may have been present inside during the lifetime of the woman."

The age of the maggots was estimated as four days (4x 24 hrs). However, judging from the deep tissue loss at the foot, it was discussed that most likely, the maggots had been feeding on the living woman for at least a week whilst she was still alive but then left the bag to pupate elsewhere. The apartment could not be checked for pupae, however.

Case 3: In March 2002, the corpse of an old woman found in her apartment in an urban apartment in a western German town. The apartment was not cleaned up, and on the actual corpse, the following insects were found: Larval *Fannia canicularis* flies, larval *Muscina stabulans* flies, and adult *Dermestes lardarius* beetles. These insects are known to build up populations inside of human housings but *Fannia* frequently hints towards the presence of feces, and urine in cases of neglect. In this case, further evidence for this possibility was found in the fact that the skin of the corpse was not fed on by the larvae. Pupae (of an unknown species) were reported but not collected. The son of the woman who was convicted of misconduct of taking care of his mother. It remained however unclear if the insects had inflicted pain on the woman or not.

Case 4: On the skin surface under the diaper (anal-genital area), third instar larvae of the false stable fly *Muscina stabulans* FALLEN, and the lesser house fly *Fannia canicularis* L. were found. *F. canicularis* adults are attracted to both feces and urine. From the face, larvae of the bluebottle fly *Calliphora vomitoria* L. were collected. *C. vomitoria* maggots are typical early inhabitants of corpses. From the developmental times of the flies, it was estimated that the anal-genital area of the child had not been cleaned for about 14 days (7-21 day range), and that death occurred only 6-8 days prior to discovery of the body.

Conclusion: From the actual case work, we get the impression that misconduct of elderly people currently becomes a severe problem in our aging societies. From a juridical standpoint, it is – and will be – very difficult to judge if the care giver is guilty of misconduct, or not. Forensic entomology can give important insights into the dynamics, the amount, and the final state of bodily care that was given to the neglected person.

At the same time, forensic entomology helps to excuse care givers who did actually do their duty whilst maggot infestation of a person's wounds occurred during a normal interval of non-visits.

Forensic Entomology, Child Neglect, Neglect of the Elderly

G69 DNA-Based Identification of Forensically Significant Blowflies of Australia and Southern Africa

Michelle L. Harvey, BSc, BA and Ian R. Dadour, PhD, Centre for Forensic Science, University of Western Australia, Stirling Highway, Nedlands, Perth, Western Australia 6009, Australia; Martin H. Villet, PhD, Department of Zoology and Entomology, Rhodes University, Grahamstown 6140, South Africa; Mervyn W. Mansell, PhD, Plant Protection Research Institute, Private Bag X134, Pretoria, Gauteng 0001, South Africa*

After attending this presentation, attendees will understand the DNA-based identification of flies; potential of improved identification of flies to increase the efficiency and accuracy of forensic entomology as an investigative technique; the importance of consideration of DNA variation between geographically isolated populations in estimating time since death; species status and implications for forensic entomology.

This presentation will impact the forensic community and/or humanity by demonstrating the potential of DNA for use in improving

the accuracy of the estimation of time since death will be explored. This will aid scientists to incorporate DNA-based forensic entomology into investigations, increasing the efficiency and accuracy of the technique for aiding investigators to focus their investigations more effectively. These DNA-based techniques improve the performance of entomology in casework, an important facet of any science used in criminal investigation, as standards must constantly be improved.

Entomology is an important forensic investigative tool, commonly applied to the estimation of time since death, referred to as post mortem interval (PMI). Blowflies (*Diptera: Calliphoridae*) are commonly found in association with corpses and may be used to estimate PMI. A critical step in entomologically based PMI estimation is the identification of insects to species level. Many species display affinities with corpses in any given area, and all will develop at different rates. Blowflies, and particularly their immatures must therefore be accurately identified. Based on morphological characters this was generally problematic, but more recently DNA-based techniques have been utilised for identification.

In applying DNA-based techniques, careful consideration is required to ensure that DNA characters used are robust and thus present throughout the entire of a species. This requires not only study of many individuals of a species from a locality, but analysis of individuals from isolated populations of the species.

The majority of studies have addressed the corpse fauna of the United States, Europe, Britain and Australia, but generally neglected Africa. In southern Africa, forensic entomology is being incorporated increasingly into death investigations.

This study consequently focused on the molecular-based identification of flies from southern Africa and Australia, considering distinction between species as well as differences between geographically isolated populations. The cytochrome oxidase I (COI) encoding region of mitochondrial DNA (mtDNA) was sequenced over 1167 base pairs, and analysis performed using phylogenetic techniques to compute similarity and difference between individuals.

Results proved the region to be useful in species level identification, with robust characters present. Variation between species was consistently calculated at 3.0% or higher, while intraspecific variation did not exceed 0.8%. While the distinction between these two values indicates the ability to clearly distinguish between species, there is little scope for identifying the geographical provenance of insects considering the low variation between conspecific populations. Consequently, an alternate region is suggested for this purpose. In conclusion, many southern African and Australian species of blowflies can be successfully distinguished on the basis of DNA.

Entomology, DNA, Blowflies

G70 Fatal Pediatric Head Impact Biomechanics: Homicide vs. Accident

John B. Lenox, MD, PhD, PE, Design Excellence, Inc, 435 Isom Road, Suite 224, San Antonio, TX 78216-5144*

After attending this presentation, attendees will develop skill in determining the head impact accident scenario and injury mechanisms responsible for fatal pediatric head injuries. In addition, attendees will develop skill in determining injury causation in possible homicide cases involving complex, interdisciplinary medical and biomechanical engineering concerns.

When handling death cases where issues involving occupant dynamics and impact injury biomechanics have to be addressed, medical examiners should increasingly feel more comfortable seeking input and support from skilled biomechanical engineering colleagues.

A 14-month-old male in good health sustained a severe closed head injury at a babysitter's house, and he died in the hospital few hours later. Head CT Scan performed prior to his death demonstrated a large

occipital fracture, diffuse cerebral edema and tentorial subarachnoid hemorrhage with no midline shift. An autopsy was performed 27 hours post death. Autopsy findings are provided below, prior to addressing accident witness statements and reconstruction of the accident versus homicide scenario responsible for the death of this child.

Autopsy findings Summary:

1. Blunt Force Craniocerebral Injury:

- a. No lacerations, abrasions or contusions seen on skin of posterior scalp.
 - b. A 15 x 11 cm area of subscapular and periosteal blood extravasation in occipital and posterior parietal regions.
 - c. Extensive displaced fractures of occipital bones extending into the posterior aspect of both parietal bones.
 - d. Film of epidural blood extravasation over skull fractures.
 - e. An estimated 10 ml of liquid and partially clotted subdural blood extravasation, predominately over vertices of cerebral hemispheres, but also over base of skull.
 - f. Moderate diffuse subarachnoid blood extravasation over entire brain with increased concentrations in left para sagittal/sagittal cortex and left temporal lobe.
 - g. Apparent tear of falx cerebri anteriorly.
 - h. A 2 x 1.5 cm contusion, right cerebellar hemisphere.
 - i. A 1 cm contusion, right parieto-occipital lobe.
 - j. Blood extravasation surrounding each optic nerve.
 - k. Retinal blood extravasation.
 - l. Blood extravasation on the left nerve roots of C1 and C2 vertebrae.
 - m. Subdural spinal cord blood extravasation.
2. Evidence of hypoxic-ischemic encephalopathy:
 - a. Diffuse gyral flattening and sulcal narrowing.
 - b. Cerebral tonsillar herniation.
 - c. Cerebral edema and early neuronal degeneration on histology.
 3. Small, scattered, circular areas of erythema with central dried punctures resembling insect bites on skin.

Witness Statement:

The babysitter, the only adult witness to this accident, provided accident scenario descriptions (a) during the 911 call post-accident, (b) to the EMS crew, (c) to the emergency room and hospital personnel, and (d) to investigating police officers; all of the accident scenario statements provided by the babysitter remained consistent. Namely, the 14-month-old boy was standing at rest, having just picked up a popular toy from a toy box, and he was facing two older children who were playing across the room. Suddenly, these two older children ran together fast towards the 14-month-old boy. As these two older boys approached this 14-month-old boy, still running fast, these older boys became entangled and they tripped and fell toward the 14-month-old boy. The 14-month-old boy was, in effect, gang-tackled by the two older boys, causing the 14-month-old boy to rotate backwards at a high rate of speed, pivoting about his feet, resulting in the back of his head violently impacting the bare, hardwood floor.

Impact Injury Biomechanics:

1. Analysis of all of the injuries sustained, and of the possible injury mechanisms responsible for each injury, led to the conclusion that one, single, violent, blunt blow, sustained by the back of the head of the 14-month-old boy, induced all of the injuries sustained. This injury biomechanics analysis included study of the pattern and extent of the skull fractures sustained and consideration of how this depressed skull fracture resulted in an increase in intracranial pressure sufficient to have induced hemorrhages in the region of the optic nerves and retinae.

2. Dynamic and impact biomechanical analyses were then performed to study (a) the kinematic consequences of collisions of the two older boys into the 14-month-old boy, along with (b) the magnitudes of the collision-induced increases in head-to-floor slam down velocities.

These engineering analyses demonstrated that the collision of the two older boys into the 14-month-old boy standing at rest could have increased the 14-month-old boy's head-to-floor slam down velocity to a level more than capable of producing the severe skull fractures and fatal brain injuries sustained. In addition, these analyses demonstrated how unlikely it would have been for simple fall, starting at rest from a standing height and not involving a collision, to have caused these catastrophic head injuries.

Recommendations:

In an interdisciplinary case such as this one, whether or not the death of this 14-month child was caused by homicide would be difficult for most medical examiners to judge absent feedback and support from a team member skilled in biomechanical engineering. When the quest for accurately determining injury causation involves consideration of complex medical and biomechanical engineering issues, forensic pathologists should seek support from skilled biomechanical engineering colleagues.

Head Impact Injury Biomechanics, Skull Fracture Mechanics, Occupant Kinematics

G71 The Enigma of SIDS: Variations in Diagnosis and Recommendations

Peter Vasilenko, PhD, Michigan State University, College of Human Medicine, Department of Obstetrics, Gynecology, and Reproductive Biology, 227 West Fee Hall, East Lansing, MI 48824; Joyce de Jong, DO and Brian Hunter, MD, E.W. Sparrow Hospital, Department of Pathology, 1215 East Michigan Avenue, Lansing, MI 48912*

After attending this presentation, attendees will understand how SIDS is diagnosed differently by medical examiners and to discuss recommendations to enhance consistency in diagnosis and contribute to prevention efforts.

Consensus is needed on guidelines to diagnose SIDS and suffocation. These guidelines should be based on the definition of SIDS, autopsy data, death scene investigation, and pertinent medical and social history, as well as consistent decision making on whether these factors are positive or negative. The next phase of this effort will involve forensic pathologists, medical examiners and other interested parties forming a task force with the goal of developing a greater consensus regarding the diagnosis of SIDS. Forensic science should strive to produce the most accurate and truthful diagnosis of sudden unexpected infant deaths, both as a professional standard, and to benefit prevention. Since many prevention efforts are based on vital statistics data, the more accurate and consistent diagnosis of SIDS or other forms of sudden and unexpected deaths would serve to focus and enhance the reduction in preventable infant deaths.

Purpose: There is great debate about the diagnosis of SIDS in deference to other causes such as accidental asphyxia. In fact there is accumulating evidence that unsafe sleep environments are linked to many infant deaths although the diagnoses are controversial. Variations in diagnosis lead to inconsistency in vital statistics and confusion or misdirection of prevention efforts. The purpose of this session is 1) to present information on a study which investigated differences in the diagnosis of SIDS among medical examiners using case scenarios and 2) to use these study results as a starting point to discuss efforts and recommendations to increase consensus among forensic pathologists and medical examiners regarding the diagnosis of SIDS.

Methods: A mailed survey was obtained from Medical Examiners/Deputy Medical Examiners (ME) in Michigan. The survey included 28 case scenarios with varying diagnostic factors, questions about the diagnosis of SIDS, and demographics.

Results: A total of 53 surveys were returned for analysis representing a 59% return rate. Only 15% of MEs believe SIDS is a distinct

syndrome, 58% think SIDS is a catch-all diagnosis but includes actual SIDS cases, and 27% believe SIDS is a catch-all category and that SIDS does not exist. Among MEs, 21% say they would sometimes give SIDS as a comfort diagnosis so the parents would not feel guilty. In a case that classically meets the definition of SIDS, 80% called it SIDS, 11% indicated accidental asphyxia (AAX), and 9% would call it undetermined (UDTM). In a similar case with the only change being a 14-month-old baby, 32% of MEs would still call it SIDS, while 66% would call it UDTM. If a baby was found prone on a pillow, 17% call it SIDS and 73% AAX. When an infant was found alone on a waterbed or air mattress there was a fairly even split on SIDS vs. AAX. When bedsharing was involved, the diagnostic distribution was 42% SIDS, 39% AAX and 19% UDTM. As factors were added to cases which make suffocation more likely, AAX increased as a choice, but a substantial proportion of MEs continue to call these cases SIDS. When an intoxicated parent is bedsharing both AAX and homicidal asphyxia (HAX) increased as cause of death. (10% SIDS, 63% AAX, 8% HAX, 19% UDTM). Cases in which parents were sleeping with infant on couches elicited the highest rates of AAX (77-85%).

Conclusions: There is significant variation in the way that SIDS is diagnosed in Michigan. Even in cases that have accepted definitions of SIDS or AAX there are marked differences in diagnosis, in part based on beliefs of what SIDS actually is. This variance makes it difficult to use and interpret death certificate data concerning SIDS. These results will be used to stimulate discussions and recommendations toward a consensus on the diagnosis of infants suffering sudden and unexpected deaths.

This study was funded by a grant from First Candle (National SIDS Alliance).

Sudden Infant Deaths Syndrome, SIDS, Infant Mortality

G72 Investigations and Eye Findings in Crush and Other Accidental Traumas in Lethally Injured Infants and Children

M.G.F. Gilliland, MD*, Brody School of Medicine at East Carolina University, Department of Pathology, Forensic Division, Greenville, NC 27858-4354

After attending this presentation, attendees will understand the extent of systemic and ocular findings in a group of injured children as well as the histories and investigations leading to the conclusion that the children were accidentally injured as a basis for comparison with their cases. Crush injuries of the head are a subset of accidental trauma but in this group they did not have extensive ocular injuries.

Observations have been the basis of the scientific study of phenomena for many years. Presentation of these observations allows others to consider and compare the material with personal experience and the literature, validate the observations, use them as a basis for making determinations in their own cases. Our "cases" impact the family members of that part of humanity which is affected by our determinations. The more scientific they are, the better our determinations should be for the forensic sciences and humanity.

Attendee can know the extent of systemic and ocular findings in a group of injured children as well as the histories and investigations leading to the conclusion that the children were accidentally injured. Attendee can be aware that crush injuries of the head may be a subset of accidental trauma with more extensive ocular injuries.

Concerns are sometimes raised because infant and child deaths are attributed to abusive injuries when explanations of caretakers are not accepted as sufficient to cause death. The following is a review of 35 cases in which the explanations of the events leading to the fatal injuries were regarded as adequate. It was concluded that the children were accidentally injured.

A prospective ocular and systemic study of infants and children was undertaken at the Southwestern Institute of Forensic Sciences between 1981 and 1989. The study group included 169 infants and children. Death was attributed to accidental injuries in 35 of the children.

Most of the accident deaths were attributed to non-abusive head injury, 18 cases. Six children were unrestrained passengers involved in motor vehicle collisions. The heads of two of these six were partially out of the vehicles during rollovers. Four other children were run over by motor vehicles, two were ejected from the vehicles prior to being run over. The other two were upright pedestrians. Four children fell: one fell from a second story window to concrete, another from an unknown height to a conglomerate patio. Two others were standing, on a washing machine and a bed above concrete floors, and fell onto their heads. One was ejected from a motorcycle. One child was being carried on a bicycle by an adult who fell on top of her when the bike hit an obstacle. A child's stroller rolled downhill and collided with a wall; a respiratory tract infection contributed to that death. The eighteenth child suffered a gunshot wound of the head and the ipsilateral eye was examined.

Analyzing the pattern of autopsy findings by the mechanism of injuries allows the identification of a subset of children with crush injuries of the head. Crush injuries were defined by the presence of extensive skull fractures and head deformity. Five of the six passengers had such injuries including the two with heads out of the vehicles during rollovers. All four of the children who were run over by vehicles had crush injuries. None of the other nine children had such extensive head injuries ©© one of the passengers in a motor vehicle collision, the four children with falls, the child ejected from the motorcycle, the child on the bicycle, the child in the stroller, and the child with the gunshot wound.

However, only four of the children with crush injuries had ocular hemorrhages. Retinal hemorrhages were seen near the optic disk in one of the two children whose heads were partially out of the vehicle when it rolled. Impact was a significant component of the injury mechanism in this child. More extensive retinal hemorrhages were found in three children. The hemorrhages included the superficial retina under the internal limiting membrane and the macula in two children who were run over at relatively low speeds and one of the unrestrained back seat passengers. Impact probably contributed to the injuries in the two children who were run over. Impact was a more significant component of the injury mechanism in the back seat passenger.

Although extensive skull fractures and head deformity was not seen with falls, two of the four had retinal hemorrhages — the two who fell the greatest distance. One of these two had hemorrhages at the ora serrata and under the internal limiting membrane as well as the disk and macula. The other's retinal hemorrhage were limited to the optic disk and macula. Similar findings were seen in one of the unrestrained passengers. The child who was ejected from the motorcycle and the child who fell from the bicycle both had retinal hemorrhages limited to the optic disk. All of these children had significant impact components in the mechanisms of injury

The other seventeen accidental deaths were attributed to less traumatic but equally lethal injuries. Nine children had asphyxial deaths: four positional, three overlays, and two aspirations. Eight children drowned: three were unattended in bathtubs, two were in pools, and one each into a bucket, a creek, and a live birth into a commode. Not surprisingly, none of these children had ocular injuries, subdural hemorrhages, or skull fractures.

Conclusions: Thorough investigation of history and scene circumstances coupled with a complete autopsy including ocular examination will allow identification of patterns of accidental injury. In this group approximately half of the deaths (eighteen) were the result of head injuries. A subset of more severe head injuries with multiple fractures and deformity were seen in nine of the children involved in motor vehicle collisions as passengers and as pedestrians in this series. Retinal hemorrhages were found in four of these children. Impact as well as crush mechanism was involved in the injuries. Five of the other nine head injured children also had retinal hemorrhages and all of these had significant impact injuries. In this group impact injuries were a confounding variable.

Head and ocular injuries were not found in the other seventeen deaths in this series. The presence of such injuries would be inconsistent with the explanations of the traumatic mechanisms and would have required additional explanations before the deaths could be regarded as accidental.

Retinal Hemorrhages, Accidental Head Injury, Accidental Injury

G73 Meningitis Mimicking Inflicted Abusive Head Trauma

Christie L. Elliott, MD* and Ellen G.I. Clark, MD, Forensic Pathology Consultants, 475 Kirman Avenue, Reno, NV 89502

After attending this presentation, attendees will be reminded to consider other etiologies for markers of inflicted abusive head trauma which may prevent misdiagnoses of shaken baby syndrome.

The main goal impact of this presentation is to prevent misdiagnoses of inflicted abusive head trauma and the resulting consequences.

The current consensus regarding the triad of retinal hemorrhages, cerebral edema, and subarachnoid or subdural hemorrhage in non-ambulating infants is that it is virtually pathognomonic for inflicted abusive head trauma (i.e., shaken baby/shaken-impact syndrome - SBS). This case illustrates that while these findings are highly sensitive for SBS they are not 100% specific.

The local forensic pathologists were contacted by the pediatric intensivist to evaluate an eight-week-old male infant under treatment in the hospital's intensive care unit. The child had been admitted to the unit two days prior. The history given by the mother was that the child had a rectal temperature of 104° F at home, for which she gave him an ice bath. She then took him to the local health clinic. He was noted at the clinic desk to be "acutely ill." The mother was instructed to immediately take the baby to the hospital emergency room. She complied. Upon admission to the hospital the infant had a rectal temperature of 100.2° F and a heart rate of 240 beats per minute. Very little additional information is documented regarding the initial physical exam. The HEENT exam record consists of, "flat anterior fontanelle and a clear nose." Medical treatment focused on evaluating and treating the baby's rapid heart rate, and the child was "pan-cultured." Approximately 12 hours after admission the child's anterior fontanelle was noted to be bulging. A neurosurgical consult and a CT scan of the head were ordered. These revealed, "diffuse bilateral retinal hemorrhage, cerebral edema, and possible subarachnoid hemorrhage." The diagnosis of SBS was made. Local law enforcement and child protective services personnel were notified. Based upon the clinical diagnosis, the infant's older sibling (15 months) was removed from the custody of his parents.

The consulting forensic pathologists requested the results of all microbiology cultures, with particular attention to the spinal fluid cultures. They were advised that no lumbar puncture or spinal fluid culture had been performed upon admission, or at any time during the hospitalization. The tracheal aspirate culture was positive for *Streptococcus pneumoniae*. Throughout the child's hospitalization the mother maintained her position that she had not harmed her child. Regarding events leading up to her child's hospitalization, the mother specifically described the baby as having fever, jumping-like movements, "eyes rolling up into the head," and the presence of a hard red lump on the infant's head. The story did not change upon repeated interviews. The infant was pronounced brain dead on the fourth hospital day, and life support was withdrawn. The body was transported to the morgue. A complete autopsy was performed approximately 18 hours after death.

The autopsy revealed no external evidence of injury. All markings were a result of therapeutic intervention. The internal examination of the torso and neck was also negative for injuries. Examination of the head revealed a markedly swollen brain with herniation, very scant subdural and subarachnoid hemorrhage, and very extensive bilateral retinal hemorrhages. The meninges were remarkable for multifocal dull gray-green discoloration. The dura and overlying scalp around the anterior fontanelle grossly exhibited thickening and discoloration, suggestive of granulation

tissue/inflammation. The middle ears were opened revealing a cloudy green exudate on the left. Based on these findings, the case appeared to represent undiagnosed bacterial meningitis. A more definitive diagnosis required microscopic examination of the brain, meninges, and retinas. The "red lump" reported by the mother was a calcifying cephalohematoma of parietal skull. This was attributed to birth-related trauma. Upon these initial findings, the police and child protective services were notified, and the older sibling was returned to parental custody.

Thorough microscopic examination revealed severe acute meningitis with necrosis of the small to medium sized meningeal blood vessels. The inflammatory process completely encased the optic nerves. Microthrombi were noted in the blood vessels of the optic nerves and retinas. Sections of the eyes showed bilateral diffuse intraretinal hemorrhage. No optic nerve sheath hemorrhages were noted. Swabs of the middle ear fluid were remarkable for acute inflammation and cocciform bacterial organisms consistent with *Streptococcus pneumoniae*. The cause of death was ultimately attributed to acute bacterial meningitis.

Review of the literature reveals numerous papers on retinal hemorrhages, all of which state that the most common cause of retinal hemorrhages in infants is inflicted head trauma, particularly shaken baby syndrome. However, most papers also state that other rare causes, such as infection and bleeding disorders, must be ruled out. Only one case report was found documenting retinal hemorrhages in the setting of bacterial meningitis and without suspected abuse. The hemorrhage in this report was focal, and the patient recovered.¹ The meningitis did not result in massive cerebral edema and death, as was seen in this case.

This case should serve to remind the forensic pathologist and the clinician of the importance of investigating other potential causes of the "markers" of shaken baby syndrome, regardless of how unlikely they may be. The presenter will discuss possible explanations for misdiagnosis and recommendations for evaluating similar cases.

Retinal Hemorrhage, Shaken Baby Syndrome, Meningitis

G74 Fatal Hyponatremia, Cerebral Edema and Seizures Associated With Bilateral Peripheral Retinal Hemorrhages in a 20-Month-Old Child Following Hypotonic Fluid Administration for Dehydration: Case Report with Critical Appraisal of the Current Literature

Patrick E. Lantz, MD*, Department of Pathology, Wake Forest University School of Medicine, Medical Center Boulevard, Winston-Salem, NC 27157-1072

After attending this presentation, attendees will understand that, based on the lack of evidence base within the current medical literature, peripheral retinal hemorrhages cannot be regarded as specific for non-accidental head injury in children.

The importance of critically reviewing the medical literature before ascertaining that certain ocular findings are specific for non-accidental head injury.

A 20-month-old child was parenterally rehydrated with 0.2% normal saline in 5% dextrose in water for mild dehydration from gastroenteritis. He received more than 750 mL of the hypotonic fluid intravenously during a four-hour period. He became severely hyponatremic and developed diffuse cerebral edema and seizures. Numerous bilateral intra-retinal hemorrhages extending to the periphery were noted and considered worrisome for nonaccidental head injury (NAHI) or Shaken Baby Syndrome (SBS). A forensic autopsy confirmed the intracerebral and intraocular findings and subsequent investigation by the medical

examiner, child protective services and law enforcement uncovered no evidence of child abuse. Retinal hemorrhages have been reported in cases of hyponatremia, cerebral edema and seizures although the pathogenesis has been disputed. No previous reported cases of retinal hemorrhages in infants or young children who died following intravenous hypotonic fluid administration were found following an electronic database search, although two articles described infants with nonfatal oral water intoxication who had retinal hemorrhages. The proximate cause of these ocular findings has been disputed. In one case the peripheral retinal hemorrhages, cerebral edema and seizures with hyponatremia were presumably due to Shaken Baby Syndrome, although the history of oral water intoxication could explain the infant's low serum sodium, cerebral edema and seizures. Subsequently, a Letter to the Editor described another infant with hyponatremia and seizures with posterior retinal hemorrhages due to water intoxication. The authors concluded that the infant had not been abused and questioned published studies of retinal hemorrhages and seizures pointing out that infants with hyponatremic seizures rarely receive an ophthalmologic examination. The initial authors responded that the distinguishing feature between the cases was the location of the retinal hemorrhages. They stated that localized posterior retinal hemorrhages could be attributed to unintentional head trauma and increased intracranial pressure, whereas peripheral and multilayered retinal hemorrhages are more often associated with abusive head trauma. Therefore, the background question became: Are peripheral retinal hemorrhages diagnostic of NAHI when observed in infants and young children? Using the National Institutes of Health National Library of Medicine MEDLINE (1966- 2002) electronic database a search was done on reported childhood deaths due to the administration of hypotonic fluids and articles discussing peripheral retinal hemorrhages and child abuse. One case-controlled study that exhibited selection bias discussed peripheral retinal hemorrhages and NAHI in children but none of the children in this study died from hyponatremia associated cerebral edema secondary to hypotonic fluid administration. The remaining articles consisted of case reports, non-comparative case series and unsystematic review articles. Based on the lack of objective scientific evidence, peripheral retinal hemorrhages cannot be regarded as diagnostic for NAHI or SBS.

Peripheral Retinal Hemorrhages, Hyponatremia, Shaken Baby Syndrome

G75 Delayed Jejunal Rupture in a Three-Year-Old Child After Minor Blunt Impact

Leah L.E. Bush, MD, Office of the Chief Medical Examiner, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510-1046; Wendy M. Gunther, MD, Office of the Chief Medical Examiner and Department of Legal Medicine, Virginia Commonwealth University, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510; Gregory Raczniak, MPhil, Eastern Virginia Medical School, 714 Woodis Avenue, Norfolk, VA 23510*

After attending this presentation, attendees will understand role of history, scene information, autopsy, and histologic examination in differentiating ischemic from traumatic lesions of the small bowel. Be aware of an infrequent cause of traumatic death in children (delayed jejunal rupture). Review what is known and what is controversial about aging lesions by histology. Be cognizant of the pitfalls and controversies in establishing accident versus homicide as manner in similar cases.

This presentation will impact the forensic community and/or humanity by reviewing an unusual cause of traumatic death in children. Invite the forensic community to consider a difficult question of manner of death in this case and similar cases, using the tools of scene investigation, autopsy findings, histology, and attempted dating of traumatic intra-abdominal lesions by histology.

Histologic examination of tissue from the intestinal wall, to determine whether ischemia or impact is the primary cause of necrosis, may allow differentiation between accidental death and child abuse. A healthy three-year-old girl arrived at an emergency department with a report of head injury. The child described to nurses and investigators how she tripped and fell down three concrete stairs while running after a ball. No significant head injury was found, and no evidence of abuse was detected at that time. Three days later, the child complained of gradually increasing nausea and abdominal pain, and died suddenly. Autopsy revealed ischemic small bowel with perforation. Microscopic findings showed inflammation with both fresh and remote hemorrhage. Possible etiologies included three-day-old child abuse with blunt impact to abdomen, fresh child abuse with blunt impact to abdomen, and delayed jejunal rupture due to ischemia after minor blunt impact to abdomen. The characteristics of ischemic versus traumatic lesions are discussed. Controversies in determining aging of lesions are reviewed, along with the issues for the examining pathologist.

Delayed Jejunal Rupture, Histologic Dating of Lesions, Forensic Pathology

G76 Virulence Factors in Neisserial Meningococcemia

Wendy M. Gunther, MD, Office of the Chief Medical Examiner and Department of Legal Medicine, Virginia Commonwealth University, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510-1046; Gregory Raczniak, MPhil, Eastern Virginia Medical School, 714 Woodis Avenue, Norfolk, VA 23510; Elizabeth L. Kinnison, MD, Office of the Chief Medical Examiner, 830 Southampton Avenue, Suite 100, Norfolk, VA 23510*

Attendees will review new research into factors that make neisserial meningitis fatal for one person, while subclinical for another. Virulence factors include microbial adaptations, such as adhesive pili, lipopolysaccharides, and opacity proteins (Opa); host factors include toll-like receptors, cytokines, mannose-binding proteins, and immunoglobulin G receptors.

All of pathologists deal with the impact of cases of fulminant neisserial meningitis on communities, but rarely do is there an opportunity to review the science which lies behind the current understanding of what makes one victim die, while another survives. This "snapshot" overview of what is understood about the genetics behind host and microbe virulence factors will update the medical community, and will allow physicians to go on following the science as results continue to come in, and perhaps point the way for tests in the future on meningitis cases.

A 13-year-old boy underwent a rapid progression, over a period of hours, from normal health to septic shock and death, while family members remained healthy and free of disease. At autopsy, despite grossly clear meninges, evidence of Waterhouse-Friderichsen syndrome led to the suspicion of meningitis. Microbial culture determined the agent to be *Neisseria meningitidis*. This child's extreme susceptibility to the devastating effects of neisserial infection, while his family remained well, was likely due to the interplay of microbial virulence factors, with newly understood host factors. Newly understood microbial factors, recently described by functional genomics and microbiology research, include genes that play essential roles in the pathogenesis of meningococcemia. These are neisserial genes involved with quorum sensing, and with variation of surface antigens, such as adhesive pili, lipopolysaccharides, and opacity proteins (Opas). Regulation of expression of these genes is likely to underlie incomplete virulence among close patient contacts. However, the development of sepsis rather than an innocuous commensal relationship is not only a function of the microbe, but also of increased susceptibility of the host. A variety of gene products implicated in a diminished immune response to *Neisseria meningitidis*

include genetic polymorphisms in toll-like receptors, cytokines, mannose-binding proteins, and immunoglobulin G receptors on neutrophils, monocytes, and macrophages. This affords us an opportunity to review the recent research into the critical determinants of meningococcemia, from the aspect of both host and microbe.

Neisserial Meningitis, Virulence Factors, Host

G77 SARS, Monkeypox, West Nile, Dengue, and Plague: Pitfalls of Globalization

Saul B. Wilen, MD, International Horizons Unlimited/Litigation Strategies Group, PO Box 40578, San Antonio, TX 78229*

After attending this presentation, attendees will explore the ramifications of political, social, and economic forces that impact mortality, morbidity, and public health issues. They will learn about the global mechanisms that foster aberrations in traditional biological and scientific relationships, and how to utilize the knowledge gained to create solutions.

Participants will consider the challenges and positive implications of unexpected phenomena. The development of new methodologies and technologies, and the applications of these unexpected experiences offer the potential for predictive modeling processes to expedite future valid solutions.

Forensic specialists and experts must be well grounded in factual elements. For truth to prevail forensic scientists must bring to light the crucial and all related ancillary facts. These must include the limitations of the science employed and the extent to which the opinions generated represent subjectivity, causality, and validity.

Over the past few decades and especially in the last few years changing patterns relating to human infectious diseases have emerged. For example, with the encroachment of human living environments especially in the western United States, into traditional animal habitats, the Hanta viruses have crossed over from being infections solely carried by the deer mouse, to ones infecting humans. Lyme disease (named in 1977) has emerged and has become embedded in a geographic distribution (the northeast, mid-Atlantic, upper north-central regions, and northwestern California) with progressive infection of humans manifesting an acute and/or chronic form of the disease. This is an infectious disease transmitted by an arthropod (the deer tick) and causes more than 16,000 cases in the United States each year. An effective vaccine has been developed and produced, but has been abandoned. In addition, the re-emergence of known but thought to be controlled infectious diseases such as Smallpox and Anthrax has occurred, including the potential use of these biological agents as weapons of terrorism. Smallpox vaccine exists in sufficient quantities to protect all 280 million United States citizens. Phase I of a stepwise program that would initially vaccinate 500,000 healthcare workers has been placed on hold. A program which protects most of the U.S. population would render the Smallpox virus ineffective as a terrorism weapon and truly be the application of prevention.

The Ebola virus has caused disease periodically since 1976 when it was initially recognized in Africa. It produces a severe, acute disease in humans and non-human primates with a high death rate. The origin and natural reservoir of the virus remains unknown but is suspected to be animal-borne (zoonotic). Death occurs due to a hemorrhagic fever. Dengue fever is caused by four closely related, but antigenically distinct virus serotypes. Infection with one of the serotypes does not render cross-protective immunity. However, until the late 20th century each of the serotypes remained primarily in its endemic region. The introduction of additional serotypes and mosquito vectors into various regions has resulted in the human population now being at risk for two or more Dengue infections. Dengue has emerged as a major public health problem in the region consisting of the Americas. In 1997 it was determined that the geographic distribution of the mosquito vector has pro-

gressively widened. Dengue is presently the most important mosquito-borne viral disease affecting humans, with a case-fatality rate of 5%.

A number of human diseases are spread by mosquito vectors. In addition to Dengue, Malaria, Yellow fever, West Nile virus, and filariasis are included. Some mosquitoes are great travelers. However, much depends on the facilities for travel. The mosquito is, in fact, a hardy and enterprising colonist, ready to exploit any and every chance. The advent of the airplane in the 20th century provided the mosquito, including disease-bearing members of its family, with the opportunity to spread to the far reaches of the world. If the mosquito cannot get there as an adult, it sends an egg or a larva as a substitute.

Though West Nile virus was first found in Uganda in 1937, its progression in the United States, identified first in New York in 1999, has generated great interest and concern. In that year only four states were affected, with 62 cases and seven deaths. By 2002, West Nile was present in 40 states, resulting in 4156 cases and 284 deaths. West Nile has proven to be extremely aggressive and versatile and can affect more than 130 species of birds, and is carried by at least 36 types of mosquitoes. No medical treatment or vaccine presently exists. The rapid expansion of this disease in only three years raises significant questions and serious problems to be evaluated.

This past year, 2002-2003, brought the emergence of SARS (Severe Acute Respiratory Syndrome) caused by a corona virus and spread human-to-human via droplet infection. The world outbreak began in Guangdong Province of mainland China in November 2002. The four month silence about the existence of the epidemic by the Chinese government until February 2003 played a significant role in the uncontrolled spread of the disease. Open communication and cooperation with healthcare entities like the World Health Organization (WHO) would have proven successful in alleviating the ensuing consequences. Healthcare workers played a significant role in the spread of SARS throughout the world, and closing healthcare facilities helped bring the epidemic under control. SARS infected 8439 people in 30 countries on five continents with a death rate of 10% (812 people). No vaccine or specific treatment presently exists. The disease has primarily been controlled by isolating patients and quarantining those in close contact with them. Re-training of hospital doctors and healthcare workers in infection control measures (proper use of gloves, masks, face shields, barrier techniques, strict isolation) was necessary because hospital workers were exposing others. SARS may prove to be a seasonal disease that returns in the winter each year. There is a need to develop predictive models in preparation for its return should a reservoir exist as many experts believe. The application of techniques like forensic patterns would be most helpful. No rapid laboratory identification testing presently exists to help in the early identification of SARS. All present approaches are focused primarily on response while they should be equally focused on prevention. The SARS epidemic, its rapid progression and world-wide public health and economic impact, provide a unique opportunity to use the SARS experiences in developing models for the control of future disease epidemics, and even terrorism planning.

Globalization, Predictive Models, Forensic Patterns

G78 Pure Group A Beta Streptococcal Peritonitis in a Child With Inflammatory Bowel Disease

Sally S. Aiken, MD, Spokane County Medical Examiner, 5901 North Lidgerwood, Suite 24B, Spokane, WA 99208*

After attending this presentation, attendees will be able to discuss the rare phenomenon of pure Group A Beta Streptococcal peritonitis, and to describe the possible relationship between this death, previous colonic biopsy, and childhood inflammatory bowel disease. Current surgical practice regarding colonoscopic perforation will be described.

The forensic community will be more familiar with the rare occurrence of pure Beta Streptococcus peritonitis, and of current practice related to bowel perforation during colonoscopy.

A seven-year-old child with a history of ulcerative colitis presented to the emergency department with increased abdominal pain and collapsed, expiring after prolonged resuscitative efforts. He underwent colonoscopy with biopsy 4 days prior to death. Peritonitis was diagnosed in the Emergency Department, and microbiologic culture subsequently yielded a pure culture of Group A, Beta Hemolytic Streptococcus.

Autopsy revealed peritonitis resulting from a perforation of the descending colon. Diffuse erythematous skin discoloration, typical of streptococcal infection, was observed. Changes of ulcerative colitis extended from the midtransverse colon to the anocutaneous line. Original biopsy slides were reviewed and were shallow mucosal specimens, without full-thickness extension.

Pure Group A, Beta Streptococcal peritonitis has rarely been reported, and has been described only in cases of primary peritonitis. In streptococcal primary peritonitis, toxic shock syndrome often accompanies the abdominal findings. Adults who present with streptococcal primary peritonitis often have chronic ascites, nephrotic syndrome, or immunosuppression.

The incidence of perforation from diagnostic colonoscopy ranges from 0.2 to 0.8%. Non-operative management in cases of known perforation is acceptable in some circumstances.

Perforation occurs in less than 5% of cases of childhood ulcerative colitis. Colonic perforation in ulcerative colitis usually occurs in association with toxic megacolon or severe fulminant disease.

Beta Streptococcal Peritonitis

G79 Acute Dissection of the Left Subclavian Artery in a Patient With Ehlers-Danlos Syndrome

Cristin M. Rolf, MD*, University of Kentucky/Office of the Associate Chief Medical Examiner, Commonwealth of Kentucky, 100 Sower Boulevard, Suite 202, Frankfort, KY 40601-8272

After attending this presentation, attendees will have reviewed of pathogenesis, complications, and the methods for the diagnosis of EDS as a cause of sudden death.

The presentation will help one recognize this unusual cause of internal hemorrhage, and will emphasize the need for communication with families about the genetic implications of EDS.

This presentation consists of a case study of a female who died from complications of Ehlers-Danlos Syndrome Type IV and includes a discussion of the pathogenesis, complications and diagnostic workup of Ehlers-Danlos syndrome with emphasis on EDS Type IV, the vascular type.

EDS is a heterogeneous group of connective tissue disorders characterized by the inability to produce sufficient amounts of collagen or by a defect in the structure of collagen. At least 10 variants of EDS have variable modes of inheritance. This paper reviews the syndrome as a whole but will emphasize the vascular type, or EDS Type IV. Affected patients usually have hyperextensible skin and hypermobile joints, hence the designation "rubber man." Patients have a predisposition for joint dislocations and fragility of the skin and soft tissues. The most serious complications include rupture of a viscous, or vascular rupture or dissection. Death may result from internal hemorrhage. Diagnosis is based upon physical and laboratory examination of a living patient or autopsy findings. The specific collagen defect can be elucidated through electrophoresis of collagen products produced by a fibroblast culture of the patient's skin, soft tissue or organs. DNA molecular studies of the fibroblast culture pinpoint the gene locus mutation.

A 33-year-old white female was admitted in asystole to an emergency department after awaking suddenly during the night stating that

she "was passing out." Despite ACLS protocol she could not be resuscitated. She had been admitted to the hospital earlier that week with headache and gastrointestinal symptoms including nausea, vomiting and abdominal pain. Endoscopy revealed gastritis, chronic enteritis of the duodenum, and the colon grossly was significant for a small cluster of dark red polyps clinically suspicious for juvenile polyps or hamartoma. She was also found to have a microcytic hypochromic anemia. Treatment included red blood transfusion. Preliminary autopsy findings included thin, transparent skin of the trunk and extremities revealing the subcutaneous vasculature. Internal findings included unusual friability of vasculature, soft tissue, and viscera. The organs were extremely soft, and the skin tore upon restoration of the body after autopsy. The embalmers reported severe friability of the vasculature and difficulty in the embalming procedure. Grossly there was a dissection of the left subclavian artery with adventitial hemorrhage, which extended from its origin at the aorta to 10 cm distal in the upper arm. Significant sequelae included a left hemothorax of 1,050 ml and visceral pallor. Microscopic sections of the vessels revealed a dissection of the outer third of the muscle wall of the left subclavian artery and the left renal artery. Thrombus and rupture of the vascular wall involved the mesenteric arteries of the transverse colon with subsequent segmental early necrosis of the colon. Samples of lung, skin and kidney underwent fibroblast culture. Electrophoretic mobilities of collagen produced by cultured fibroblasts revealed diminished type III procollagen and intracellular storage of abnormal type III procollagen. cDNA responsible for encoding pro alpha 1 (III) chains of the type III procollagen was synthesized from RNA isolated from the patient's fibroblast culture. Normal cDNA and an abnormal cDNA that demonstrated a mutation of the gene COL3A1 were present. The mutation was a change in the second nucleotide of intron 14 (IVS14 + 2T>A). There was no family history of adverse vascular events. The final diagnosis in this case is left hemothorax due to dissection with rupture of the left subclavian artery due to Ehler's Danlos syndrome type IV.

Ehler's Danlos syndrome is an entity to be included in the differential diagnosis of sudden death in a patient with internal hemorrhage cause by spontaneous vascular rupture or dissection. The implications to the patient's family are serious, and genetic counseling follow up is required.

Ehlers-Danlos Syndrome, Arterial Dissection, Hemothorax

G80 A Case of Sudden Death in a 3-Year-Old Infant With Prader Willi Syndrome

Cristoforo Pomara, MD*, Department of Forensic Pathology, University of Foggia, Viale Pinto n°1, Foggia 71100, Italy; Stefano D'Errico, MD and Irene Riezzo, MD, Institute of Legal Medicine, University of Foggia, Ospedali Riuniti, via L.Pinto 1, Foggia 71100, Italy

A case of sudden death of a 3-year-old infant affected by Prader Willi Syndrome is presented. The aim of the paper is to analyze the macro-microscopic findings in Prader Willi Syndrome and to focalize the forensic implication in sudden death cases.

To the best of our knowledge, this is a rare case of sudden cardiac death in infant with Prader Willi Syndrome. This datum is confirmed by means of histological study of cardiac tissues. It would be an important contribute to the scientific community for the diagnosis of the cause of death in Prader Willi Syndrome.

The Prader Willi Syndrome has a variable prevalence of 1:10000 – 25000.

The syndrome is a rare genetic disorder caused by a chromosomal aberration. Most common a deletion on chromosome 15q11-13 in the portion inherited from the father, less frequently the child has two chromosomes 15 from the mother and none from the father, rarely there is an

imprinting mutation on chromosome 15q11-q13. The Prader Willi Syndrome is characterized from a hypothalamic dysfunction that leads to hyperphagia and obesity and has secondary consequences of diabetes, heart disease, stroke and sleep apnea. It is also characterized by severe muscular hypotonia, short stature, cryptorchidism, learning disabilities, mental retardation.

We present a sudden death case in a 3 years old young male, affected by Prader Willi Syndrome diagnosed by means of DNA methylation. The infant was referred apparently unconsciousness by his mother to the Emergency Area. Pulse was absent, he was breathless and in fixed mydriasis. The cardiopulmonary resuscitation was unsuccessful. In the history, mother referred that her son suddenly collapsed while he was on bed.

The external examination was performed showing an uninhabited scrotum, a severe hypo tonic muscular body mass and an excessive accumulation of fat. At the post mortem examination the skull cup was uninjured, the brain was congested and edematous with convolutions reduced (microgyria) in correspondence of parietal and occipital lobes, but normal in size, volume and weight. It was fixed in formalin and later it was sectioned with coronal cuts according to the Pitres technique, showing hypoplasia of olive of medulla oblongata and haemorrhage on periventricular surface. Cervical and thoracic organs were removed "en block" according to the Ghon's technique, appeared edematous and congested but anatomically normal; tracheobronchial tree and lungs, were unremarkable except for white fluid in upper respiratory tract. Heart was fixed in formalin and a dissected according to "Four – Chamber" method was completed. Cardiac size was normal, with conical shape, the color of fresh subepicardial myocardium was reddish-brownish. Macroscopic study (cut in cross-section 3 mm intervals) of coronary arteries was unremarkable. Left ventricular thickness, measured 2 cm below mitral anulus, was cm 1; ventricular septum 1.2 cm; right ventricular thickness 0.4 cm. Histological cardiac findings were represented by spotty area of fibrosis; myocells showed eosinophilic cross-bands consisting of segments of hyper contracted or coagulated sarcomeres, to a total disruption of myofibrils and cells with granular aspect. In particular, the contraction band necrosis were variously distributed in multiple foci, formed by few myocells. Sarcomeres appear shorter than their normal length and this finding was associated with marked thickening of the Z-lines. Granular destruction of myofibrils were also associated with a paradiscal lesion (paradiscal contraction band) without rhesis of the myofibrillar apparatus. Adjacent normal myocells show a typical "wavy" disposition, possibly induced by the hyper contracted myocells. Myocardial fibers appear also stretched and broken. (A quantitative morphometric analysis has been conducted). In the lung mild pulmonary oedema was observed; a limited bronchial phlogistic infiltration, and large areas of atelectasia were also observed.

The histological findings lead to the definition of a cardiac death with a typical picture of contraction band necrosis (CBN). The cardiac findings should be judged sufficient to explain the cause of death. Pulmonary hypoxic alteration is frequently reported as primary cause of death in PWS cases. The chronic hypoxic stimuli should trigger a fatal cardiac arrhythmia, as demonstrated by typical myocardial damage (Contraction Band Necrosis).

In conclusion, this case contributes to a better definition of morphological findings in sudden death related to Prader Willi Syndrome.

Prader Willi Syndrome, Sudden Cardiac Death, Histological Findings

G81 Pediatric Asthma Mortality in the Cook County Medical Examiner's Office, 1 to 14 Years: 1998 - 2002

Eupil Choi, MD and Edmund R. Donoghue, MD, Cook County Medical Examiner's Office, 2121 West Harrison Street, Chicago, IL 60612*

After attending this presentation, attendees will understand trends and patterns of pediatric asthma death and how to diagnose pediatric asthma at an early age.

The management of pediatric asthma should take optimal treatment with current therapies and continued public education for available care. Asthma mortality can be reversed.

The purpose of this presentation is to provide pediatric asthma death data between 1 and 14 years of age in the Cook County Medical Examiner's cases. This report has the following goals: 1. To describe trends and patterns of pediatric asthma death. 2. To identify the prevalence of risk factors. 3. To understand how to diagnose of the condition in children younger than 5 years of age. We examined case records of the Cook County Medical Examiner's Office (CCMEO) over the five year period from January 1, 1998 through December 31, 2002. The number of deaths investigated by CCMEO between 1 to 14 years of age totaled 42 cases in the five year period. Twenty-two cases involved males and twenty involved females. Blacks were predominate in 79% (33/42) of the cases. The highest incident occurred at the age of 10. This report highlights pediatric asthma mortality in an early age. Three cases involved under 2 years of age. Asthma is a chronic inflammatory disease of the airways clinically characterized by recurrent episodes of wheezing, breathlessness, and chest tightness. It is associated with variable airflow limitation that is at least partly reversible, either spontaneously or with treatment. In recent years, the prevalence and severity of asthma is noted to be increasing. In the United States, current estimates indicate that the number of children with asthma has increased by about 100% in the past 20 years. Between 1980 and 1995, the number of U.S. children with asthma rose from 2.3 million to 5.5 million, and this rise now seems continuing. The number of deaths from asthma increased gradually during 1980 to 1995, from 2891 to 5637 in all ages and from 94 to 185 in ages 0 to 14. Although without certainty, data for 1996-1998 indicate that mortality rates are starting to plateau or decrease. Asthma is a worldwide problem. The prevalence of asthma in adults is between 5% and 10% in the industrialized countries, and about 10% of these patients have a severe disease that is not optimally treated with currently available therapies. One-third of asthmatics are pediatric asthma. Asthma runs in families and has heritability. The hallmark in its pathogenesis is the development of chronic airway inflammation leading to bronchial hyper-responsiveness and airway remodeling. Exposure to inhalant allergen results in inflammatory mediators. The principal effector cells are eosinophils, mast cells and others. Diagnosis of pediatric asthma relies on a combination of meticulous history and the objective evidence of airway liability.

Pediatric Asthma, Mortality, Diagnosis

G82 Fatal Accidental Intravascular Injection of Air in Infants

Angela R. Wetherton, MD and Tracey S. Corey, MD, Office of the Chief Medical Examiner, 810 Barret Avenue, Louisville, KY 40204*

After attending this presentation, attendees will have reviewed cases of fatal accidental intravascular injection of air in infants. The importance of a thorough scene investigation, review of medical records, and complete postmortem examination in sudden death will be highlighted – even those occurring in the hospital.

This presentation will remind the forensic pathologist to consider this type of event in sudden death of hospitalized infants.

Air embolism may be difficult to diagnose in any age group. A review of the literature indicates that air embolism in infants may occur as a complication of ventilator therapy in hyaline membrane disease, during neurosurgical procedures, and as a complication of nasal continuous positive airway pressure (CPAP). To our knowledge, there are no reported cases of fatal accidental intravascular injection of air in infants. We report three such cases.

Case 1: A 29-week estimated gestational age baby boy was admitted to the neonatal intensive care unit (NICU) with a diagnosis of prematurity. At eleven hours of age he suffered a cardiac arrest. A chest radiograph during the unsuccessful resuscitation effort was suggestive of intracardiac and portal air. The nurse stated that she had mistakenly injected 10 ml of air into the arterial line as she attempted to “clear” the nasogastric gavage tube. A postmortem examination revealed intracardiac and intravascular air.

Case 2: A 30-day-old, former premature infant boy was admitted for observation for difficulty breathing. Shortly after the placement of an IV line, he developed facial cyanosis followed by respiratory arrest and a full code, from which he could not be resuscitated. Postmortem examination revealed no cause of death. Following up on information obtained through unsolicited telephone calls to the OCME, additional historical information obtained via deposition indicated that the intravenous (IV) line tubing had not been flushed prior to initiating the IV line. An “air bubble” was subsequently noted in the tubing, and the tubing was flushed. Immediately after re-initiation of IV fluids through the flushed line, the baby decompensated and died. The autopsy findings, historical information, and temporal sequence of events were consistent with death arising from an air embolus introduced through the IV tubing.

Case 3: A 31 week gestational age infant boy was admitted to the NICU for prematurity. At 43 days of age, in a time sequence shortly after receiving a “routine” replacement transfusion of red blood cells and a scheduled gavage feeding, the baby suffered an acute decompensation, with bradycardia and abdominal distension. Chest radiographs performed during the code revealed massive intracardiac air. An autopsy provided no significant, potentially lethal, pathologic process. The clinical presentation, radiographic findings, and pathologic findings were consistent with an exogenous source of air being introduced into the vascular system. The exact source of the exogenous air has not been clearly elucidated to date.

Air embolism presents a diagnostic challenge in adults, and is even more difficult to diagnose in infants. A thorough review of case information including specific nursing activities around the time of decompensation may suggest air embolism as a possibility. Review of radiographs taken during resuscitation may document the air embolus. Extensive follow-up may elucidate possible sources of exogenous air. These cases highlight the importance of a thorough scene investigation, review of medical records, and complete postmortem examination in sudden death – even those occurring in the hospital.

Air Embolus, Infants, Accident

G83 Lucid Interval Revisited: Delayed Onset of Unconsciousness in an Impacted Child

Darinka Mileusnic, MD, PhD, Knox County Medical Examiner’s Office, University of Tennessee Medical Center; Department of Pathology, Knoxville, TN 37922; Edmund R. Donoghue, MD, Cook County Office of the Medical Examiner, Chief Medical Examiner, 2121 West Harrison Street, Chicago, IL 60612*

After attending this presentation, attendees will understand the timing of inflicted childhood head trauma, depending on the mechanisms, and clarification and definition of the term “lucid interval.”

The impact of the mechanisms of injury, interplay of the primary and secondary cerebral injury and age of the injured child on the timing of injuries.

The timing of injuries and existence of a lucid interval in non-accidental head trauma are among the most controversial issues in child abuse investigation. These issues are of paramount importance when it comes to prosecuting certain individuals who cared for the child. The current, widely held belief is that if the injured child becomes unresponsive while cared for by a certain individual then that particular caretaker must invariably be the perpetrator. This tenet, although recently challenged, is still being equally applied to impacted and “shaken baby” cases. In the present case report we discuss and correlate investigative information and court testimonies with autopsy findings in an impacted five-week-old infant. Our emphasis is on the importance of distinguishing different mechanisms of injury as well as the significance of primary and secondary cerebral injury, which have considerable impact on the clinical presentation and pathological findings in child abuse cases.

Non-Accidental Head Trauma, Craniocerebral Injuries, Subdural Hemorrhage

Pathology/ Biology

G1 Investigation of Infant Fatalities in Maryland (1990-1999)

Ling Li, MD, and David R. Fowler, MD, Office of The Chief Medical Examiner, State of Maryland, Baltimore, MD; Liang Liu, MD, Tongji, Medical University, Wuhan, China; and Mary G. Ripple, MD, Zoe Lambros, RN, JD, Havre de Grace, MD, and John E. Smialek, MD, Office of The Chief Medical Examiner, State of Maryland, Baltimore, MD*

The goals of this presentation are to learn the value of the infant death scene investigation and to identify certain epidemiological characteristics of Sudden Infant Death Syndrome (SIDS).

From 1990 to 1999, the Office of the Chief Medical Examiner (OCME) investigated a total of 1,510 sudden infant deaths. SIDS was the leading cause of death in this infant population (51%). Since 1994, the SIDS rate in Maryland has dropped significantly. However, the number of infants that died of accidental or non-accidental injuries remained consistent during the same time period.

Sleeping locations and positions of all the infants were documented in the investigations. A total of 342 infants were found sleeping in bed with an adult or adults (bed-sharing) at the time of death. Of the 342 bed-sharing infants, 265 (77%) died of SIDS, 45 (13%) died of natural diseases, and 11 (3%) died of asphyxia due to overlay. There were 21 bed-sharing infants whose cause and/or manner of death could not be determined. Of the 778 SIDS infants, 467 (61%) were found unresponsive on their stomach, 126 (16%) on their side, and 70 (9%) on their back. More than 38% SIDS infants who were placed to sleep on their side were found on their stomach. Since 1997, the proportion of prone sleeping SIDS has reduced from approximately average 60% prior to 1997 to only 25% in 1999.

During the past 10 years, 27 infants died of positional/compressional asphyxia due to unsafe sleeping environments, such as defective crib; defective side rails on crib/bed; mattresses that were too small for crib/bed, allowing space between mattress and the head or foot boards, or space between the mattress and the wall. All the situations allow the infants to slip down and become wedged. Eleven infants were suffocated by entanglement in bedding materials, such as plastic covers, quilts, blankets, and pillowcases. Since the risks for the accidental suffocation can be modified, it is very important for the investigators to carefully examine the scene and personally interview the individuals who were caring for the infant and who discovered the child. Such efforts could prevent potential dangerous sleeping environments and save lives.

This report focuses on the importance of infant death scene investigation in determination of the cause and manner of sudden infant deaths. Certain characteristics of SIDS victims are also presented.

Sudden Infant Death, Bed-sharing/Sleeping Position, Death Scene Investigation

G2 Sudden Infant Death Syndrome in North Carolina From 1999-2000: The Prevalence of Risk Factors and Its Relation to 2000 Census Data on a County by County Basis

Russell Alexander, MD, Duke University Medical Center, Department of Pathology, Box 3712, Durham, NC; Krista Ragan, BS, Castleton State College, Castleton, VT; Deborah Radisch, MD, MPH, Office of the Chief Medical Examiner, Campus Box 7580, Chapel Hill, NC; and Robin Vollmer, MD, Veterans Affairs Medical Center, Department of Pathology, 508 Fulton Street, Durham, NC*

The goals of this presentation are to demonstrate the prevalence of risk factors for Sudden Infant Death Syndrome (SIDS) in North Carolina as related to type of sleeping surface, sleeping position, and co-sleeping and to show the relationship between the SIDS mortality rate per county and the 2000 census demographic data for each county.

Hypothesis: Reported risk factors for SIDS with regards to sleeping surface, sleeping position, and co-sleeping are highly prevalent in the population of SIDS deaths studied. Demographic data as presented in the 2000 census is significantly related to county SIDS mortality rates.

Methods: The North Carolina Office of the Chief Medical Examiner's autopsy and investigative records were retrospectively reviewed for all infants aged 0-1 years who died during 1999 and 2000 in which the cause of death was SIDS or undetermined. Demographic data with regards to age, sex, and county of death were tabulated. The place where the infant was sleeping, the infant's sleeping position, and the occurrence of co-sleeping were recorded when the data was available. The anatomic diagnoses on the autopsy reports were tabulated for all of the deaths. The 2000 census data for North Carolina counties was used to determine the number of 0-1 year old infants in each county so that population at risk for SIDS could be determined. State and county SIDS mortality rates for the population at risk were then calculated. The county death rates were then compared to county demographic data as reported by the 2000 census by a general linear model using a Poisson link function to see which data significantly correlated ($p < 0.05$). The demographic data that was analyzed for each county included: birth rate; death rate; ethnicity; household, family, and per capita income; families, children, and persons below poverty; families with children under 16 with both parents in the workforce; female labor force participation rate; completion of high school or bachelors degree; persons who lived outside the U.S. 5 years ago or were born outside the U.S.; wood as principal heating fuel; and lacking complete plumbing.

Results: The authors examined 238 deaths. Of these, 131 (55.0%) were male and 107 (45.0%) were female. The ethnicity of the infants was 117 (49.2%) white, 104 (43.7%) black, 13 (5.5%) Hispanic, and 4 (1.7%) other. The ages ranged from 3 – 338 days with an average of 100 days. The causes of death were reported as 190 (79.8%) SIDS, 22 (9.2%) asphyxia, 7 (2.9%) other, and 19 (8.0%) undetermined. The manner of death was determined to be natural in 197 (82.8%), accidental in 24 (10.1%), and undetermined in 17 (7.1%). Prior to their deaths, the infants were placed in the following locations: adult mattress 68 (28.6%), crib/bassinet 51 (21.4%), couch/sofa 22 (9.2%), water bed 3 (1.3%), chair 1 (0.4%), playpen 1 (0.4%), other 15 (6.3%), and unknown 77 (32.4%). The position that the infants were in when found was: prone 85 (35.6%), supine 36 (15.1%), side 12 (5.0%), other 2 (0.8%), and unknown 103 (43.3%). Co-sleeping was present in 105 cases (44.7%), absent in 75 (31.9%), and no data were available in 55 (23.4%). If co-sleeping did occur, the number of adults and/or siblings sleeping in

bed with the infant was 1 in 52 cases (49.5%), 2 in 48 cases (45.7%), and 3 in 4 cases (3.8%), and 5 in 1 case (1.0%). The mother was the most common person in bed with the infant as found in 89 cases (84.8%). Co-sleepers also included: the father in 48 (45.7%), siblings in 18 (17.1%), and others in 4 (3.8%).

Risk factors for SIDS have been reported elsewhere to include not sleeping in a crib, prone sleeping position, and co-sleeping. These risk factors were examined in the North Carolina infants by examining the 102 SIDS deaths in which data was available for all three. Of these 102, 67 (65.7%) were not in a crib, 63 (61.8%) were prone, and 48 (47.1%) were co-sleeping. However, 94 (92.2%) of these 102 had at least one of the three risk factors present (i.e., were prone or co-sleeping or not in a crib). Only 6 (5.9%) deaths were recorded for infants sleeping supine and alone in a crib. Only 2 (2.0%) deaths were noted for infants sleeping on their side and alone in a crib. Thus, the vast majority of SIDS deaths occurred in infants exposed to a known risk factor with regard to sleeping surface, position, or co-sleeping.

The following anatomic diagnoses were reported in the infant's autopsy reports: pulmonary congestion/edema/hemorrhage 107 (45.0%), mediastinal petechiae 102 (42.9%), pulmonary inflammation 22 (9.2%) (includes pneumonia, bronchitis, bronchiolitis, and interstitial inflammation), visceral congestion 22 (9.2%), heart malformations 17 (7.1%), liver pathology 13 (5.5%) (includes fatty change, hepatitis, and necrosis), acute/chronic tracheitis 9 (3.8%), neuropathology 7 (2.9%) (includes encephalopathy, edema, subdural hemorrhage, and gliosis), and aspiration 6 (2.5%).

The SIDS mortality rate in North Carolina was 1.0 deaths per 1000 infants per year; the rate for counties varied from 0 – 5.9 deaths per 1000 per year. The following county demographic factors were found to be significantly related to SIDS: death rate ($p=0.007$), percent of families with children under 16 with both parents in the workforce ($p=0.03$), and percent Native Americans ($p=0.05$); birth rate had a borderline significance ($p=0.07$). A general linear model with Poisson link function based on these 4 pieces of data explained 68% of the variance in the county SIDS mortality rate data. None of the other demographic data was found to be significantly related to county SIDS mortality rates.

Conclusions: This study has found that of the 238 SIDS deaths in the state of North Carolina during the years 1999 and 2000, 94 (92.2%) were exposed to a known risk factor (i.e., not sleeping in a crib, sleeping in the prone position, or co-sleeping). Only 6 (5.9%) deaths were reported for infants without a risk factor with regards to bed, position, or co-sleeping. The mortality rate for SIDS in North Carolina was 1.0 deaths per 1000 infants per year with county mortality rates that varied from 0 – 5.9 deaths per 1000 per year. The county SIDS mortality rate was significantly related to the following county demographic data as reported in the 2000 census: death rate ($p=0.007$), percent of families with children under 16 with both parents in the workforce ($p=0.03$), and percent Native Americans ($p=0.05$); birth rate had a borderline significance ($p=0.07$). The most common anatomic diagnoses found on postmortem exam of the infants were pulmonary congestion/edema/hemorrhage and mediastinal petechiae.

Sudden Infant Death Syndrome, North Carolina, 2000 Census

G3 Epidemiological Study of SIDS in an Apulian Population

Nunzio Di Nunno, MD*, and Luigi Vimercati, MD, Sezione di Medicina Legale, Dipartimento di Medicina Interna e Medicina Pubblica, Università degli Studi di Bari, Policlinico, Piazza G Cesare n. 11, Bari, Italy; Barbara Boninfante BSc, Dipartimento di Scienze Statistiche, Facoltà di Economia e Commercio, Università degli Studi di Bari, Italy; and Francesco Vimercati, MD, Sezione di Medicina Legale, Dipartimento di Medicina Interna e Medicina Pubblica, Università degli Studi di Bari, Policlinico, Piazza G Cesare n.11 Bari, Italy

This work investigates the trend of sudden infant death syndrome (SIDS) in the period from 1970 to 1999, as shown in the case series documented by the Legal Medicine Section of the Department of Internal Medicine and Public Medicine (DIMIMP) of Bari University Hospital. The goal of the study was to assess whether the epidemiological data on SIDS have changed over time and how data compare with those in the literature.

In recent years the number of cases of SIDS seems to have dropped, but although this positive result can be attributed to the efforts of the scientific community in terms of the progress made in pediatric medicine and neonatal care, no etiopathogenetic hypotheses have yet been formulated that can individuate all the causes of the syndrome. In 1997 the death rate in the industrialized world ranged from 0.17 in Holland to 1.12 in Australia. Despite the low incidence of SIDS, it is a real social problem because no precise cause of the death can be referred. The parents and family are unable to accept the diagnosis of "unexplained" death of the infant and tend to impute responsibility to third parties, especially the doctors. The main difficulty in nosographic classification of SIDS is due to its peculiar diagnosis by exclusion, defined by Marie-Dapena and Marion Willinger as "Sudden death in infancy unexplained after review of the clinical history, examination of the circumstances of death and postmortem examination".

The present work analyses the records of autopsy of infants who died between 1970 and 1999, reviewed by the Legal Medicine Section. After excluding all cases in which the cause of death was identified (ascertained responsibility of medical staff, maltreatment, homicide, congenital anomalies, infectious diseases, etc.), a total of 63 cases of SIDS (31 M, 32 F) were found. In these, autopsy and histological examinations had not revealed any organ disease such as to cause death but only aspecific signs, that could have been correlated to the final outcome or were chance findings, such as: acute polyvisceral stasis (45%), pulmonary congestion (30%), petechiae at the level of the serosa (26%), pulmonary edema (25%), cerebral edema (20%), hypertrophy of the thymus (10%).

The distribution of the 63 cases of SIDS by calendar month showed that the highest number of deaths (43) occurred in the months of February, March, April, and December, although there was no significant relationship with seasonal affections of viral or influenza type. Distribution by age demonstrated that 51 deaths occurred in the first six months of life and only 12 from the sixth to the twelfth. Analysis of the national trend of infant mortality in the same period identified two different periods: from 1970–1980 the infant mortality rate in Italy ranged from 19 to 36.3% and 51 of the deaths in the authors' sample occurred, featuring peaks of 9 deaths in the years 1970 and 1973. From 1981 to 1999, instead, the infant mortality rate in Italy ranged from 7 to 18 and 12 SIDS occurred in this sample.

The population was therefore subdivided into 2 groups for statistical analysis: SIDS between 1970 and 1980, and SIDS between 1981 and 1999. The χ^2 test showed that there was no statistically significant difference in age distribution between the two groups ($p=0.43$; $\chi^2 10.08$), nor in distribution by calendar month ($p=0.76$; $\chi^2 6.25$). The results confirm the hypothesis that SIDS is a multifactorial affliction. They also confirm that study of this syndrome is conditioned by circumstantial factors, such as a progressive reduction of autopsy orders for suspected SIDS.

SIDS, Autopsy, Postmortem Examination

G4 A Five Year Retrospective Study of Unnatural Deaths in Children 12 Years and Younger in Singapore From 1997-2001

Paul Peng Sun Chui, MBBS, DMJ, MRCPPath, MBA, Centre for Forensic Medicine, Health Sciences Authority, 11 Outram Road, Singapore*

The goals of this presentation are to identify the recent 5 year trend of unnatural deaths in children aged 12 years and below, in Singapore, so that greater awareness can be directed at preventing such deaths. The outcome is the identification of significant characteristics in the major subgroups of unnatural deaths.

The Death Investigation system in Singapore is a Coroner's system where all sudden unnatural and violent deaths are reportable to the Coroner. Annually, some 3300 Coroner's cases are reported and of which 2000-2200 cases are autopsied. All unnatural deaths are autopsied. The Centre of Forensic Medicine of the Health Sciences Authority carries out all forensic autopsies centrally for all of Singapore.

A previous study of accidents and poisoning in children in Singapore from 1979-1984 by the late Professor T.C. Chao revealed the three leading causes as road-traffic accidents (28.3%), drowning (26.75%), and falls/falls from height (25.10%). Since then, Singapore has undergone tremendous social and technological change. Economic development has seen Singapore moving into the ranks of developed countries. The population has also increased to 4 million with the influx of foreign talent.

Over the 5-year period of 1997-2001 under study, there were a total of 139 unnatural deaths in children aged 12 and below (average of 27.8 cases per year, or an incidence of 3.17 per 10,000 population). This marks a substantial fall in the absolute number of fatalities even when compared against the narrower scope of the previous study which covered only accidental deaths. Presently, the 4 leading manners of death are: Fall from Height (25.9%), Drowning (18.7%), Road Traffic Accidents (17.3%), and Homicide/Non-accidental Injuries (NAI) (13.7%). The age distribution is 40.3% (birth to 3 year olds), 20.1% (4 to 6 year olds), 13.7% (7 to 9 year olds), 25.9% (10 to 12 year olds). Overall gender Ratio is M: F 2.2 to 1.

Some Interesting Findings:

1. The vast majority of fall from Height took place at high-rise residential buildings. Of particular interest is the appearance of childhood suicides in this group.
2. The pattern of drownings has shifted from the younger age group to the older age group. Drowning is in the majority now occurring outdoors.
3. As for Road Traffic Accidents, childhood fatalities now accounted for 2.27% all RTA fatalities over the same period, the group being almost evenly divided between pedestrians and vehicular passengers.
4. The appearance of Homicides/NAI within the top 4 leading causes of unnatural deaths.
5. Asphyxia due to Foreign Body has largely disappeared.

The presentation will provide further study of the leading causes and compare the results of the previous study and the present one. It will also offer possible reasons to explain the differences.

Unnatural Childhood Deaths, Childhood Suicides, Accidental Deaths

G5 Bone Scintigraphy and Battered Children: Limit and Indication About a Case Report

Laurent Martrille, Anne Dorandell, MD, Lauren Boismenu, Oliver Cougnenc, and Eric Baccino, MD, Service de Médecine Légale, CHU Lapeyronie, 191 av, Montpellier, France*

The goals of this presentation are to clarify the place of bone scintigraphy in the diagnosis of child abuse.

The diagnosis of battered child is difficult to make in certain cases. Because this diagnosis can have legal and administrative implications, a reliable diagnosis is crucial. A false-positive diagnosis of ill treatment could have as serious consequences as a false negative diagnosis. Bone scintigraphy may reveal some bone lesions which are undetected on standard radiography. Conversely, images on bone scintigraphy are not specific to non-accidental injury syndrome. The authors present the case of a young child who had an abnormal image on bone scintigraphy. Based exclusively upon these results, the pediatrician notified the authorities. The resulting inquiry revealed that the image was due to accidental muscular lesions and not to inflicted skeletal trauma.

Most traumatic injuries are identifiable by routine radiography which is highly sensitive, particularly in the detection of skull fractures and subtle metaphyseal injury. False negatives may occur however. The superior sensitivity of bone scintigraphy is most evident in the assessment of rib fractures, acute non-displaced long bone fractures, and subperiosteal hemorrhage. This exam also lacks specificity and should not be performed individually as it may lead to mistakes as in the presented case. In addition, bone scintigraphy is not ideal for certain body areas principally the cranium, and there is no broad consensus on indications for bone scintigraphy. Literature review indicates that certain authors suggest the use of radiological surveys before the age of 2, and after the age of 2 only perform bone scintigraphy. If images are noted on scintigraphy, examination is completed with focus radiography. Other authors suggest that both exams be carried out systematically, while still others suggest bone scintigraphy after the age of 1 with radiological survey or a scintigraphy recommended.

Faced with the absence of consensus, the authors have proposed a multicenter (5 hospital) study to clarify the role of radiographic skeletal survey versus scintigraphy in the diagnosis of child abuse. A concordance study is used between the diagnosis of child abuse based upon clinical features and skeletal survey either with clinical features or bone scintigraphy. Bone scintigraphy and radiographic skeletal surveys are performed on all children within the first 48 hours of hospitalization if possible based upon strict protocols which are followed in all centers. Independent examinations will be carried out and the findings correlated. Because the pediatrician and the medical examiner need precise diagnostic tools for the diagnosis of battered child syndrome, the final stage of the project is to quickly improve recognition of child abuse by reliable methods to limit the number of complementary examinations and irradiation.

Battered Children, Bone Scintigraphy, Skeletal Survey

G6 Fatal Capnocytophaga Infection Associated With Splenectomy

Mary H. Dudley, MD, Lawrence A. Czarnecki, DO, and Mark A. Wells, BS, Sedgwick County Regional Forensic Science Center, 1109 North Minneapolis, Wichita, KS*

The goal of this presentation is to correctly diagnose fatal sepsis due to Capnocytophaga in those at risk. This poster will address the source, site of colonization, and laboratory growth characteristics of Capnocytophaga. A clinical case study will be summarized.

Capnocytophaga can cause rapidly progressive sepsis leading to adult respiratory distress syndrome (ARDS), disseminated intravascular

coagulation(DIC), and death in splenectomized individuals. The forensic pathologist should be aware of the characteristic features and clinical presentations of *Capnocytophaga* infections in order to make this diagnosis.

This case study involves a 44-year-old male who was taken to the emergency room complaining of "not feeling well" for several days. On admission, he was hypotensive and febrile. He was placed on oxygen, but became progressively worse over a four-hour period. His X-Ray was clear on admission, but four hours later showed changes consistent with ARDS. The differential diagnoses included hantavirus, plague, and tularemia. A Wright stain of the peripheral blood smear revealed rod-shaped intracellular bacterial forms within polymorphonuclear cells. He developed DIC, and died. His medical history included a past motorcycle accident, which resulted in rib fractures, pleural adhesion, and a splenectomy for a lacerated spleen. Socially, he lived in a trailer and spent time outside collecting scrap metal to sell. He hunted squirrels and rabbits, and was recently given a German Shepherd puppy. Several cuts and scratches were observed on his forearms and hands.

Autopsy revealed congested lungs, weighing over 1000 grams each, bilateral pleural effusions, hemorrhagic skin lesions, lymphadenopathy, and status-post splenectomy. At the time of autopsy, cultures were obtained. The slow growing organism *Capnocytophaga* was considered in the differential diagnoses and chocolate agar cultures proved positive.

Canine *Capnocytophaga* is found in normal flora within the oral cavity of healthy dogs and cats. *C. canimorsus* and *C. cynodegmi* can cause localized wound infections and/or systemic infections in people who have been bitten, licked, scratched, or merely exposed to cats or dogs. The cuts and scratches on the decedent's arms may have been the exposure site for the zoonotic infection. Those at highest risk are generally individuals with an underlying disease or condition predisposing them to infection with this organism. Risk factors commonly include previous splenectomy and alcohol abusers, and less commonly chronic obstructive pulmonary disease, pulmonary fibrosis, Hodgkin's disease, hairy cell leukemia, Waldensrom's macroglobulinemia, malabsorption syndrome, renal disease, and steroid use (systemic or topical). Because the association with asplenia is frequent, it suggests that the reticuloendothelial system plays an important role in containing the infection. Illness can range from self-limited disease to severe infection characterized by DIC and death. Some of the major clinical features have included cellulitis, meningitis, fulminant bacteremia with septic shock, renal failure, hemorrhagic skin lesions reminiscent of menigococcal disease, pneumonitis with empyema, and bacterial endocarditis. The clinical picture can look identical to menigococcal disease with Waterhouse-Friderichsen syndrome, DIC, purpura fulminans, and symmetrical peripheral gangrene. *Capnocytophaga* has previously been misdiagnosed as plague.

The diagnosis of *Capnocytophaga* is made by culture. *Capnocytophaga* is a fastidious gram-negative bacillus that grows slowly on blood or chocolate agar, leaving a yellow pigment. Because it grows slowly and will not grow on MacConkey's agar, it is advisable to inform the lab that this diagnosis is being considered. *Capnocytophaga* has gliding motility, requires carbon dioxide under either anaerobic or aerobic conditions, and ferments glucose.

In summary, it is important for the forensic pathologist to be aware of *Capnocytophaga* as an organism resulting in overwhelming sepsis and death in splenectomized individuals. A thorough social, medical, and surgical history, clinical presentation, and cultures are important in making the diagnosis of *Capnocytophaga* infections.

Capnocytophaga, Sepsis, Zoonotic

G7 Look Until You See: An Unexpected Delayed Death Following a Motor Vehicle Accident

*Julie Wilson Lemmon, MD**, Tripler Army Medical Center, Tripler Army Medical Center, Tripler AMC, HI; *Cynthia D. Gardner, MD*, Department of Forensic Pathology, University of Tennessee Health Science Center, 1060 Madison Avenue, Memphis, TN

By attending this presentation, the participant should expect to gain a renewed appreciation for the fact that small and seemingly unrelated phenomena can coalesce to produce a significant outcome. This poster has three objectives: to highlight the importance of a thorough review of all available resources from the events surrounding an accident and subsequent death; to reinforce the importance of approaching the complete autopsy without bias to avoid missing important details; and, to provide a brief review of the literature pertaining to splenic injury in motor vehicle accidents.

Although deaths due to motor vehicle accidents are commonplace in today's mobile society, this case report emphasizes several important points. Careful attention must be given to multiple aspects of an individual's life when conducting a medico-legal death investigation. Coupling information from the accident scene with the antemortem medical encounter and the medical history was essential, in conjunction with a complete autopsy, to arrive at an understanding of all the contributing factors in this initially surprising cause of death.

A 37-year-old white female sustained apparently minor injuries in a single vehicle accident in which she was the belted driver. At the emergency room of a rural hospital, she complained only of a headache and some lower back pain. The physical exam noted a frontal contusion and specified that the abdomen was soft and non-tender. All imaging studies obtained (plain film only) were negative, and the only significant lab test revealed thrombocytopenia. The patient was discharged home, reportedly feeling fine, at 2000 that evening. She woke up at around 0230 with nausea and vomiting but returned to bed with no further complaints. Her parents found her cold and without vital signs at 0630.

Postmortem external exam revealed the previously noted frontal contusion and a newly prominent periorbital ecchymosis. A few scattered contusions were also noted on the extremities. Notably absent were any abdominal contusions. The internal exam began with the unexpected discovery of free blood trickling from the abdominal cavity. The hemoperitoneum was significant, with slightly over 1000cc of free blood recovered from the abdomen. Further exploration of the organs *in situ* demonstrated a pale, nodular liver and a grossly enlarged spleen with a large subcapsular hematoma. Examination and dissection of the spleen revealed a rent in the capsule in addition to the Grade III laceration in the body of the organ. The exam of the head revealed a subgaleal hematoma but was negative for any deeper trauma including epidural, subdural, or subarachnoid bleeding and parenchymal contusions.

The deceased in this case was the unfortunate victim of synergistic activity between her disease processes and the injuries she sustained in the accident. The overtly cirrhotic liver was the result of her known history of chronic ethanolism and her questionable history of viral hepatitides. The cirrhosis, in its obviously advanced stage, had caused a significant degree of splenomegaly. This splenomegaly in turn was likely responsible for the thrombocytopenia indicated by the lab results at the emergency room.

The blunt injury to the abdomen sustained in this apparently minor car accident was sufficient, partly due to the massively engorged state of the spleen, to cause a Grade III splenic laceration. The injury to the parenchyma of the spleen continued to bleed into the subcapsular space. Because of the thrombocytopenia, likely caused by the hypersplenic state resulting from the cirrhosis, the victim was apparently unable to achieve sufficient hemostasis. The subcapsular hematoma continued to

expand and eventually ruptured the capsule, perhaps by simply extending an existing defect sustained in the initial impact injury. This resulted in the generous hemoperitoneum and subsequent death of the victim. The automobile accident in this case would have caused minor to moderate injury in an otherwise healthy person. However in this victim, the diseased organ systems in conjunction with the mechanism of injury resulted in the lethal outcome.

Motor Vehicle Accident, Blunt Abdominal Trauma, Splenic Laceration

G8 Basketball-Related Sudden Deaths in Young Adults: A Medical Examiner Study

Dennis J. Chute, MD, Division of Neuropathology, UCLA Medical Center, 650 Charles Young Drive, South, Room 18-126, Los Angeles, CA; and David R. Fowler, MD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD*

The goal of this presentation is to examine the cause of sudden deaths in non-professional adult athletes playing basketball.

Twenty-three cases were reviewed of sudden cardiac death of young adults who were playing or had just stopped playing basketball at the time they expired. The time period of this study was four years, 1997 to 2000. All 23 cases underwent complete autopsy and toxicologic examination at the Office of the Chief Medical Examiner (OCME) for the State of Maryland. Of all the sports-related sudden deaths examined at this office during this time period, basketball was the sport associated with most sudden deaths. This particular type of exercise may be unusually stressful for certain people. This presentation will examine why, as well as look for the anatomic basis for the sudden deaths in this population of non-professional athletes who were relatively young adults and physically active. Of the 23 cases, all were male; the average age was 30 years. The authors found that most showed evidence of at least one significant heart condition, unknown prior to autopsy. The most frequent abnormality was atherosclerotic cardiovascular disease (almost one third of the cases). Less common findings included: congenital heart disease, left ventricular hypertrophy, right ventricular dysplasia, and myocardial scarring. Of note, several deaths occurred in those who were overweight; there also appeared to be an association between the amount of obesity and left ventricular hypertrophy observed in some.

In conclusion, in the authors' population of non-professional adult athletes dying of sudden death while playing basketball, the most common cause of death was atherosclerotic cardiovascular disease.

Sudden Death, Basketball, Autopsy

G9 The Significance of Tattoos in Forensic Autopsy

Oguz Polat, MD, Bulent Sam, MD, and Esra Saka, MD, The State Institute of Forensic Medicine, Ministry of Turkey, Istanbul, Turkey; and Nevzat Alkan, MD, Istanbul University, Istanbul Medical Faculty, Department of Forensic Medicine, Istanbul, Turkey

The attendees will learn the profile of tattoos in forensic autopsies in Istanbul, Turkey, and the importance of tattoos.

The oldest tattoos have been found on Egyptian mummies with tattoos of various body parts reflecting the profession, life style, psychological state and habits of the tattooed in the past. In recent years, tattooing has become fashionable among youngsters and revision of the significance of tattooing may be required, though tattooing still remains

an important indicator of the particular peer group tendencies, life style, and personality traits.

In this study, the forensic autopsy records of the State Institute of Forensic Medicine, Ministry of Justice of Turkey were reviewed for 4 years (1998-2002) and those with tattoos were further evaluated. Data regarding the personal information, the cause and origin of death, tattoos, self destructive and figurative scars, and their locations and features were recorded in detail. The data were then analyzed and discussed within the scope of the literature.

Of the 10,966 forensic autopsies in that 4-year interval, 269 (2.4%) had tattoos. 10.4% were female and 89.6% were male. In both sexes, 25.3% were in the 21-25 year age group, 39.4% had self-destructive scars, and 1.8% had figurative scars. The frequencies of cause of death in descending order were as follow: 14.9% drug intoxication, 13.4% gunshot wounds, 13.4% stabbing, and 7% methanol intoxication.

Tattoos, Death, Turkey

G10 Epilepsy—A Major But Disregarded Health Problem

Annie Vesterby, MD, DMSc, Department of Forensic Medicine, Peter Sabroes Gade 15, Aarhus, Denmark; Soren Dalager-Petersen, MD, Department of Forensic Medicine, Aarhus University Hospital, Aarhus, Denmark; Simona Tigaran, MD, PhD, Department of Neurology, Aarhus University Hospital, Aarhus, Denmark; and Ulrik Baandrup, MD, Department of Pathology, Aarhus University Hospital, Aarhus, Denmark*

Myocardial fibrosis might be the organic substrate for malignant arrhythmia in patients with epilepsy, which can lead to sudden death either due to natural causes or due to traffic accidents.

It seems to be the general opinion that epilepsy is of no risk to traffic and there is a tendency all over the world to be less restrictive to provide a driver's license to patients with epilepsy. A study from Denmark, the Accident analysis group, Odense, has shown that epileptics have a seven times increased risk to be involved in traffic accidents compared to controls.

Moreover, epidemiological studies have established sudden unexpected death (SUDEP) to be the most important cause of epilepsy-related death as a direct consequence of seizure activity. Postmortem reports have shown patchy subendocardial fibrosis in the otherwise normal hearts of these epileptic patients, although these findings are controversial. However, it is well known that such small areas of myocardial fibrosis may serve as a potential substrate for malignant arrhythmia causing sudden death.

The following two cases illustrate this issue and should encourage researchers and the public to focus on the problem.

A 33-year-old truck driver drove for no apparent reasons in low speed off the road and into a train wagon. The front of the truck was crashed and he was found wedged in behind the steering wheel. The cause of death was bleeding due to lesion of the left axillary artery. He was known to suffer from epilepsy since the age of 17, was seen at the neurological department twice a year, and was on antiepileptic treatment. He had earlier been disqualified from driving for one year due to a solo accident and later on for 3 month due to an epileptic fit.

An otherwise 23-year-old healthy woman with drug refractory epilepsy was found dead in her bed. The cause of death was an epileptic fit based on findings at the scene, autopsy, microscopy including neuropathological examination and toxicology. Especially, microscopy of the myocardium including the conduction system showed focal myocardial fibrosis of the endocardium located to the posterior papillary muscle.

Conclusion: focal myocardial fibrosis can be the organic substrate for malignant arrhythmia triggered by an epileptic seizure which cannot

be avoided by antiepileptic treatment and which has to be taken into consideration when authorizing an epileptic driver with a driver's license.

An ongoing not yet published prospective case-control study from the authors' group has shown epileptics to have focal myocardial fibrosis.

G11 Death at Dinner: Foreign Body Asphyxiation – An Unknown Cause of Death in the Elderly?

Andrea M. Berzlanovich, MD, Institute of Forensic Medicine, University of Vienna, Sensengasse 2, A - 1090 Vienna, Austria; Thomas Waldhoer, Institute of Cancer Research, Department of Epidemiology, University of Vienna, Borschkegasse 8a, A - 1090 Vienna, Austria; Ernst Sim, MD, Meidling Traumatology Center, Kundratstraße 37, A - 1120 Vienna, Austria; Peter Fasching, Geriatric Center Baumgarten, Huetteldorfstraße 188, A - 1140 Vienna, Austria; and Manfred A. Muhs, Department of Cardiothoracic Anesthesia and Intensive Care Medicine, University of Vienna, Waehringerstraße 18 - 20, A - 1090 Vienna, Austria*

Food asphyxiation is a common problem whenever and wherever people eat. Knowledge of predisposing factors might help to prevent asphyxial deaths.

The authors reviewed 42,745 consecutive autopsies done during an 18-year period (1984 to 2001) at the Institute of Forensic Medicine, Vienna. Demographic features and predisposing factors were determined for the 232/42,745 (0.5%) cases of fatal foreign body asphyxiation.

There was a predominance of men (134 men, 98 women); the overall male-to-female ratio was 1.4:1. 105/232 persons (44 males, 61 females) were aged 65 years or older. 69% of the fatal incidents occurred in private homes, about 15% in a restaurant. The remainder died in nursing institutions (9.5%), public areas (5%), or in hospitals (1.5%).

On 137/232 (59%) occasions observers were present at the time of the incident and subsequently called the Emergency Service. In 125 (91%) cases, neither the observing laymen nor the majority of the emergency medical technicians and physicians who would have been able to intervene recognized the definite diagnosis. Only 12 cases, most of all victims younger than 65 years, have been correctly identified during cardiopulmonary resuscitation. Misdiagnoses were cardiovascular failure (59%), intoxication from medication, drugs or alcohol (26%), and epileptic seizures (10%).

By medical history 21% were considered to be chronic drinkers. Blood alcohol concentration was determinate in all of the 232 cases. 44% of the victims were sober at the time of death. The other deceased (56%) had blood alcohol levels ranging from 0.05 % to 4.35 %. In another 39 (17%) corpses, findings from toxicological analysis were positive for sedative and/or hypnotic drugs.

Only 22 (9%) victims had intact dentition. 29% had partial or complete dentures, 25% were edentulous, and 37% had defective or partial dentition without dental prostheses at the time of death.

The food most often choked upon was either a segment of unchewed meat (48%) or a large piece of sausage (20%). A bolus consisting of bread, cheese, egg, cookies or pastries was found in 14%, while fruit or vegetables accounted for another 7%.

In 71% the obstructing foodstuff or other foreign objects were located in the supraglottic region or within the glottis itself, presumably in reach of fingers. In the other cases (29%) the bolus was lodged in the infraglottic area.

Concomitant with the advanced age groups is the problem of inadequate dentition. Whereas meat and sausages were the obstructing food in all cases of the people with intact or defective dentition - soft, friable, or loosely textured foods were found predominately in the edentulous, elderly victims. Future improvements in rescue techniques should take this into consideration.

Such fatal accidents could have been prevented easily. Effective prevention depends on understanding of the nature and frequency of the accidental asphyxial deaths, the facts that led to their occurrence, and a high degree of suspicion.

Foreign Body Asphyxiation, Elderly, Autopsy

G12 Death During EMS Transportation

Istvan F. Szentmariay, MD, DMJ, and Gyorgy Dunay, MD, Institute of Forensic Medicine, Semmelweis University, Budapest, Hungary, Ullio Street 93, Budapest, Hungary*

The goal of this presentation is to study the cause and manner of death and other important epidemiological data of those individuals who die in an ambulance car during EMS transportation.

Materials and Methods: Retrospective analysis was made of 1,001 ambulance reports and autopsy records of deaths during EMS transportation between 1996 and 2001. According to local regulations, everyone who passes away while being in an ambulance car, after a 911 call, should undergo forensic autopsy evaluation. Statistical calculations were done from many points of view.

Results and discussion: Averagely 62% of the deceased were male, 38% were female (average m/f ratio was 1.58, but it was 2.18 in accidental deaths, and 1.29 in suicides). Natural cause of death was listed in 81.2% of the males (out of this was 71% cardiovascular mortality). Breaking down to age categories, natural cause of death was present in only 19 % in the age group between 21-30 y. and it was in 94% in the older age group (over 71 years of age). In females, the natural cause of death represented 82.2% and out of this cases 78% were cardiovascular origin, with scatter similar to males.

Upon further investigation natural causes of death, particularly cardiovascular deaths (pre-hospital cardiac arrest), it was obvious, that the majority of these events happened at home. Analysis will be given on other scenes of occurrence in different age categories by gender. Pathologic condition of the hearts was analyzed, regarding weight of the heart (left ventricular hypertrophy), myocardium (recent and old myocardial infarction), coronary arteries (AS, plaque rupture, etc.) and pulmonary arteries. Also compared were the accuracy of diagnoses made by ambulance personnel and diagnoses made after forensic autopsy.

Accidental cause of death was listed in 10.3% of males and 7.5% of females, with somewhat different age distribution curves. Major injuries will be detailed and the usefulness of resuscitation on moribund trauma patients while being in an ambulance car.

Suicide cases died during transportation represented 3.7% of all male cases and 4.6% of all female cases. Important details will be provided on the methods of suicides most likely lead to fatal outcome in such a short transportation time.

Homicidal victims were only 4.8% of all transported male patients and 5.7% of all female patients. Again, the method of homicides and the associated serious injuries will be presented.

Data will be presented on what part of the transportation process during which the patient was declared dead (before leaving the scene, first or second part of the transportation, dead-on-arrival/DOA). Also an important factor determining survival is the ambulance response time, how fast the ambulance crew can reach the patient and how they can follow the chain-of-survival concept. These particular issues will also be discussed.

Death in Ambulance Car, EMS Transportation, Out-of-Hospital Cardiac Arrest

G13 Sudden Asphyxial Death Due to Regurgitation of a Pedunculated Esophageal Lipoma: A Case Report and Review of the Literature

Tasha Zemrus, MD, Assistant Medical Examiner, Office of the Chief Medical Examiner, 111 Penn Street, Baltimore, MD; Adrienne Segovia, MD, Deputy Medical Examiner, Office of the Cook County Medical Examiner, 2121 West Harrison Street, Chicago, IL*

The goals of this paper are to present an unusual case of sudden death due to asphyxia by regurgitation of a pedunculated esophageal lipoma is presented, and a review of relevant literature is performed.

Of all esophageal neoplasms, 20% are benign. Benign esophageal tumors include leiomyomas, which are the most common, as well as fibromas, hemangiomas, and lipomas. Lipomas are extremely uncommon, representing approximately 4% of benign esophageal tumors. They usually present in the elderly and more commonly in men, although no other definitive risk factors have been identified. Most arise in the submucosa, and may be sessile or pedunculated. When pedunculated, the most common symptom is dysphagia, followed by a sense of fullness in the throat or respiratory symptoms such as wheezing or recurrent respiratory infections. However, the first sign may be regurgitation of a mass into the mouth following coughing, eructation or vomiting. In rare patients, the mass obstructs the oropharynx, leading to asphyxia. To date, less than ten asphyxial deaths due to regurgitation of a pedunculated esophageal tumor have been reported in the literature.

The authors present a case of a 44-year-old man with a history of seizures that suddenly collapsed after a witnessed seizure. Upon arrival at the emergency room, he was apneic. The anesthesiologist identified food and gum in the mouth, which were cleared, and a white mass was identified in the pharynx. When oral intubation was impossible, a tracheostomy was performed for airway control. Unfortunately, resuscitation efforts were unsuccessful and the patient was transferred to the medical examiner's office for examination.

At the time of autopsy, a pedunculated esophageal mass was present obstructing the oropharynx. The mass was consistent with a lipoma on gross and microscopic examination. Additional significant autopsy findings included two small cavitary lesions in the left temporal and occipital lobes of the brain, which were most likely responsible for his seizure disorder.

Although rare, pedunculated esophageal tumors are important entities to consider in patients with complaints of dysphagia or vague respiratory complaints, especially in otherwise healthy individuals. When undiagnosed, the presenting symptom may be sudden unexpected death as in this case.

Sudden Death, Asphyxia, Pedunculated Esophageal Lipoma

G14 First Report of Fatal Outcome by Accidental Intrathecal Injection of Vindesine

Gilles Tournel, MD, Anne Becart-Robert, DDS, Philippe Courtin, MD, Valéry Hedouin, MD, and Didier Gosset, MD, PhD, Forensic Department, Institut de Médecine Légale de Lille, Lille, France*

The goal of this presentation is to describe the first case of fatal accidental intrathecal injection of vindesine.

Patients who are treated for cancer are exposed to risks including mistaken doses or routes of administration of toxic agents. The authors describe a case of the accidental intrathecal administration of vindesine which resulted in a fatal outcome. Pathologic findings of the central nervous system are reported and compared to the literature. Medical responsibility is also examined.

History: This 25-year-old woman had stage III non-Hodgkins lymphoma with clinical manifestations including asthenia. Lymphomatous cells were present in the cerebrospinal fluid (CSF), but neurologic function was reportedly good. Therapy included systemic vindesine and intrathecal administration of methotrexate and methylprednisolone. Vindesine, which should only be injected intravenously, was accidentally injected intrathecally. Prior to removal of the needle, a first washing of the CSF was performed. The woman was then transferred to the neurosurgical department to drain and wash the CSF. Her clinical course was slowly progressive over 6 weeks resulting in death. On the first week she suffered from leg pain with decrease in motor activity, and distal paresthesia and sensory loss occurred. On the second week, lower extremity paralysis occurred followed by upper extremity paralysis. Ascending sensory and motor dysfunction were observed. Her consciousness level began to decline and confusion progressed to lethargy. On the fourth week she was comatose and respiratory arrest occurred 2 weeks later; she died 6 weeks after the intrathecal injection of the vindesine. An autopsy was performed and included spinal cord examination by a pathologist.

Autopsy and Discussion: Autopsy was performed 2 days after death. The terminal event was pulmonary edema. Two fibrotic masses filling the upper mediastinum and infiltrated by lymphocytes were thought to represent residual tumor. The brain weighed 1250 g and was edematous. The microscopic findings in the spinal cord will be described.

Vindesine, a widely used anti-tumor agent, binds tightly to microtubules including mitotic spindle cell tubules and neurotubules. Experimental intrathecal administration of vincristine or vinblastine produces striking neuronal changes, creating vast aggregates of neurofilaments and crystalline masses possibly composed of neurotubules with the crystals appearing within 30 minutes of direct exposure but disappearing by 8 days. Neurotoxicity of vindesine has the same physiopathology. Some cases of accidental injection of vincristine have been reported. No case involving vindesine has been previously reported. The clinical, autopsy, and microscopic findings in this case are compared with others.

There is no recognized antidote to vindesine neurotoxicity leaving the clinician few therapeutic options. Immediate attempts to remove the toxin seem the most rational approach at present but limited experience in these cases indicates that piecemeal CSF drainage or exchange is not significant in preventing vindesine effects. In this new case, fatal ascending clinical progression could not be avoided.

Vindesine, Intrathecal, Death

G15 The Importance of an Interdisciplinary Review Process in the World Trade Center Mass Disaster Investigation

Jason M. Wiersema, MA, and Eric J. Bartelink, MA, Department of Anthropology, Texas A&M University, Department of Anthropology, College Station, TX; Zoran Budimlja, MD, PhD, Mechthild Prinz, PhD, Robert Shaler, PhD, and Amy Zelson Mundorff, MA, Office of Chief Medical Examiner, New York City, 520 First Avenue, New York, NY; and Gaille MacKinnon, MS, Department of Conservation Sciences, University of Bournemouth, Bournemouth, England, United Kingdom*

Upon completion of this presentation, attendees will be informed about potential problems associated with the recovery and identification of human remains after a mass disaster and illustrate the value of cooperative effort between medical examiners, anthropologists, DNA specialists and other experts.

In the wake of the events of the September 11, 2001, terrorist attacks on the World Trade Center, the Office of Chief Medical Examiner, New York was faced with the daunting task of identifying the nearly 3000 victims of the attacks. For over 10 months, a constant and heavy flow of remains was delivered to the OCME with which the pathologists, anthropologists, DNA experts, dentists, investigators, and numerous other members of the OCME staff were forced to deal in a rapid fashion. During the triage process, in the interest of avoiding the potential complications of commingling the OCME pathologists and anthropologist were supposed to consider only those remains that were connected by tissue (bone, skin, muscle, etc) to be definitively the remains of a single individual and assign a single identifying case number. Due to the long shifts and large number of remains that needed to be processed this was not always the case as was discovered after the first identifications had been made and from commingled DNA results.

It could not be assumed, for example that the remains delivered in a single body bag were those of a single individual. Even remains delivered within clothing might not belong to a single individual given the number of factors that may have influenced their deposition especially later in the recovery process. Initially, during the triage process of sample collection, little effort was made to use traditional anthropological methods for sex, age, and ancestry determination. In addition, there was also a need for more detailed descriptions of the remains because victims' families were interested in receiving this information.

Hence, on May 28th, the Anthropology Verification Project was initiated. Without the same time constraints endured by the OCME pathologists, a team of anthropologists reopened each of the more than 19,000 logged in sets of remains to verify the existing descriptions and look for inconsistencies and commingling. During the verification process, the anthropologists encountered extreme levels of fragmentation, variable decomposition, varied stages of mummification and skeletonization, and the effects of prolonged exposure to fire, all of which complicate the effects of commingling. In addition to the verification of the existing file material, the anthropologists were also able to add detail to the descriptions with regard to skeletal tissue, which was often more easily recognizable than the soft tissue remains. These descriptions can be revisited in the event that DNA matches are made for individual remains. It can be insured for instance using DNA that there are no duplicated body parts sharing the same case number. Non-human remains recovered from the site were separated from the remains of victims of the attack.

DNA typing confirmed the value of this effort. All cases in which the Anthropology Verification Project decided to assign additional identifying numbers were retested and in each case at least one of the fragmented remains was determined to be from a second individual. This process not only eliminates wrong associations but might also allow for additional identifications that otherwise might have gone undetected.

Mass Disaster, Anthropological Review, DNA Typing

G16 Media Relations and the Identification of the September 11 Pentagon Terrorist Attack Victims: The Perspective of the Office of the Armed Forces Medical Examiner

Christopher C. Kelly, MMgmt, Armed Forces Institute of Pathology, 6825 16th Street, NW, Building 54, Room 1106, Washington, DC*

The goals of this presentation are to review challenges faced by the Armed Forces Medical Examiners in effectively responding to the international news media following the September 11 Pentagon terrorist attack; and to provide guidance to medical examiner offices when dealing with intensive media interest following mass fatality incidents.

The September 11 terrorist attack at the Pentagon posed new challenges to the Office of the Armed Forces Medical Examiner (OAFME) in responding to intensive, international media interest. This response included extensive message development coordination between OAFME's spokesperson and other Department of Defense officials; creation of a "virtual" Joint Information Center (JIC) to communicate findings; and detailed attention towards delivering the appropriate message on the status of identifications while remaining sensitive to the needs of the victims' families.

In the chaotic hours immediately following the attack, the OAFME spokesperson notified DoD public affairs officials of his availability to respond to media inquiries; provided 24-hour pager/home telephone information; and prepared background papers about OAFME's role in the investigation. This information proved essential in helping to refer media inquiries rapidly to OAFME for reply.

The spokesperson completed this preparatory phase with jurisdictional issues over custody of the remains still unresolved between OAFME and the Office of the Chief Medical Examiner of Virginia in the first 24 hours following the attack. Media inquiries began in earnest on September 12, when a reporter from The Washington Post called seeking an explanation and clarification of the situation. The resulting September 13 article ("Recovery Continues and Scientists Wait for Bodies") portrayed OAFME as prepared to act, but by that time the victim identification operation had commenced in Dover.

Communications with the media commenced in earnest two days after the attack. The JIC enabled OAFME to exchange information and coordinate appropriate responses with Dover AFB and DoD officials. U.S. Air Force casualty affairs officials held a short briefing when the remains arrived at the mortuary; however, OAFME officials did not participate, and at no point during the operation did OAFME conduct a press briefing. Instead, OAFME's spokesperson represented the chief medical examiner to the media and provided timely and accurate commentary over the next two weeks regarding the status of the operation. He referred journalists to former OAFME chiefs for expert analysis, and focused media attention on the work being conducted at the Armed Forces DNA Identification Laboratory (AFDIL).

Over the next two weeks approximately two dozen international print and electronic media representatives conducted interviews with the OAFME spokesperson or AFDIL staff, including CNN, National Public Radio, The News Hour with Jim Lehrer, the Associated Press and The Times of London. AFDIL staff also received positive coverage for their work providing DNA identifications of the United Airlines Flight 93 crash victims in Somerset County, Pa. DoD officials provided daily updates regarding the number of identified victims and the return of remains to family members.

From late September until early November 2001, media interest lessened and focused almost entirely on the identification and disposition of the terrorists' remains. At the close of the investigation in November 2001, OAFME's spokesperson participated in a joint DoD

planning session for release of information to the families. He also developed background papers for DoD officials on the complexity of the identification process and served as a contact point for questions from next-of-kin and interested media. DoD did not formally release information about the close of the investigation; however, The Washington Post on November 21 covered the story under the headline "Remains Unidentified for 5 Pentagon Victims; Bodies Were Too Badly Burned, Officials Say."

In conclusion, OAFME achieved generally positive and timely coverage for its work following the attacks. Multiple requests for information were handled simultaneously, and AFIP experts were utilized for comment as needed. Future OAFME communications following mass casualty incidents could benefit from the posting of background information on the AFIP website, and from an initial press briefing by OAFME personnel, subject to DoD guidance and approval. OAFME experience in this and other mass fatality incidents reflects the importance of appointing a single spokesperson, developing and releasing messages in a joint setting with other investigating agencies, and utilizing selected experts for public commentary as needed.

Armed Forces Medical Examiner, Media Relations, Pentagon 9-11 Identification

G17 Victim Identification Following the Crash of United Airlines Flight 93

Paul S. Sledzik, MS, Region III DMORT, National Museum of Health and Medicine, Armed Forces Institute of Pathology, 6825 16th Street, NW, Washington, DC; Wallace Miller, BA, Somerset County Coroner's Office, 555 Tayman Avenue, Somerset, PA; Dennis C. Dirkmaat, PhD, Mercyhurst Archaeological Institute, Mercyhurst College, 501 East 38th Street, Erie, PA; Joyce L. de Jong, DO, Sparrow Hospital Pathology, 1215 East Michigan Avenue, Lansing, MI; Patricia J. Kauffman, MD, GlaxoSmithKline, 2187 Harts Lane, Whitemarsh, PA; David A. Boyer, MFS, Department of Defense DNA Registry, 1413 Research Boulevard, Armed Forces Institute of Pathology, Rockville, MD; Fedric N. Hellman, MD, Delaware County Coroner's Office, Fair Acres, Lima, PA*

This presentation examines the overall victim identification forensic response to the crash of United Airlines Flight 93 on September 11, 2001. The various stages of the response will be examined, and the unique issues of this event will be discussed. Final figures on the methods of victim identification will be presented.

The last of the four terrorist attacks on September 11, 2001, was the crash of United Airlines Flight 93 (UA93). The Boeing 757, carrying 44 passengers and crew, was en route from Newark, New Jersey, to San Francisco when the plane was overtaken by four hijackers and turned back towards the Washington, DC, area. At about 10:10 am, the aircraft crashed into an abandoned strip mine near the town of Shanksville, PA. According to media accounts based on cell phone calls, several passengers attempted to take control of the cockpit shortly before the crash.

The Somerset County coroner and law enforcement and fire/rescue personnel were the first to the crash scene. It became evident to the coroner that outside support would be needed to help identify the remains. State volunteer response teams, including the Pennsylvania Dental ID Team (PADIT) and the Pennsylvania Funeral Director's Association, assisted the coroner in selecting and organizing a morgue site. The Federal Bureau of Investigation took control of the crash scene because of the criminal nature of the event. Initial confusion regarding the proper procedure of the deployment of the U.S. Department of Health and Human Service's Disaster Mortuary Operational Response Team (DMORT) delayed arrival of the team. Attempts to have the site declared a federal disaster through the state proved unsuccessful and the crash did not fall under the Aviation Disaster Family Assistance Act.

Ultimately, DMORT responded under a memorandum of understanding with the FBI. A team of nearly 60 DMORT members, comprised largely of the Region III team and augmented by members from other DMORT regions, was on site for two weeks. DMORT operation focused on victim identification and the family assistance center.

This response featured several firsts for DMORT, of note because of their importance for future responses. These included the first use of a contract morgue, the deployment of the DMORT DNA team, the establishment of protocols documenting the operation of each morgue section, the response of the DMORT Family Assistance Center team, the collection of family blood reference samples, and the inclusion of a formal remains triage station.

Typically, DMORT relies on the Portable Morgue Unit (DPMU) to supply and equip the team for victim identification operations. However, the DPMU was deployed to the World Trade Center disaster, so equipment and supplies for the UA93 response was pieced together from a variety of sources. A majority of the materials for the morgue were obtained under a contract with Kenyon International Services. Kenyon maintains a mobile morgue that is a scaled down version of the DPMU. Kenyon transported the mobile morgue to Somerset and provided staff for resupply and equipment purchasing. The local hospital and area funeral homes also provided morgue materials. Other pieces of specialized equipment were obtained elsewhere from local universities and hospitals.

This activation marked the first response of the DMORT DNA team. This three-person team (consisting of a team leader/pathologist, an anthropologist, and a dentist) provides reliability in the collection of DNA specimens. Because the Armed Forces DNA Identification Laboratory (AFDIL) conducts most of the DNA identification work during a DMORT response, the team was trained by AFDIL earlier in 2001. Initial assessments of the UA 93 crash scene revealed highly fragmented remains, indicating that DNA would play an important role in ensuring positive identifications. The delay in the DMORT response allowed the DMORT team commander to meet with AFDIL staff to address DNA requirements were met before starting the operation in Somerset. During the morgue operation, DMORT DNA team personnel worked closely with AFDIL staff during the collection of DNA samples.

The DMORT Family Assistance Center (FAC) team, who had completed training a few days before September 11, had their charter deployments in Somerset and New York. The UA 93 FAC team worked out of the Seven Springs Mountain resort (nearly 25 miles from the morgue site), the location of the family center selected by United Airlines. The FAC team worked closely with the airline, the Red Cross, and the National Transportation Safety Board to collect victim information. The national travel restrictions in the weeks following the crash posed some problems in obtaining records, and some families chose not to travel to the assistance center. To assist the FAC team, the U.S. Department of Health and Human Services deployed a Disaster Medical Assistance Team nurse to collect family blood and direct reference samples for DNA analysis.

Given some of the concerns involving the numbering and processing of fragmented remains at previous responses, a triage station was established. Staffed by a pathologist, two anthropologists, and a dentist, the triage team sorted through the remains, first separating personal effects from remains. Once the personal effects were transferred to the FBI, the remains were examined to ascertain their potential for identification. Potentially identifiable remains, those with dental remains, friction ridge patterns, unique characteristics, or potentially usable for DNA analysis, were assigned a sequential number, a file was created, and the specimen was sent through the morgue. Non-identifiable remains (small pieces of fatty tissue, burned tissues, and other small fragments that would be unsafe for DNA collection) were placed in containers, weighed daily, and stored separately from the numbered remains. The triage process helped to focus work on remains that would most likely lead to identification, eliminated unidentifiable remains from

the morgue flow, reduced unnecessary paperwork, and allowed the numbering process to remain simple and easily understandable.

The nature of the crash required creating written protocols for each morgue station. Team members at each morgue station submitted the protocol to the morgue manager, who then provided them to the FBI for review. These protocols were compiled, producing a document describing the particulars of the United 93 morgue operation.

The DMORT response concluded on September 25. The final numbers for victim identification indicate that DNA was the primary tool for identification. There were nearly 1500 fragments of human remains collected during the initial response and subsequent recoveries. Of these, 592 specimens were taken for DNA analysis, and 546 yielded profiles adequate for identification. From these remains, forty positive DNA identifications were completed, and four additional unique DNA profiles were isolated (probably representing the four terrorists). Fourteen positive identifications were made using traditional methods: five dental identifications, seven fingerprint identifications, and two using both dental and fingerprint methods.

Disaster Victim Identification, United Airlines Flight 93, DMORT

G18 Domestic Homicide or International Terrorism? A St. Louis Murder Crosses the Line

Phillip M. Burch, MD, Saint Louis University, 1300 Clark Avenue, St. Louis, MO*

This presentation will provide forensic investigators incite into the workings of an international terrorist group set up in the U.S., and it will provide some clues to exposing and identifying them.

This case was originally presented as a domestic homicide. The daughter of a Palestinian family in St. Louis, MO, was found stabbed to death in her family's home in November of 1989. Her father said that he had stabbed her to death in self-defense. The teenaged girl supposedly had just come home after her first day at work outside of the family's business in a wild state "on drugs." She allegedly demanded \$5000.00 from her father. When the father refused the request she supposedly grabbed a knife and attacked him with it. He said he somehow grappled with her and stabbed her in self-defense and she fell to the floor of their residence, unconscious. According to the father's story, he then got a better knife and finished his daughter off by stabbing her to death while she lay unconscious on the floor.

The father's story does not coincide with the autopsy findings. In addition the murder had been tape recorded by the FBI because that agency was tracking a terrorist cell at the residence where the killing took place. The FBI released some of the information on those tapes, which indicated that the girl's parents murdered their daughter with premeditation, to the St. Louis, MO, Office of the District Attorney to ensure the arrest of the suspects because it was known that the suspects were prepared to imminently flee the country.

What really happened was that the parents ambushed their daughter. The unwitting girl never attacked anyone. During a heated verbal argument with her father, the mother grabbed the girl from behind and held her while the father stabbed his daughter to death. This was all recorded on audiotape and transcribed into English and the transcripts were read into court during the ensuing murder trial. The parents were both found guilty of first degree murder and they were both sentenced to death. Because of evidence on the audiotapes, at the time of the trial it was thought that the girl's murder was a so-called "honor death" because she had shamed the family by dating a black man and working outside of the family's business. Subsequently, it was disclosed that the girl's father was being tracked by the U.S. Government because he was a member of the Abu Nidal international terrorist group. The father, Zein Isa, was to go on trial with other Abu Nidal members in the U.S. who

were subsequently found guilty of terrorism, but he did not go to the second trial because he was already on death row and he was seriously ill (he died of natural causes a few months later). After the second trial it became known that the female victim, 17-year-old Palestina Isa, was probably murdered not as an "honor death" but more probably because she knew too much about her father's terrorist activity and was likely to disclose this knowledge to others if she were allowed to leave the family and go out on her own.

As a result of the scene investigation of the homicide, together with the autopsy findings and the audiotapes of conversations leading up to the murder and of the murder itself, authorities and a St. Louis, MO, jury were able to come to the conclusion that this was actually a first degree murder punishable by death. In addition, the FBI was also able to establish that Zein Isa was a member of the Abu Nidal terrorist group and that the murder of his daughter may have been a terrorist act committed in the U.S. prior to 911 and prior to the WTC bombing in 1993.

This case required extraordinary good fortune to crack; 6 separate wiretaps recorded the murder so that justice could prevail in court. In the future experts will have to be more vigilant than in the past and will have to develop even better technologies to root out terrorists and protect the public.

Honor Death, Abu Nidal, Terrorism

G19 Smallpox and the Medical Examiner/Coroner System

Donald R. Jason, MD, JD, Wake Forest University School of Medicine, Department of Pathology, Medical Center Boulevard, Winston-Salem, NC*

The goals of this presentation are to familiarize the medico-legal community with the possible pathological presentations of the initial cases in a smallpox epidemic because of the probability that, in the event of a bioterrorist induce outbreak, such cases will be seen by these first line death investigators.

Medico-legal death investigators are very likely to be the first professionals coming into contact with deaths from a bioterrorist caused smallpox outbreak and must be prepared for this eventuality. This is because (1) in a new eruption of this disease in a non-immune population initial fatal cases often have atypical presentations, and will probably not be definitively diagnosed, even if coming under a doctor's care, and (2) few clinical physicians have seen even suspected cases of smallpox. Pathologists performing official autopsies will and should be called upon to examine such cases and must be cognizant of the possible appearance of any lesions and what specimens are required to confirm the diagnosis.

The threat of a bioterrorist attack in the U.S. using smallpox is being taken quite seriously by all, in spite of no known source of infection outside of either U.S. or Russian control. Terrorists have already done the unthinkable within the borders of the U.S. It is not impossible for bioterrorists to obtain smallpox virus from known or some unknown source. If smallpox were to be released into this country, a number of facts need to be considered by medical examiners who have a high probability of seeing the first undiagnosed cases.

- The probability of a medical examiner seeing these cases depends upon the particular state medical examiner law and the customary reporting procedures in the various jurisdictions. The laws governing public health hazard medical examiner jurisdiction and the customs in places without such statutes will be examined.

- Even without public health hazard jurisdiction, bioterrorist-caused deaths are a type of homicide and should be investigated and certified by the official medico-legal death investigation system. Medical examiners are fully aware of the legally necessary procedures, such as chain of custody in handling specimens that must be followed to support a

criminal prosecution. How this may play out in an international terrorist attack within the U.S. will be discussed.

- This presentation will show what to look for in possible smallpox cases early in a bioterrorist attack. This is important because the first mortal cases will contain a high proportion of victims with atypical disease. Most of us, particularly those who received their medical training after the supposed eradication of smallpox in the early 1970's, received a superficial instruction in the clinical and pathological appearance of the disease. It is time for a knowledge booster.

- It must also be recognized that the civilian population in the U.S. has not been vaccinated against smallpox since 1972. This means that medical examiners do not have immunity to smallpox since vaccination is not effective after about 20 years! Unless there has been a policy shift to vaccinate medical examiners and pathologists performing medical legal autopsies before this presentation, a bioterrorist attack with smallpox is likely to cause casualties within the profession. It is also time for a smallpox immunity booster.

Smallpox, Medical Examiners, Bioterrorism

G20 Autopsy Procedure and Findings in a Case of Inhalational Anthrax

Mary G. Ripple, MD, Jack M. Titus, MD, and David R. Fowler, MD,
Office of the Chief Medical Examiner, State of Maryland, 111 Penn
Street, Baltimore, MD*

The goal of this paper is to present to the forensic community the autopsy procedures and findings in a case of inhalational anthrax so that the attendee can learn how to approach and what to expect in this type of case.

In the fall of 2001, there were eleven confirmed or suspected cases of inhalational anthrax of which 5 people died. Prior to the anthrax attacks in 2001, autopsy experience with inhalational anthrax was limited. Reporting the autopsy procedure and findings will make forensic pathologists aware of the precautions that need to be taken and of what to look for at autopsy in this hopefully rare type of case.

By report, this 47-year-old, Black male was an employee of the Brentwood postal facility in Washington, DC. He complained of "flu like" symptoms with a mild non-productive cough, sneezing, nausea, vomiting, and stomach cramps on October 16, 2001. While attending church on October 20 he had a brief self-limited syncopal episode and did not request transport to the hospital. Early the next day he went to the emergency room complaining of vomiting and profuse sweating. He was afebrile and had orthostatic hypotension and was treated with intravenous hydration and was released. Later that day he complained of myalgia, vomited and passed out again. Early in the morning of October 22 his wife found him unresponsive. On arrival to the emergency room he was afebrile, hypotensive, tachycardic and tachypnic. He required intubation and was treated with multiple intravenous antibiotics. Computerized tomography scans were remarkable for pleural effusions, perihilar infiltrates, probable mediastinitis, small bowel wall edema with small bowel air, portal venous air, and ascites. He had a progressively downhill course and was pronounced dead within six hours after arrival to the hospital. Gram stain of sputum and the buffy coat smear of the blood identified gram positive bacilli and direct fluorescent antibody test (dFA) and polymerase chain reaction performed by the Centers for Disease Control and Prevention (CDC) were positive for *Bacillus anthracis* on antemortem blood specimens. In addition, antemortem blood cultures grew *Bacillus anthracis* within 18 hours.

An autopsy, based on CDC recommendations that minimized the number and extent of procedures, was performed on October 22, 2001, using standard universal precautions in the isolation room at the OCME. It is recommended that the CDC be contacted prior to performing the autopsy for their suggestions and also to inquire about what type of

specimens that they will require for future analysis. Three forensic pathologists and an autopsy assistant performed the autopsy. Since the organisms that one is dealing with at autopsy are vegetative bacteria and not spores, the primary, but minimal risks to personnel are through splashes to mucous membranes and skin injury. Therefore, the eyes, nose, mouth and any prior open skin defects must be covered and protection against cuts and puncture wounds is necessary. As the body warms up and is exposed to air, it is unclear if and when the bacilli can sporulate, therefore gross contamination of the environment that could eventually lead to spore formation should be limited.

Gross autopsy findings showed marked soft tissue edema, pleural effusions, ascites, multifocal mediastinal and mesenteric soft tissue hemorrhage with extension along the hilar and pulmonary parenchymal bronchi and blood vessels, mild pulmonary hilar lymphadenopathy, friable and hemorrhagic hilar lymph nodes, no gross pulmonary consolidation, and a portion of hemorrhagic distal small bowel without mucosal ulceration. The mesenteric lymph nodes, terminal ileum, and large bowel were unremarkable. The brain and cerebrospinal fluid were not examined. Microscopic examination revealed hemorrhagic necrotizing hilar lymphadenitis, mediastinal soft tissue hemorrhage with mildly increased acute and chronic inflammation, pulmonary perivascular and peribronchial hemorrhage, no evidence of pneumonia, and a section of small bowel with necrotizing infection extending from the periintestinal soft tissue to the lamina propria and not involving the mucosa. Brown and Brenn special stains showed gram positive rods consistent with *Bacillus anthracis* in the hilar lymph nodes, mediastinal soft tissue, lungs, affected small bowel, stomach, liver, kidneys, adrenals, and spleen. Postmortem blood culture for *Bacillus anthracis* was negative.

Post autopsy, the isolation room, all instruments, body tray, and outer body bag were washed with at least 10% bleach with at least five minutes of contact time. The body was triple bagged, placed in the freezer, and subsequently transported to the funeral home with the recommendation that mortuarial care be limited to only what is necessary which included the avoidance of embalming and the consideration of cremation.

Investigation and autopsy determined that the cause of death was inhalational anthrax and the manner of death was homicide. The diffuse presence of gram positive bacilli in almost every organ indicates *Bacillus anthracis* sepsis. This report suggests an anthrax autopsy protocol and presents the autopsy findings. It emphasizes the relatively non-specific gross autopsy findings and the importance of clinical information, mutual cooperation with the CDC, and microscopic special studies that are required to make the proper determination as to the cause of death in this relatively rare type of case. In addition, it reinforces the fact that medical examiners play an important role in public health surveillance.

Anthrax, Bioterrorism, Necrotizing Lymphadenitis

G21 Discrepancy Between the Legal and Medical Definitions of Homicide

Jeffrey M. Jentzen, MD, Milwaukee County Medical Examiner's Office, 933 West Highland Avenue, Milwaukee, WI; Ayako Kobayashi, University of Wisconsin at Milwaukee, 1-3-4 Nozawa, Setagaya-ku, Tokyo, Japan; Eileen Weller, RN, MHA, Milwaukee County Medical Examiner's Office, 933 West Highland Avenue, Milwaukee, WI; and Mallory O'Brien, PhD, Harvard School of Public Health, 2501 East Menlo Boulevard, Shorewood, WI*

The goals of this presentation are to compare the manner of death as certified by a medical examiner (ME) on a death certificate to a district attorney (DA) charging decision and final disposition of the case in the court system; and to measure the frequency of and identify factors

contributing to any disparity in classification of homicide by medical examiners and prosecutors.

Hypothesis: Medical examiners and district attorneys have differing responsibilities and interests in processing homicidal deaths, which results in disparity between the medical examiner classification as homicide, and the legal definition for the purpose of criminal justice.

Methods: All cases certified by the Milwaukee County Medical Examiner's Office as homicide; accidental motor vehicle deaths and accidental firearm deaths from 1990 through 1999 were matched to cases presented to the homicide unit of Milwaukee County District Attorney's office from October 14, 1991 through 1999.

Results: Of the 1247 cases certified as homicide by the ME, 766 were matched to the corresponding DA homicide cases. Approximately 40% of cases were not matched. Factors influencing successful matching included apprehension of perpetrator(s) and prosecution in adult court. In a sample of 67 homicide cases reviewed but not charged by the DA's office, almost half (47%) were determined to be self-defense, 26% insufficient evidence, 11% no defendant or death of the defendant, 3% accidental shooting, and 13% other.

Conclusions: There is significant variation in how medical and legal practitioners define "homicide." This variation results from the different goals of the practitioners as expressed in levels of intentionality and differing burdens of proof (reasonable medical certainty vs. beyond a reasonable doubt) that contribute to variations in definition of homicide. The effect of such variation requires additional research.

Homicide, District Attorney, Medical Examiner

G22 Rape/Sadistic-Homicide vs. Accidental Death During Voluntary Violent Sexual Activity: Three Case Reports Illustrating Difficulties in Assessing the Circumstances of the Deaths

Dominique Lecomte, MD, and Paul Fornes, PhD, Forensic Institute of Paris, Medical School Cochin Port-Royal, Paris, France*

Three case-reports are presented to illustrate difficulties in assessing whether violent sexual activity has been forced or consensual. Didactic figures are displayed to illustrate various features in violent sexual intercourse and instrumental penetration.

In investigating a suspicious death, where there is evidence of sexual intercourse, the forensic pathologist has not only to determine the cause and manner of death, but also to answer the question of whether sexual intercourse was forced. The three following case-reports illustrate difficulties in assessing whether violent sexual activity has been forced or consensual.

Case 1. A 56-year-old woman was found dead in her bed, in the morning, by her husband. According to him, they had sex in the evening and fell asleep. The autopsy showed multiple hematomas on breasts, arms, hands, legs, shoulders, and head, as well as severe damage to the perineum, vagina and rectum. The anal margin had hematomas. There were large tearings of the rectal wall and perirectal muscles, of the vagina with complete prolapse of the cervix through the vulva. The victim was found with 3.68 g/l of alcohol in her blood. Death was assessed to have been caused by massive hemorrhage. Rectal and vaginal lesions were assessed to have been caused by a fist or a foreign object. The man confessed that he had beaten his wife and forcibly penetrated her with his fist while her consciousness was impaired by alcohol.

Case 2. A 22-year-old woman was found dead in her home, in her bathtub. Her boyfriend reported that she fainted during sexual intercourse. He said he carried her to the bathroom, put her in the bathtub,

and showered her with water, but she had fatal cardiac arrest. The autopsy showed evidence of asphyxia. There were hematomas in the perineum, the vagina and rectum, and large tearings of the vaginal wall. Toxicology was negative. The man confessed that they had sadomasochistic sexual activity, including fist penetration and strangulation with a dog's leash, when she fainted.

Case 3. A 40-year-old woman was found dead in her bed, by her husband. According to him, they had sex in the evening and fell asleep. At autopsy there were hemorrhages around the right carotid artery and infiltrating the right neck muscles. Lungs were found emphysematous. The anal margin was dilated with congestion of the mucosa, but there were no tearings. Histologically, hemorrhage was found in the rectal submucosa. The victim was found with 1.94 g/l of alcohol and 2.18 microg/l of Zolpidem (toxic level > 0.15) in her blood. There was no sperm. The cause of the death was assessed to have been mechanical asphyxia following neck compression. The rectal lesions were assessed to have been caused by a fist. Alcohol and Zolpidem contributed to the death.

In conclusion, severe lesions to the sexual organs are not always synonymous of sadistic/rape homicide. Thorough examination of the death scene, complete autopsy, histology and toxicology are necessary in assessing the cause and manner of death, and determining the circumstances of the sexual activity, whether voluntary or forced.

Rape, Sado-Masochism, Forensic Sciences

G23 Postmortem Genital Examinations and Evidentiary Protocol With Colposcopy

Sharon R. Crowley, RN, MN, Forensic Clinical Nurse Specialist, 122 Emeline Avenue, Santa Cruz, CA*

This paper proposes to describe a sequential methodology and evidentiary protocol for the postmortem genital examination of sexual homicide victims. To this end, salient findings from baseline studies of postmortem genital anatomy, and the effects of postmortem changes, will be discussed.

A methodology for the genital exam of homicide victims by forensic nurse examiners to assist in the determination of concomitant sexual assault was first described in 1998 (Crowley, AAFS). This earlier protocol has been further defined during ongoing accumulation of baseline studies of genital anatomy and the nature of the anogenital tissues in the postmortem interval. This clinical research is done in collaboration with Brian Peterson, M.D., of Forensic Medical Group, Fairfield, CA. Further study will compare this baseline group with cases that present with genital trauma. Study of the nature and patterns of injuries found in sexual homicide victims will allow comparisons to those types of injuries previously noted in living victims of sexual assault. The use of colposcopy is well established as a component of the medical legal exam of living victims of both adult and child sexual assault. Patterns of injury have been described and findings compared to a control group of women who engaged in consensual sex (Slaughter, Brown, Crowley, and Peck, 1997).

Examination solely via gross visualization yields a paucity of genital trauma (10-30%) in living rape victims. Similarly, during the autopsy, gross visualization alone may preclude the more subtle findings of genital trauma that usually constitute injury in sexual assault. The use of colposcopy for the evaluation of postmortem cases by this author has demonstrated its usefulness and efficacy as an adjunct to the examination. The colposcope affords magnification at different settings, photographic capability via standard 35mm SLR or digital imaging, and if desired, video capacity. Photocolposcopy provides a mechanism for photodocumentation; this increases reliability and facilitates peer review. Higher magnifications afforded by the colposcope (e.g., 15X)

allow careful study of the effects of the postmortem interval and other variables on the genital tissue. Other equipment used in the postmortem genital examination in addition to the colposcope, include camera(s), various lenses, various sizes of vaginal speculums, anoscopes, Wood's Lamp +/or Alternate Light Source, sandbags, and disinfectant.

Materials and Methods: 28 postmortem patients (25 females; 3 males) were evaluated using a protocol that included colposcopy. Causes of death included suicide, accidental, and natural. All cases were examined with the mobile system of technology described by Crowley (AAFS, 2001). The postmortem interval varied from <24 hours (fresh) to 1 month (decomposed). Ages ranged from 32 months to 90 years old. Photographs were available for review on 18 of these cases, all females. Ages in this group ranged from 32 months to 89 years old, with a mean age of 47.9 years. Two of the 18 (11%) were pre-pubertal. Seven were in their 20s-40s (39%), and 9 (50%) were ≥ 50 years old. Two of the 18 were photographed only with macrophotography. Sixteen were photographed with colposcopy, at a fixed magnification rate of 7.5X, 15X, or both. In some cases, 35mm photographs were available for comparison to the colposcopic photos. Cases were assigned an ID number and entered into a modified version of the Sexual Homicide Database. Salient data include age, ethnicity/race, date/time body found, date/time of examination, cause of death, past medical history, reproductive status, and exam techniques. Eleven anatomic sites were evaluated on female cases: labia majora, labia minora, posterior fourchette, fossa navicularis, perineum, hymen, peri-urethral area, vagina, cervix, anus, and rectum. The genital findings were categorized by a system developed by Crowley and Peterson, to describe the nature of any postmortem changes to the anogenital tissues.

The Sexual Homicide Evidentiary Protocol is a sequential methodology for conducting the postmortem genital evaluation of the suspected victim of a sexual homicide. Specific features will vary by state/local jurisdiction. Prior to the actual autopsy, it is advisable to clarify individual roles and responsibilities in areas of potential overlap. If possible, conduct the genital examination and collect anogenital specimens prior to the general autopsy. This may be done after the medical examiner has conducted a preliminary overview of the body and noted gross features, such as clothing. This will allow prompt collection of biological evidence and avoid obscuring the genital area by leakage of body fluids through the vaginal opening. Salient features of the protocol include:

- Review of available data and historical information; much information may be missing at the time of the autopsy.
- General physical examination and general description of nongenital trauma.
 - a. Head/oral: items for Sexual Assault Evidence Kit and photographs, as appropriate.
 - b. Scan of body with Wood's Lamp and/or Alternate Light Source
 - c. Bite mark evaluation: documented on traumagram, in a manner consistent with ABFO guidelines, i.e., location, shape, color, size, type of injury
 - d. General description of nongenital trauma. Note "Defer to Medical Examiner's Report."
- Sexual Assault Evidence Kit and Clothing: integrated into general and anogenital examination, to ensure consistency and completeness.
- Genital/Anal Examination: includes collection of foreign matter/debris, pubic hair combings, evidentiary swabs/slides, reference standards, and lab. After patient has been positioned for genital examination, as many sites as possible should initially be evaluated using gross visualization.
- **Colposcopic** examination: Use labial separation and/or labial traction to visualize and photograph the following anatomic sites: **labia majora, posterior fourchette, labia minora, hymen, fossa navicularis, perineum, and peri-urethral** area. Inspect all aspects of the hymenal borders. Insert vaginal speculum; inspect

and photograph the **vagina** and **cervix**. Use the colposcope to visualize & photograph the perianal area, including the anal verge and anal folds. Insert an anoscope into the **anus** to inspect the **rectum**; collect rectal forensic swabs and make appropriate slides. For the male, the following sites should be evaluated: penis (glans, foreskin, shaft), urethra, scrotum, anus, and rectum. Adjuncts used to augment the examination should be documented. These include a 1% aqueous solution of **Toluidine Blue Dye** and balloon-covered swabs. Positive dye results show up as deep, linear staining in areas of denuded tissue. Both techniques should be done after collection of evidentiary samples.

The dye should not be applied to mucosal surfaces.

- **Specimen** packaging, storage, and chain of custody: Properly code and package all swabs, slides, and specimens. Employ measures to ensure that there is no cross-contamination of specimens.
- **Documentation** of the examination includes medical-legal forms, photodocumentation, narrative reports, summary of findings, and a discussion of the nature and pattern of genital findings. Documentation may require modification of existing medical-legal forms. Conventional terminology, i.e., blunt vs. sharp trauma, should be incorporated into the description of traumatic findings. It will be useful to develop a taxonomy, similar to that used by Crowley and Peterson (2001), to describe the nature and pattern of postmortem changes to the anogenital tissues at various postmortem intervals.

Suspect examination: a medical-legal examination of the suspect is suggested. Protocols for this will vary by jurisdiction. In addition to routine collection of reference and evidentiary samples, the Alternate Light Source is a useful adjunct. Barsley has described the use of the alternate light source with narrow-band illumination and reflective imaging (Crowley, Barsley, Peterson, Wood, AAFS, 2000). Photograph any identification marks, such as tattoos, moles, or birthmarks, which may appear in photos taken by the offender with the victim. Patterned injury may be the result of weapon use during the commission of the crime, or inflicted by the victim in self-defense.

Colposcopy, Postmortem Genital Exams, Sexual Homicide

G24 Validation of the Anthropology Research Facility in Knoxville, TN, as a Research and Training Site For Forensic Entomology

Adam Shahid, MS, University of Missouri, Columbia, Department of Entomology, 1-87 Agriculture Building, Columbia, MO; Kenneth G. Schoenly, PhD, California State University, Stanislaus, Department of Biological Sciences, Turlock, CA; Neal H. Haskell, PhD, Forensic Entomology Consultant, 425 Kannal Avenue, Rensselaer, IN; and Robert D. Hall, PhD, JD, University of Missouri, Columbia, Department of Entomology, 1-87 Agriculture Building, Columbia, MO*

The goal of this paper is to present to the forensic sciences community the latest findings on the scientific validity of the Anthropology Research Facility (University of Tennessee, Knoxville) as a research and training site for forensic entomology.

The on-campus Anthropology Research Facility (ARF) at the University of Tennessee, Knoxville, established by Professor William Bass in 1972, remains the only global site devoted to the study of human decomposition. The 20-year history of arthropod exposure to decomposing bodies at ARF led Tennessee v. Coe (1993) to speculate that this site is saturated with sarcosaprophagous arthropods thus rendering it biased and atypical. Here the authors report results of a comparative field test of the arthropod saturation hypothesis conducted during summer 1998 at ARF and three other sites at varying distances from ARF (S1): S2 (700 m away), S3 (6 km) and S4 (40 km). Three dead pigs

(*Sus scrofa* Linnaeus) of known weight were spaced 1.8-2.5 m apart at each of the four sites with two pigs placed on wire screens to record daily weight loss. Ground and flying arthropods were sampled from each pig using pitfall traps and sweep nets, respectively, once daily for up to 12 days. In excess of 81,000 invertebrates were collected and identified over the 12-day period representing 26 orders, 118 families, and 223 taxa. The fauna was reduced to 64,950 and 6,848 individuals after pitfall and sweep-net counts of forensically important taxa, respectively, were sorted, for a total carrion fauna of 71,758 individuals. On an experiment-wide level, pair wise tests showed carcass weight losses, surface temperatures, and maggot mass temperatures to be statistically comparable across days and sites in nearly every case. Likewise, matched abundance plots, accumulation curves, and ecostatistical tests each showed that the fauna at ARF is comparable to the other three sites with respect to colonization rates, aerial species richness, and ranked abundances of forensically important taxa. In the only exceptional case, pitfall catches were found to be statistically different in species richness (at the nominal 0.05 level) between Site 4 and the other three sites. Overall, these results support the conclusion that ARF is faunistically and statistically comparable to nearby field sites for conducting carrion ecology and forensic entomology field studies.

Forensic Anthropology Facility (ARF), Forensic Entomology, Decay Rates

G25 Extracting Human DNA From the Crops of Maggots That Have Been Collected During Different Stages of Development and Preserved Using Different Methods

Jason G. Linville, BS, Department of Biology, University of Alabama at Birmingham, 2909 Highland Avenue, S Apartment 207, Birmingham, AL; Jeffrey D. Wells, PhD, Department of Justice Sciences, University of Alabama at Birmingham, 901 15th Street South, Birmingham, AL*

Upon completion of this presentation, participants will understand the effect of the maggot preservation method on the ability to extract human DNA from the maggot's crop and will understand how the size of a maggot and its crop affect the strategy for human DNA extraction from the maggot.

The type of corpse a maggot has been feeding on can be identified through DNA analysis of the maggot crop contents. The crop is a food storage organ located at the anterior end of the alimentary canal. Maggot dissection, followed by extraction of only the crop, is favored since it leaves the maggot's exterior available for identification purposes. Recently, Wells *et al.* identified several situations when maggot crop analysis would be useful in a forensic investigation (*J Forensic Sci* 46(3):685-687). DNA analysis could help investigators identify a missing victim if maggots are discovered at a suspected crime scene in the absence of a corpse. Maggot crop analysis also could provide a forensic entomologist with another way to associate a maggot with a victim. When making a postmortem interval (PMI) estimation, it is assumed the maggot's entire development took place on the victim. DNA analysis of the crop could reveal that the maggot had moved onto the victim from a different nearby food source. Maggot crop analysis also could be used to resolve a chain of custody dispute in which the origin of maggot evidence is in question.

The method of maggot preservation may affect the investigator's ability to successfully extract vertebrate DNA from the maggot's crop. The storage temperature and type of preservation fluid can alter the stability of human or other vertebrate DNA within the maggot crop. Also, the type of preservation fluid can change the physical characteristics of the maggot, which may inhibit the investigator's ability to dissect the maggot and remove the crop intact.

Another factor the investigator should consider during analysis is the maggot's stage of development. The size of the maggot and its crop may

render different strategies for extracting vertebrate DNA from the maggot. Young maggots may be too small for dissection and crop removal. In older, post-feeding maggots, the maggot stops feeding and the crop contents are emptied into the remainder of the maggot gut. Alternative methods of analysis, such as extraction of the entire maggot, may provide better results for maggots that are too small for dissection, or for post-feeding maggots when the crop is no longer visible.

For the preservation study, maggots raised on human spleen were preserved using eight different preservation methods (70% ethanol, 95% ethanol, 4°C in 70% ethanol, 4°C, -70°C, room temperature, Kahle's solution and formaldehyde). Maggots were dissected after time periods of 2 weeks, 8 weeks and 6 months. Each maggot's crop was removed and extracted. Human DNA recovered from each crop was quantitated using Quantiblot® Human DNA Quantitation Kit (Applied Biosystems, Foster City, CA). Amplification of the human mitochondrial hypervariable regions (HVI, HVII) was attempted for all crop extractions. Amplification of STRs using Promega's (Madison, WI) Geneprint Powerplex 1.2 System was also attempted for all crop extractions. Successful HVI and HVII amplifications were sequenced using a PE-Biosystems (Foster City, CA) 310 genetic analyzer and BigDye Terminator® sequencing kit. Successful STR amplifications were analyzed using the 310 genetic analyzer.

Preliminary results suggest that the preservation method does affect the ease of dissection and the quantity of DNA recovered. For example, in maggots preserved in 95% ethanol at room temperature, the dehydrated crop became attached to other internal organs, often resulting in a broken crop during dissection. In maggots preserved in formaldehyde, although the crop was easily removed, quantitation results suggest a reduced amount of DNA had been extracted, in some cases preventing the amplification of HVI and HVII regions. Additional preservation results will be discussed.

For the development study, maggots raised on human spleen were removed and preserved at half-day intervals until the maggots began to pupate. The collected maggots were dissected and, if possible, the crops were removed and extracted. In maggots that were too small for crop removal, the entire maggot was extracted. In older, post-feeding maggots that no longer contained a visible crop, the intestines were extracted. DNA sequencing and STR analyses were performed as described above.

Preliminary results suggest that in maggots too small for dissection, extraction of the entire maggot did allow for the recovery of human DNA. However, in older, post-feeding maggots, extraction of the intestines did not result in the recovery of human DNA. Additional results will be discussed.

The results demonstrate that the chosen preservation method does have an effect on the ability to dissect a maggot and on the quantity of DNA extracted from the crop. Also, recovery of human DNA is possible in maggots that are too young for crop extraction, but is not likely in older post-feeding maggots with empty crops.

Forensic Entomology, Maggot Crop, Mitochondrial DNA

G26 Bioterrorism Response and Training: Building Upon Mass Disaster and Multiple Fatality Preparedness at the Office of the Chief Medical Examiner, Boston, MA

Richard J. Evans, MD, Office of the Chief Medical Examiner, 720 Albany Street, Boston, MA; Ann Marie Mires, PhD, Office of the Chief Medical Examiner, 7416 Falmouth Street, Boston, MA; and Alexander Chirchov, MD, PhD, Faryl Sandler, MD, and William M. Zane, MD, Office of the Chief Medical Examiner, 720 Albany Street, Boston, MA*

After attending this presentation the participant will understand how Massachusetts has sought to continue to build a multiple fatality plan with bioterrorism applications and will understand creative

solutions to administering anti-terrorism response modalities in level-funded state agencies.

In the aftermath of September 11, 2001, the Office of the Chief Medical Examiner (OCME) has a need to both augment its ability to respond to a mass casualty event involving nuclear, biological, and chemical agents; and to increase surveillance of deaths in Massachusetts for unusual infectious agents such as anthrax, smallpox, plague, and tularemia. Currently, the OCME must rely solely on the infrastructure and personnel of its headquarter office in Boston and personnel located at three minor satellite offices, resulting in insufficient resources to respond to a mass casualty disaster. This situation has been dramatically improved by the creation of partnerships with pathology departments of major academic medical centers in the Commonwealth, which have effectively served to "virtually" expand the infrastructure and personnel available for response and death surveillance.

The Office of the Chief Medical Examiner in Massachusetts has received level funding for a period of years. The forensic terrain over that time has become more complex and expensive. To provide current investigative techniques and analyses that contribute to case documentation and eventual courtroom presentation has taxed operational budgets. As a state agency, the OCME has access to and liaisons with other state agencies that provide analytical techniques and research resources. Through programs developed in response to complying with Mass Fatality Preparedness Initiatives, the office has established linkages with departments within the Executive Office of Public Safety, Public Health, the Boston Medical Hospital Community and the University System. The coalescence of state and public agencies has provided continued opportunity for state-supported grants and research partnerships. The OCME applied and received three phases of funding through the Executive Office of Public Safety, entitled the Edward Byrne Memorial State and Local Law Enforcement Assistance Formula Grant Program. The third phase is allowing the office to implement a virtual expansion of medical staff, through the greater Boston community by providing training in bioterrorism preparedness and surveillance.

In order to achieve these goals, it was necessary to create partnerships with several academic pathology departments in the greater Boston area. The purpose of these partnerships has been to provide training to personnel at each participating department in policies and procedures used in forensic death investigation and victim identification. Additionally, an early detection and surveillance system has been developed to recognize unusual infectious agents at autopsy, and to become familiar with procedures required in the processing of deaths due to chemical and nuclear agents. Training materials developed for this project will be made available for distribution.

Bioterrorism, Training, Virtual Staff Extension

G27 Computerization of the Autopsy Report "How to Build Your Own Desktop"

Coleen Crawford, MFA, and William M. Zane, MD, OCME
Commonwealth of Massachusetts, 720 Albany Street, Boston, MA*

Upon completion of this presentation, attendees will understand integration of the major components of the case file as well as how current software and computer technologies allow for a personalized desktop application that increases the productivity of the forensic pathologist and support staff.

Goals of Poster: The goals of the poster are to show the stages of development of a case file on the computer screen. The authors will create case specific folders and subfolders or nests of files and incorporate them into "Palettes." Those portions of a case file the pathologist reviews most often, i.e., the diagrams, dictated report and images are made available by clicking icons that represent specific documents, digital images or drawings. In this presentation the files and icons have

been chosen to meet the needs of a particular doctor. Other doctors may want different files immediately available and this presentation will show how he or she can create their own computerized case file.

Method: Flash, a *Macromedia* software program is first used to create an interface or form that will contain the palettes. Flash works with many types of media and allows the user to create his or her own case file, linked to a database of multiple file types.

First anatomy diagrams used in the autopsy room are scanned and then enhanced by using common drawing software such as *Adobe Illustrator*. The illustrations are then saved as JPEG, EPS, or PDF files in a folder. Icons of each diagram are created and organized within a palette. These diagrams or templates are now available for printing as a hard copy for use in the autopsy room or enhanced with additional icons symbolic of lesions.

The next step involves providing diagrams that show the sites of trauma for police and attorneys. A palette is designed with icons representing gunshot wound entrances, exits as well as abrasions, lacerations and sharp force injuries. Using simple drag and drop motions, the pathologist chooses an icon and places a small rendition of the lesion on a template, creating a simple and accurate diagram of the findings. These diagrams can then be printed as hard copy or attached to e-mail messages.

A third palette is created with dictation templates created in *Microsoft WORD* and saved in a folder. Icons of each template are inserted into a new palette. The appropriate template is opened and the autopsy report is dictated. A transcriptionist can then cut and paste the text into the office format.

Next a palette with icons representing digital images is added. Thumbnails of a particular case's digital images are called up from the physician's hard drive or office server. The optimum time to review the digital images is at the time of dictation and final sign out. Currently there is a tendency not to refer to the images as various browsers or steps are required to recall the files.

A file can contain any type of media, i.e., video, documents, images or recordings. Palettes for video and audio files will be used. This will enable the pathologist to record commentary while demonstrating a wound or create recorded notes about pending outstanding tests required to complete a report.

Conclusion: A personalized application has been created which reduces the steps to call up various files in the case folder. This application relies on readily available software for construction of an interface with links to many file types. Different software applications now share enough similarities in file management and language allowing for linkage. Some applications such as video rely heavily on memory as well as processor speed. Other advances in technology, i.e., cost reduction and software development have increased accessibility to the computer user. Here is an application that allows for a specific interface that is designed to suit a single pathologist.

G28 Using STR Analysis to Detect Human DNA From Exploded Pipe Bomb Devices

Kelly J. Esslinger, MS, 1805 Arbor Lane, #304, Crest Hill, IL; Jay A. Siegel, PhD, School of Criminal Justice, Michigan State University, 560 Baker Hall, East Lansing, MI; and Heather Spillane, BS, and Shawn Stallworth, Michigan State Police Crime Laboratory - Northville, 42145 West Seven Mile Road, Northville, MI*

The goal of this presentation is to inform the forensic community about this pilot study on the potential applicability of DNA testing on exploded pipe bomb devices.

Previous research has shown that DNA can be recovered from a variety of objects handled by the human hand, but it is unknown if DNA can withstand the effects of a low explosion. This study investigated

whether it was possible to recover a bomb assembler's DNA from an exploded pipe bomb device. It was hypothesized that the DNA from the sloughed skin cells may in some instances withstand the heat generated from the explosion. Two different surfaces, metal and PVC pipes were examined to determine if one surface type would have "more success" than the other due to heat conductivity properties.

Each of the ten participating subjects handled components (pipe, caps and fuse) of one metal and one PVC pipe bomb with a 10 second handling time per component, thus transferring sloughed skin cells onto the pipe bomb pieces. Using disposable gloves the Michigan State Police bomb squad assembled and deflagrated each pipe bomb in separate holes in the ground; each hole was covered with a large rock to contain the fragments. The fragments from each bomb were collected separately and swabbed using the double swab technique to recover any remaining skin cells. An AmpF/STR® Profiler Plus™ kit as well as an ABI 310 Genetic Analyzer® with Genescan® 2.0.2 and Genotyper® 2.1 software were utilized to generate DNA profiles from these swabbed bomb fragments.

The results indicated that enough human DNA from the "bomb manufacturer" could be recovered from exploded pipe bombs, both metal and PVC, to produce reportable genetic profiles. Overall, 1 of the 20 bombs rendered a full reportable DNA profile that matched the known DNA profile, and 3 others rendered partially reportable DNA profiles that also matched the known profiles. Additionally, there were 5 bomb samples with activity at some of the loci, although these did not meet the reportable standards followed by the Michigan State Police Crime Laboratory in Northville, Michigan.

There was no evidence to suggest one surface had more success with DNA recovery than the other; both surfaces were equally successful. The variable that appeared to have the greatest influence on the success of generating a DNA profile was the amount of fragmentation and recovery of the bomb device. The more intact the device after the explosion and the more pieces swabbed the better the results.

These findings are promising. However, problems such as allele dropout, heterozygote imbalance, elevated stutter, and contamination were observed with some samples due to low amounts of DNA and the extreme sensitivity of the method. Suggested improvements in the method could potentially double the success rate and eliminate some problems, which is exciting to consider and should be explored with future research. Recommendations for the collection of bomb fragments at a scene as well as guidelines for DNA tests on bomb fragments will also be displayed.

STR, DNA, Pipe Bombs

G29 An Atypical STR Genotype, Including a Three-Banded Allelic Pattern, From a Biopsy Tissue Sample

Sobia Malik, MSc, Centre of Forensic Sciences, 25 Grosvenor Street, 4th Floor, Toronto, Ontario, Canada*

The goal of this paper is to present to the forensic community an instance of a STR genotype that may have been misinterpreted as a mixture. The profile was confirmed by a comparison sample and included allelic peak height discordance and a discordant three-banded allelic pattern using the AmpFISTR ProfilerPlus™ system.

In support of a medical diagnosis carried out at a local hospital, the Centre of Forensic Sciences (CFS) was asked to identify the source of two biopsy samples due to a potential mix-up of samples using a third biopsy sample from a known individual. The results resolved the mix-up and in the process also identified, in a single source sample, allelic peak height discordance at amelogenin and vWA as well as a discordant three-banded allele pattern at D18S51.

Two paraffin blocks were submitted. The first contained two biopsies, one malignant and one benign, which raised suspicion that the two biopsies were from different individuals. The second block contained a malignant biopsy sample from a known source. The three biopsy samples were extracted using a xylene extraction technique followed by amplification of 1ng of DNA in the AmpFISTR Profiler Plus™ system. The paraffin block with the malignant and benign biopsies showed two different DNA profiles confirming that these biopsies were from different people.

One of these profiles showed peak height concordance of only 19% at amelogenin and 32% at vWA, as well as a 25% peak height concordance between two alleles as compared to the third allele in a three-banded allelic pattern at D18S51. Based on both internal and published validation studies, the presence of such anomalies is atypical when dealing with a sample known to have originated from a single individual. The fact that the anomalies are compounded is even more rare. CFS internal validation of the STR loci used in the AmpFISTR Profiler Plus™ system has shown that minimum peak height concordance observed at most STR loci where 1ng of single-source DNA has been amplified is 60%. Interpretation of this sample as an unknown or questioned sample would indicate a mixture. However, the comparison sample (of known origin) in the second block also showed peak height discordance at similar percentages at amelogenin, vWA and at the discordant three-banded allelic pattern at D18S51. The peak height discordance at amelogenin, vWA and discordant three-banded allelic pattern at D18S51 may indicate a chimeric genotype since the anomalies are seen at more than one locus and therefore occur at more than one chromosome. It is also possible that more than one genetic event may account for the observed profile.

This example emphasizes that caution should be taken when using tissue block samples as comparison samples in forensic casework. Information that a tissue sample is cancerous may not always be available. Therefore, when forensic DNA analysis involves tissues (a notable example is mass disaster identification), issues involving identification, interpretation and statistical significance regarding atypical profiles and three-banded allelic patterns may become increasingly important.

Biopsy, Three-Banded Pattern, STR

G30 DNA Databank Hits: Identification of the Perpetrator?

Sarah Johnston, MSc, Roger Frappier, MSc, and Jonathan Newman, BSc, Centre of Forensic Sciences, 25 Grosvenor Street, 4th Floor, Toronto, Ontario, Canada*

Participants attending this presentation will learn of a variety of case scenarios where a convicted offender hit provided investigative information that was not a direct link to the perpetrator of a crime. This will further demonstrate the utility of DNA data banks as an investigative tool.

As a result of the DNA Identification Act of 1998, the Canadian National DNA Data Bank (NDDB) became operational in June of 2000. The Data Bank consists of two indices. The Convicted Offender Index (COI) is the electronic index that has been developed from DNA profiles collected from offenders convicted of designated primary and secondary offences as defined in section 487.04 of the Criminal Code of Canada. The Crime Scene Index (CSI) is a separate electronic index comprising DNA profiles obtained from crime scene investigations of designated offences. COI profiles are generated centrally at the Data Bank lab facility, while CSI profiles are generated at the various forensic laboratories throughout Canada. The Centre of Forensic Sciences (CFS) provides Forensic Science services for Ontario, a province with a population of approximately 10 million people.

Over the first two years of operation of the NDDB, the CFS submitted 1,803 (31%) of the Crime Scene Index profiles to the Data Bank. Of the nearly 25,000 convicted offenders profiled, 53% were from the province of Ontario.

To complement the national legislation that established legal requirements for entering profiles onto the Data Bank using CODIS software, the CFS has developed a Standard Operating Procedure, which includes the criteria for a profile to be uploaded, the format and content of reporting statements, a process for communicating and dealing with the disposition (once followed up with investigators), and the criteria and procedures for deleting profiles from the NDDB. The potential dispositions include the following categories:

Offender hit: Indicating one or more forensic samples are linked to a convicted offender sample at SDIS. This provides investigators with the identity of a known offender and thereby provides an investigative lead that may ultimately link the crime scene DNA profile to the perpetrator. Alternatively the hit may provide investigative information that subsequently eliminates the crime scene profile as having originated from the perpetrator.

Conviction Match: Indicates that a DNA profile developed from crime scene evidence match a DNA profile from an offender, but the crime from which the evidence was collected has already been solved and linked with the offender. This match serves as a form of blind external testing as the offender should match the evidence for which s/he was convicted.

The DNA profiles eligible for upload to the CSI are subject to both legal and scientific restrictions. The DNA identification act outlines the legal criteria as follows. In order to enter a DNA profile into the data bank, a designated offence (e.g. murder, sexual assault, robbery, break and enter) must have occurred. There must also be a sample of a bodily substance from an "unsolved" crime that was found at a place, on or within the body of a victim, on anything worn or carried by the victim, or on or within the body of a person, thing or place associated with the commission of a designated offence. The scientific criteria were agreed upon by a working group of scientists from the three government laboratory systems in Canada (CFS, Royal Canadian Mounted Police Forensic Laboratories, and Laboratoire de sciences judiciaires et de médecine légale). The criteria were designed to limit the frequency of adventitious matches to the databank. In contrast to similar criteria from the U.S., for an unknown profile to be uploaded to the national CSI, a result for at least 7 Profiler Plus loci is necessary, in addition, a CSI sub index is used to capture profiles derived from mixtures. To be eligible for the forensic mixture index, a result at all 9 Profiler Plus loci is required with no more than three of the loci with up to five alleles entered.

Any DNA profile, generated during the scientific examination of items submitted in connection with an investigation, that cannot be attributed to the victim or a person who has been excluded as the perpetrator is automatically uploaded to the CSI.

Over the first two years of the Data Bank's operation CFS has been notified of 287 CSI to COI hits and 72 CSI to CSI hits. Of the crime scene to convicted offender hits, 62% have been conviction matches and 32% of the hits have been classified as offender hits. Of the 32% of investigations aided a number of the offenders have been ruled out as the perpetrator, however in these instances the identification of an offender as the source of a crime scene DNA profile has nonetheless aided the investigation. Some examples of this include:

Homicide investigation where a bloodstain on the victim hit to a convicted offender who ended up being a witness to the crime, who was ultimately able to aid in the identification of the true perpetrator.

Sexual assault investigation in which the first suspect was excluded as the source of semen recovered from complainant. The profile was entered onto the CSI and hit to an offender, the complainant was interviewed further and it was determined that the person identified by the hit was actually the boyfriend. This information allowed the police to account for the semen and to re-investigate the original suspect.

Investigation of an attempted murder in which a DNA profile from the tape wrapping around a pipe bomb hit to an offender. The offender was identified as the police officer who originally collected the pipe bomb for submission to the laboratory. Upon investigation, it was found that he had been convicted of a designated offence some time after his involvement in this case.

This presentation will outline other such cases in order to emphasize how important it is for the scientist to critically evaluate all samples being uploaded to a data bank and the need to keep an open mind when dealing with data bank hits. A hit to a convicted offender does not necessarily equal a hit to the perpetrator.

DNA Databank, Offender Hit, Conviction Match

G31 Everything Old is New Again: A Program to Examine "Cold" Sexual Assault Cases

Linda Parker, MSc, Jack Laird, MSc, Elida Kafarowski, MSc, Brian Peck, MSc, Suzanne Lima, MSc, and Jonathan Newman, BSc, Centre of Forensic Sciences, 25 Grosvenor Street, 4th floor, Toronto, Ontario, Canada*

The goal of this paper is to demonstrate the processes that can be employed in a dedicated program for the examination of sexual assault cold case. The poster will also present some of the challenges encountered and overcome in the cases submitted.

This poster will provide an overview of a purpose-built program recently established at the Centre of Forensic Sciences (CFS) to deal with the examination of cold sexual assault cases. Cold cases can be defined as cases where the police investigation has been scaled down and the case is effectively lying dormant. In addition, some interesting and challenging cases submitted as part of the program will be described to illustrate the types of samples encountered and the methods employed to extract information and contribute to the investigation of unsolved sexual assaults where investigative leads have been exhausted.

Recently, a joint initiative was undertaken by the Centre of Forensic Sciences (CFS) in partnership with the Toronto Police Service, an agency serving a large metropolitan area with a population of approximately 2.5 million. This initiative was undertaken to examine or re-examine unsolved sexual assault cases with the goal of uploading DNA profiles from perpetrators to the National DNA Databank (NDDB) of Canada. For the purposes of this project, the term 'unsolved' refers to any case for which a conviction has not been registered. Criteria for eligibility were established first and consisted of the following categories:

1. Cases for which a submission had never been made to the CFS previously;
2. Cases submitted to the laboratory but not previously examined due to the absence of a suspect (in accordance with CFS policy prior to 1997);
3. Cases in which material suitable for DNA analysis was detected, however DNA analysis had not been attempted as the identity of the perpetrator was not at issue;
4. Cases in which DNA analysis was attempted using RFLP technology but was not successful at the time (RFLP has been discontinued at CFS since 1995); and
5. Cases in which a DNA profile had been obtained but was not compatible with the requirements of the databank (i.e., profiles developed in the RFLP, DQA1, PM, or STR Quad systems).

The Centre of Forensic Sciences is a provincial government laboratory (Ministry of Public Safety and Security) that serves a population base of approximately 10 million people throughout the province of Ontario, and carries out forensic analyses free of charge for all police agencies in the province, as well as other clients. In consideration of an

already heavy caseload and a commitment to timely results, a key requirement was that the laboratory be able to regulate the number of items submitted in support of this project, while providing effective scientific consultation and expertise in the process. To this end cases were assigned to one of two stages for examination.

Stage 1 submissions were those that consisted strictly of a limited number of relevant swabs (in accordance with the case history) from the Sexual Assault Evidence Kit (SAEK). A user-friendly flowchart was developed at the CFS so that investigators could review their files and readily target only those swabs with a high probability of success, given the case history. The provision of this tool developed by forensic scientists allowed investigators¹, as opposed to forensic scientists, to carry out the task of identifying relevant items according to scientific expectations of success given the case history. Moreover, restricting stage 1 submissions to swabs only allowed the development of a streamlined screening protocol for the presence of semen, which in turn allowed for batch processing and turnaround times of 30 days or less. Any case that did not meet the criteria for a stage 1 submission, as well as any case determined to be negative following a stage 1 submission, was directed for consideration at stage 2.

Since stage 2 cases normally involved the examination of clothing or other scene items not as readily amenable to rapid processing as internal swabs, a senior scientist was made available to provide consultation as to which items in these cases, if any, would be suitable for examination based on the history. Once accepted, stage 2 cases were blended with normal operations.

The Biology Section of the CFS has successfully integrated the analysis of cold cases with ongoing workload with no disruption to work flow. This is the result of an effective partnership between the laboratory and the police service and a mutual, reciprocal respect of one another's capacity and constraints. Within the first few months of implementation, DNA evidence generated from submitted items led to investigative breakthroughs in four unsolved cases through a combination of crime scene to crime scene linkages as well as linkages to convicted offenders. Approximately 50% of cases submitted under the project (stage 1 and 2) have had a DNA profile from semen generated and uploaded to the National Databank.

Based on the success of the program to date, the CFS is in the process of establishing partnerships with other agencies in Ontario to provide a similar service, and is also reviewing its case and item acceptance policies to more effectively target minimum numbers of relevant and suitable items for examination, based on the case history provided and the hypotheses being tested.

1: It is important to note that the bulk of the administrative work in this project (e.g., review of case files, tracking of old evidence, etc.) was carried out by police investigators assigned to work full-time on the project.

Cold Cases, Sexual Assault, DNA Databank

G32 Bone Extraction Procedure for Nuclear DNA Analysis Used in World Trade Center Human Identification Project

Zoran M. Budimlija*, MD, PhD, Bianca Nazzarulo, MA, Sheila M. Estacio, BS, Mechthild K. Prinz, PhD, and Robert C. Shaler, PhD, Office of Chief Medical Examiner, Department of Forensic Biology, 520 First Avenue, New York, NY

The goal of this presentation is to demonstrate a highly effective method to extract and purify amplifiable nuclear DNA from severely compromised bone samples

The described extraction strategy was established for human bones recovered from the World Trade Center mass disaster site after September 11, 2001. Morphologically, the samples were in different

states of preservation - ranging from very good with preserved bone marrow, to semi-burned, and completely burned. The heat and friction forces at the disaster site had reduced many of the bones to small, severely damaged pieces. Each sample was individually assessed visually as to the amount of the bone tissue to be taken for the extraction procedure.

Osteocytes (mature bone cells), with their central, nuclear containing region are completely surrounded by the bone matrix. The bone matrix is permeated by an extensive and complex system of lacunae (cavities occupied by the cell bodies of osteocytes) and canaliculi (narrow channels that radiate from the lacunae). The predominant organic component is collagen, while the inorganic matrix is calcium phosphate in the form of hydroxyapatite, which accounts for about 75% of the bone mass. The philosophy of this protocol is to use as much bone tissue as needed, as determined by the quality of the sample, to obtain a sufficient amount of DNA, by "untrapping" the DNA containing osteocytes from compact and spongy bone matrix.

In order to minimize contamination with any external DNA each bone specimen was cleaned vigorously using a series of disposable scalpels and brushes. After sonication in a 5% Terg-a-zyme solution, the outer surface was sanded down (using a Dremel tool equipped with a disposable emery disk), until the outer surface was completely free of dirt and debris. This step was followed by an additional Terg-a-zyme and H₂O wash step; then the bone specimen was cut into approximately 0.5x0.5x0.5 cm pieces, frozen in liquid nitrogen, and ground in a MicroMill Grinder (Scienceware, Bel-Art Products, Pequannock, NJ) into a dust. The mill was cleaned vigorously after each sample.

Depending on the condition of the bone sample, the bone dust was divided into 50 ml conical tubes (2 g of bone dust per tube). 4g for good specimen, 6g, 8g, and 10g for more compromised samples. Each dust aliquot was incubated in 3 ml of organic incubation buffer (shaken at 56°C, overnight). The DNA was extracted using Phenol-chloroform-isoamylalcohol (24:24:1) in 1.5mL Phase Lock Gel tubes (Eppendorf, Hamburg, Germany) and Microcon 100 microconcentrators (Amicon, Inc., Beverly, MA). The extracts were further subdivided into smaller aliquots. As the final step all aliquots were recombined and concentrated further using Microcon 100 vials. Samples were quantified using QuantiBlot (ABI, Foster City, CA), and amplified with the PowerPlex 16 (Promega, Madison, WI) multiplex. The resulting DNA profiles were analyzed and interpreted following the standard procedure established for the WTC Human Identification Project.

Usable STR profiles with a sufficient number of loci were obtained in ~ 75% of cases. Approximately 50% of all analyzed cases even had more than 13 loci typed. The procedure has been successful for nuclear DNA based identifications even if the bones were in an extremely poor condition. The approach of dividing samples into smaller aliquots and then recombining the extracts later allows for the processing of a large amount of bone matrix. This also allows the use of the Eppendorf Phase Lock Gel technology while avoiding clogged Microcon membranes.

Nuclear DNA, Bones, Mass Disaster

G33 Digestion Time of Human Mitochondrial DNA in Blowfly Larvae, *Calliphora vicina*

Paula M. Do*, California State University, Bakersfield 2001 Stockdale Highway, Bakersfield, CA

The goals of this presentation are to determine the digestion time of human mitochondrial DNA after blowfly larvae have ceased feeding on human tissue.

This poster will display results obtained from a study measuring the digestion time of human mitochondria DNA in Blowfly larvae. The amount of time the blowfly larvae have been feeding on the human tissue will be measured over a 3-day period. Forensic entomologists

have developed a new technique that can be used to identify a corpse. This technique involves analysis of blood recovered from the digestive tract of an arthropod, which can help identify an individual host. From the blood extracted human mitochondrial DNA is recovered. Previous studies have shown that even if physical contact between the larvae and human corpse is not observed mtDNA analysis may be able to connect larvae with the corpse.

Blowfly larvae, *Calliphora vicina*, will be starved for one day before feeding on human tissue to remove previously eaten food from the larvae's digestive tract. Larvae will be placed in appropriate containers with human tissue. Three groups composed of three replicates each will feed on human tissue for varying amounts of time, 24-hours, 48-hours, and 72-hours respectively. Larvae will be placed in an incubator set at 36°C in the dark. This will help to mimic the environment of a human carcass. After being removed from the human tissue, a period of time will pass before each replicate of a group is preserved. The 3 replicates from each group will be immediately preserved, preserved after 36-hours, or preserved after 56-hour. The larvae will be preserved in 70% ethanol and stored at -20°C. An additional trial will be performed. Adhering to the protocols of the QIAamp DNA Blood Mini Kit from Qiagen, the Blowfly larvae will be analyzed to determine if human mtDNA is present in their digestive tracts.

These results will provide more adequate information for forensic investigators when determining the length of time human mtDNA remains in the larvae's digestive tract. The results of this study hold promise in enhancing the utilization of arthropods in forensic investigations, especially in the area of homicide.

Human Mitochondrial DNA, Blowfly Larvae, Digestion Time

G34 Postmortem Interval (PMI) Determined by Analyzing Temperature Variations of Maggot Masses

Sonja L. Peters, BS*, 5333 Southwest 75th Street, Apt. S-105, Gainesville, FL; Jerry F. Butler, PhD, Department of Entomology & Nematology, University of Florida, P.O. Box 110620, Gainesville, FL; Jerome A. Hogsette, PhD, USDA-ARS, CMAVE, P.O. Box 14565, Gainesville, FL; Anthony B. Falsetti, PhD, Anthropology Department, C.A. Pound Human Identification Laboratory, P.O. Box 117305, Gainesville, FL; and Roxanne Rutledge, PhD, Florida Medical Entomology Laboratory, 200 9th Street, SE, Vero Beach, FL

The goal of this presentation is to measure temperature variations within maggot masses and compare these with published temperature studies of dipteran developmental cycles conducted in labs for forensic growth rate base lines.

Hypothesis: the *in vivo* maggot mass temperature will result in increased growth rate of the larvae when compared to laboratory studies on developmental cycles.

A black bear carcass approved for research by the Florida Fish and Wildlife Conservation Commission Wildlife Research Laboratory in Gainesville, FL was placed into a remote, semi-wooded location within their grounds. The bear was struck by a car and the carcass arrived in early June 2002. Within five hours of the carcass being exposed to the environment a HOBOä external logger was placed at the carcass site and set to record wet bulb temperature, air temperature, and temperature of the soil beneath the bear carcass, and in the center of the largest maggot mass present at the time. Temperature was recorded continuous @ 10 minute intervals for ca. 1.5 months. Adult insects and developing larvae were collected about 6 PM until carcass decomposition was complete. The adult beetles and flies were killed using an ethyl acetate kill jar. Fly larvae were initially placed into empty vials, and then taken back to the lab to be boiled briefly for preservation purposes and then placed into 70% ethyl alcohol. Pictures of the various insects and the growing maggot masses were taken every other day, along with shots of the dif-

ferent decomposition stages the carcass went through. These photos were made with a 35mm camera with macro close up attachments. A separate 35mm camera with an infrared filter was used to take IR shots of the maggot mass for observation of the heat spots. Sketches of the maggot mass locations and decomposition stages were taken daily for visual reference.

Results showed varying temperatures in the maggot mass corresponding with the ever-changing Florida summer weather. The greatest temperature was recorded at maggot mass locations with the greatest number of larvae. When the weather was overcast or immediately following rain the mass temperature was much lower than on days with clear skies and no rain. The larvae were observed moving in and out of the center of the mass in a routine motion as if they are were making a circle in to the mass and back out again. The highest temperatures were taken in the center of the mass with temperatures decreasing exponentially farther away from the center. The larvae composing the first maggot masses were first instars on June 5 and began to migrate away from the carcass on June 13. Several of these larvae were taken in to the lab to be raised during the pupal stage at a set temperature of 26°C; pupation occurred by June 15 and adults emerged on June 20. The remaining larvae left in the field on the carcass developed similarly. The maggot masses began appearing at the orifices within the first four days that the carcass was exposed to the environment. From there they moved around the perimeter of the carcass encasing all of the extremities, the head and the anus region. The masses then moved in towards the center of the carcass as decomposition progressed with the last masses being observed around the exposed vertebral column. The maggot mass was composed primarily of *Chrysomya rufifacies* (Macquart) (Diptera: Calliphoridae) larvae throughout the duration with a few other species intermixed throughout.

Conclusion: Whether the hypothesis was verified has yet to be determined because data are still being analyzed. Species found in and on the carcass are summarized in the poster tables. Variations in species may have increased if insect collections were made at a different time of year and day. The insect faunal succession change with decomposition levels as related to time of day and this could lead to a variety of temperatures and developmental rates. The maggot ball temperature varied with environmental temperature. The maggot ball consisted of the hairy blow fly, *C. rufifacies*. The maggots in the maggot ball moved in and out of the high temperature center of the maggot ball.

Maggot Mass, *Chrysomya rufifacies*, Developmental Cycle

G35 A Summer Carrion Study in the North of Italy

Mirella Gherardi, MD*, Gabriella Costantini, and Marina Caligara, Institute of Legal Medicine - University of Milan, Via Mangiagalli, 37, Milan, Italy; Giancarlo Belluzzi, Veterinary Service, ASL, via Ghinaglia, 6, Cremona, Italy; and Massimo Boldini, Experimental Zooprophylactic Institute, Cremona, Italy

After attending this presentation, participants will more fully understand variables affecting postmortem changes to carrion exposed outdoors during summer. The presentation will show how weather conditions, combined with effects of extensive predation, may result in incorrect assumption of an extended PMI.

Forensic pathologists are often called upon to establish the time since death in badly decomposed bodies. Physical, chemical and biological changes start immediately after death and their development rate varies according both to external factors (temperature, humidity, and sunlight, insects) and internal factors (body characteristics).

Entomological analyses for the estimation of the postmortem interval are primarily based on the fly life cycle. Flies are rapidly attracted to the body were each female can oviposit hundreds of eggs. Within a few hours, depending on species and ambient temperature, eggs will hatch and a large

number of larvae begin actively feeding on the body. In this stage, predators such as beetles, ants, or wasps are able to remove a large amount of fly larvae resulting in a slower rate of decomposition. Conversely, later foraging activity by predators while larvae are migrating from the carriion during the post-feeding stage may result in few larvae reaching the pupal stage. This interaction between insects colonizing remains may lead to an incorrect assessment of the level of Diptera activity on the decomposition rate and suggest a longer PMI.

Data concerning this problem were obtained by research conducted on exposed carriion in the North of Italy.

One pig carcass, *Sus scrofa* L., was exposed in a rural, grassy field. The animal, weighed 32 kg, was exposed in a wire mesh cage in direct sunlight. Hourly internal temperatures were recorded by two probes inserted into the mouth and anus. Additional information such as ambient air temperature, humidity, rainfall, wind, maggot mass temperature, soil and body surface temperature were also recorded.

At least two daily samplings were performed during the first ten days. During each sampling pictures of both morphological changes and insect activity on the carcass were taken and, entomological specimens were collected for species determinations and microbiological analyses.

The observations demonstrated that a large number of green bottle flies arrived immediately after the carcass was exposed, exploring head area. Insect colonization started from primary sites of oviposition (nose and mouth). Eggs were observed less than 2 hours after exposure. Hatching was observed 20 hours later. Few Sarcophagidae occurred on the carcass on day 2 and their larvae were noted in a small area on the head.

After 24 hours, large masses of eggs were observed on the pig skin at the interface with the soil, all around the carcass. The high ambient temperature caused the death of a large number of eggs on the dorsal surface.

Highest maggot activity was recorded at 72 hours when maggots completely covered the carcass. Stressed by both increasing temperature and ventilation, fully developed 3rd instar larvae start their migration at the end of day 4, leaving a nearly completely skeletonized carcass. Ambient conditions also affected the decomposition of the small amount of tissues spared by the feeding activity of larvae. The skin covering a small area of the abdomen was dehydrated, hardened and took on a dark brown color, usually observed in cadavers exposed for a long time after death.

Coleoptera (Staphylinidae, Dermestidae) were observed all around the carcass beginning on the afternoon of day 4; other species of Coleoptera (*Necrobia*) started their activity on the carcass after day 5, reaching the maximum at day 8 (*Necrobia*) and day 10 for Dermestidae.

Coleoptera were very abundant and their presence may explain the small number of pupae found in the ground all around the cage.

In order to clarify all variables affecting insect activity on the carcass, insects were tested for bacterial and chemical contamination by both microbiological and toxicological analyses. Results of this research are still in progress.

Forensic Entomology, Decomposition, Postmortem Interval

G36 Of Leaves and Men: Botanical Evidence Leads Investigators to a Missing Girl's Body

Rebecca A. Bullard, MS*, Department of Entomology, University of California, Davis, Department of Entomology, University of California at Davis, Davis, CA; and Kristina A. Schierenbeck, PhD, Department of Biological Sciences, California State University, Chico, Department of Biological Sciences, California State University at Chico, Chico, CA

The goal of this presentation is to demonstrate the importance of botanical evidence in the location and recovery of human remains.

On 29 May 2002, a sheriff's deputy in Butte County, CA, responded to a report of an apparent suicide victim in a pickup truck parked alongside a mountain road. Inspection of the vehicle revealed a 35-year-old male decedent with a single self-inflicted gunshot wound to the head. A significant amount of blood spatter and pooling on the passenger seat indicated to the investigators that a second victim might be involved, although a thorough search of the area surrounding the vehicle revealed no additional evidence.

Identification of the male decedent quickly led deputies to a missing persons report that was filed in Los Angeles County 2 days prior to discovery of the body. The decedent had reportedly picked up his 11-year-old daughter from school on 20 May 2002, with a probable destination of Lake Havasu, Arizona. When the daughter did not return home after the trip, her mother reported her missing.

Detailed examination of the decedent's pickup truck produced several pieces of evidence, including a receipt from a Las Vegas hotel and a bloodstained girl's jacket with a significant amount of plant debris inside one of the sleeves. Investigators conjectured that the girl was likely deceased or seriously injured; however, they were somewhat daunted by the size of the search area. Based on witness accounts and evidence collected from the truck, the girl could be in Arizona, Nevada, or California.

In an effort to narrow the search area, investigators took the plant material recovered from inside the girl's jacket to California State University, Chico, for examination by a botanist. Analysis of the sample, which ranged in composition from whole to partially decomposed leaves, revealed that it had been taken from the top few centimeters of leaf litter. The species present (in order of abundance) were canyon live oak (*Quercus chrysolepis*) or interior live oak (*Q. wisileneii* var. *wisileneii*), white fir (*Abies concolor*), greenleaf manzanita (*Arctostaphylos patula*), ponderosa pine (*Pinus ponderosa*), and black oak (*Quercus kelloggii*). Additionally, the sample also contained a whole leaf of greenleaf manzanita torn from a living shrub.

Possible sites were eliminated based on known species distributions and ecological site requirements. The species identified do not occur together in Arizona, Nevada, or the eastern Sierra Nevada. The live oak, in particular, indicated that the sample was most likely from the western exposure of the Sierra Nevada. Overlapping species distributions indicated that the sample was removed from an elevation of 762 to 1,372 m. The relative abundance of the species present was a bit unusual in that the dominants were live oak and white fir, indicating that the site had to have both slightly mesic (white fir) and slightly xeric (live oak) characteristics. It was unlikely that the site was a north- or east-facing slope due to the presence of the live oak, and a south-facing slope was equally unlikely based on the presence of the white fir. The sample must have been from a west-facing slope with some available moisture. Further, the composition and dark color of the leaf litter sample indicated a high organic content, which placed the site under a fairly dense forest canopy. The notable occurrence of the greenleaf manzanita indicated that there must be some available light at the site, despite the dense canopy.

A survey of possible sites within northern California that satisfied the botanical criteria led to the discovery of the girl's body in less than two hours. Surprisingly, she was found only 0.3 km from her father's truck, an area that had been searched thoroughly following discovery of his body 8 days earlier. The girl was wrapped in a blanket and partially buried under tree limbs and litter. The site proved to be a 30 percent west-facing slope with a close canopy of coniferous vegetation, where canyon live oak and white fir were the dominant species, and was located at an elevation of approximately 1160 m. The body was in close proximity to a small patch of exposed chaparral with greenleaf manzanita as the dominant species.

This case is an illustration of the potential significance of Forensic Botany in crime scene investigation. Botanical evidence is often overlooked or underutilized by investigators, but it has the potential to provide critical and detailed information about the circumstances surrounding death, or in this case, the actual location of the remains.

Forensic Botany, Missing Persons, Scene Investigation

G37 A Study of Three Suicidal Hangings in Jail Using Telephone Cords

Reade A. Quinton, MD*, University of Texas Southwestern Medical Center Department of Pathology, 5323 Harry Hines Boulevard, Dallas, TX; David Dolinak, MD, Dallas County Medical Examiner, 5230 Medical Center Drive, Dallas, TX

The goal of this presentation is to present three cases of hanging suicides that occurred in custody, and the specific changes that were made to address the problem.

In a three month period of 2000, three suicide hanging deaths with telephone cords occurred in North Texas jails and were autopsied at the Southwestern Institute of Forensic Sciences in Dallas. The first incident was a 36 year-old woman who was arrested for outstanding traffic warrants. She had a history of depression, drug abuse, and prior arrests. On the day of her death, the decedent was discovered in a kneeling position by the pay telephone in the cell she occupied, hanging from the metal spiral telephone cord looped around her neck. She was the only occupant of the cell, which was under video surveillance. The telephone cord measured 15 and 3/4 inches in length.

The second case occurred ten days later in a different jail in an outlying county. A 24 year-old man had been arrested for a number of charges including assaulting a public servant. Because he was already on probation, these charges would mean his immediate return to prison. The decedent was found hanging from the metal phone cord attached to the pay phone in his holding cell. He was the sole occupant of the cell, which was not monitored by electronic surveillance. Investigation revealed that the man had phoned his wife to tell her he was going to commit suicide prior to the act. The telephone cord measured 19 inches in length.

One month later, a third incident occurred in another jail. A 29 year-old man had been arrested for disorderly conduct. At the time of arrest the man was under the influence of alcohol, but no other drug use was reported. He was the sole occupant of a holding cell that contained a mounted video camera. The camera was filming, but was not constantly monitored. A telephone was mounted on the wall just inside of the cell. A review of the video tape showed the decedent hanging himself with the telephone cord ten minutes after entering the cell; he was discovered approximately two hours later. According to his family, he had made two prior suicide attempts.

Autopsies were performed in each of these cases and showed typical ligature furrows without evidence of other trauma or neck injury. Blood toxicology studies were positive for methamphetamine, methadone, fluoxetine, and diazepam in the first case, a blood alcohol level of 0.12% in the second, and a blood alcohol level of 0.18% in the third.

Because of these types of incidents, solutions such as providing shortened receiver cords have been suggested. A cord-free inmate phone that has a recessed, cordless handle is also available. These phones can function similarly to a speaker-phone, but with the privacy of a telephone. Following the incidents described above, a proposal was made to the Texas Commission on Jail Standards (TCJS) to standardize the types of telephones used in detox and holding cells. The proposal did not pass at that time, and there are currently no plans to make changes on a state-wide level. The current Texas Administrative Code for the TCJS addresses inmate rights concerning telephone calls and the accessibility of telephones, but does not define a specific type of telephone to be made available. There are also no rules written regarding the placement of telephones within or around holding cells. It is currently up to the individual jails to decide what type of phones to provide and where to mount them.

The three jails above each responded to these incidents by changing their telephones. Two of the jails shortened their receiver cords to a total length of 6-8 inches. The telephones are otherwise unaltered, and are still in the same locations. The third jail replaced their entire phone with a cordless telephone. These three incidents highlight the need to provide telephones that, if placed within holding cells or other jail cells, do not provide a possible means of suicide.

Hanging, Suicide, Custody

* Presenting Author

G38 Diabetic Ketoacidosis—A Silent Death

Zabiullah Ali, MD*, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD; Mary G. Ripple, MD, 68 Bluebird Road, Port Deposit, MD; and Barry S. Levine, PhD, and David R. Fowler, MD, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD

The goal of this presentation is to determine the percentage of cases investigated by the Office of the Chief Medical Examiner (OCME) with a known history of diabetes versus de novo detection of diabetes

Diabetic ketoacidosis may be the initial manifestation of type I diabetes or may result from increased insulin requirement in type I diabetic patients during the course of infection, trauma, myocardial infarction, or surgery. It is a life-threatening medical emergency with mortality rate just under 5% (1). Type II diabetic patients may develop ketoacidosis under severe stress such as sepsis or trauma.

Cases investigated by OCME over a 6-year period whose cause of death was diabetic ketoacidosis were identified. For each case, the initial investigation and follow-up investigation report were reviewed to determine whether a history of diabetes was included. In all cases investigated by OCME, a specimen, usually blood is analyzed routinely for volatile substances, including methanol, ethanol, acetone, and isopropanol by Gas chromatography at a limit of quantitation of 0.01 g/dL

A postmortem diagnosis of diabetic ketoacidosis is based on either some or all of the following: a history of diabetes, increased vitreous humor glucose, or increased blood acetone. From January 1996 to December 2001, 20,406 autopsies were performed, with 34.49% (n=7039) natural deaths. The total number of deaths secondary to diabetic ketoacidosis was 1.43% (n=101), with 85.1% (n=86) of them available for review. A total of 35.2% (n=31) of the decedents did not have a previous diagnosis of diabetes and were diagnosed for the first time at autopsy. The age of the deceased ranged from 10 years to 70 years with a male to female ratio of 62:24. The race was not significantly different with African American to Caucasian ratio of 46:40. In this study, a total of 57 cases (66.2%) were diagnosed based on vitreous acetone and/or vitreous glucose, and/or blood acetone. In 18 cases (20.9%), vitreous and blood acetone were used for diagnosis. The urine and blood acetone were used instead of vitreous acetone in 6 cases (6.8%) with or without vitreous glucose. The other cases were diagnosed either based on vitreous acetone alone (2 cases; 2.3%), blood acetone and vitreous glucose (1 case; 1.16%), decomposition fluid (1 case; 1.16%), and vitreous acetone and glucose (1 case; 2.1%). The variability of specimens tested depended on the availability of test material. There were 4 (4.6%) decomposed cases, in which urine and blood acetone were used in 2 cases, liver acetone in 1 case, and decomposition fluid and blood acetone in 1 case. The blood acetone level ranged from 0.01 g/dL to 0.117 g/dL (mean=0.035 g/dL). The vitreous acetone range was from 0.014 g/dL to 0.97 g/dL (mean=0.05g/dL). The level of the vitreous glucose ranged from 89 mg/dL to 1233 mg/dL (mean=597 mg/dL).

A positive acetone can indicate diabetic ketoacidosis, isopropanol ingestion, or malnutrition. Acetone, a ketone body, is produced in the liver from spontaneous decarboxylation of acetoacetate, which is produced as a result of incomplete breakdown of fatty acids. Once acetone has been detected, the Medical Examiner routinely requests a vitreous glucose concentration. An elevated vitreous glucose with an elevated vitreous acetone indicates diabetic ketoacidosis. It is recommended that the volatile toxicology analysis at a Medical Examiner's Office should not only include ethanol, but also acetone to screen for the diabetic ketoacidosis in cases of sudden deaths.

Diabetes Mellitus, Ketoacidosis, Acetone

G39 Investigation of Time Interval For Recovery of Semen and Spermatozoa From Female Internal Genitalia

Tracey S. Corey, Office of the Chief Medical Examiner, Department of Pathology and Laboratory Medicine, University of Louisville School of Medicine; Angela R. Wetherton, MD*, Department of Pathology and Laboratory Medicine, University of Louisville School of Medicine; Pamela J. Froncek, RN, Office of the Chief Medical Examiner; and Dawn Katz, BS, Kentucky State Police Forensic Science Laboratory, Louisville KY

The goal of this presentation is to investigate time intervals associated with recovery of spermatozoa from various sites of the lower genital tract in adult females thus providing new data regarding the best anatomic site from which to collect evidence in victims of sexual assault.

In cases of rape-homicide, the biological evidence obtained from the body of the victim may be the only link between the victim and the suspect. This biological evidence, in the form of semen and spermatozoa, can provide proof of sexual contact and a genetic profile of the assailant. There is limited data regarding the actual recovery of spermatozoa from various areas of the genital tract. The limited anecdotal case reports available indicate that the cervical os may be the best site for recovery. However, there have not been any prospective studies to evaluate site-specific recovery times, and most standardized kits recommend vaginal pool collection only. Because of the importance of recovering spermatozoa from the female internal genitalia in criminal investigations, the authors undertook the current study to further elucidate the best anatomic site from which to collect evidence in victims of sexual assault.

The study, including the protocol and consent form, was approved by the IRB and the University Human Studies Committee at the University of Louisville. The study population consisted of patients who presented to Planned Parenthood for routine annual examination in Louisville Kentucky from May 1999 through October 2000. Prior to examination by a nurse practitioner at Planned Parenthood, the patient was asked if she would like to participate in the research study. Once consent was obtained, each participant was assigned a number to ensure confidentiality. The participant was asked a series of questions including age, method of birth control, date and time of last sexual intercourse, and history of instrumentation (i.e. douche).

Prior to routine examination and following insertion of the speculum, a nurse investigator from the Office of the Chief Medical Examiner (OCME) used cotton tip applicators to obtain separate specimens from the cervical os and the vaginal pool. Separate smear slides were made from the swabs of the cervical os and the vaginal pool. These were air dried and packaged in containers with the subject's identification number. The air dried cervical os and vaginal swabs were then placed in separate paper envelopes and labeled with the contents and the identification number.

The specimens were transported to the Kentucky State Police Forensic Science Laboratory in Louisville Kentucky for examination by a forensic serologist. The presumptive presence of semen on a portion of each cotton tip applicator was determined by testing for seminal fluid acid phosphatase activity via thymolphthalein monophosphate. An extraction procedure was performed on the cotton tip applicators. The extracted material was placed on a slide, stained with hematoxylin and eosin, and examined microscopically for the presence of spermatozoa. The slides prepared at the time of the examination at Planned Parenthood were also stained with hematoxylin and eosin and examined microscopically for the presence of spermatozoa.

Sixty-one patients participated in this study. Semen was presumptively present on the cervical os cotton tip applicators in 33 of 61 cases. In 1 of those 33 cases, semen was presumptively present only on the cervical os cotton tip applicators. The postcoital time interval in that

case was 9.5 hours. The extracted material from the cervical os cotton tip applicators demonstrated spermatozoa microscopically in 17 of 61 cases. In 6 of those 17 cases, spermatozoa were demonstrated microscopically in the material extracted only from the cervical os cotton tip applicators. The postcoital time interval in those cases ranged from 9.5 to 75.5 hours with an average interval of 47.9 hours.

Semen was presumptively present on the vaginal pool cotton tip applicators in 39 of 61 cases. In 7 of those 39 cases, semen was presumptively present only on the vaginal pool cotton tip applicators. The postcoital time interval in those cases ranged from 14 to 95.25 hours with an average interval of 53.6 hours. The extracted material from the vaginal pool cotton tip applicators demonstrated spermatozoa microscopically in 17 of 61 cases. In 6 of those 17 cases, spermatozoa were demonstrated microscopically in the material extracted only from the vaginal pool cotton tip applicators. The postcoital time interval in those cases ranged from 4.5 to 58.25 hours with an average interval of 24.9 hours.

Spermatozoa were observed microscopically in cervical os smears prepared at the time of the examination at Planned Parenthood in 25 of 61 cases. In 5 of those 25 cases, spermatozoa were observed microscopically only in the cervical os smears. The postcoital time interval in those cases ranged from 37.5 to 82 hours with an average interval of 59.7 hours. Spermatozoa were observed microscopically in vaginal pool smears prepared at the time of the examination at Planned Parenthood in 24 of 61 cases. In 4 of those 24 cases, spermatozoa were observed only in the vaginal pool smears. The postcoital time interval in those cases ranged from 17 to 95.25 hours with an average interval of 46.6 hours.

Thus, in summary, there were 2 cases from the cervical os site and 5 cases from the vaginal pool that would have been missed, had the other collection site not been included. The total number of cases from which only one site was positive was 7 of 61, or 11.4 per cent.

The information gained from this study suggests that biological samples should be collected from both the cervical os and the vaginal pool in victims of sexual assault. It also suggests that, on average, spermatozoa may be recovered from the cervical os after longer postcoital time intervals than from the vaginal pool.

Semen, Spermatozoa, Female Internal Genitalia

G40 The Role of Hyponatremia in Fresh Water Drowning and Water Intoxication: Making the Distinction at Autopsy

Kenneth S. Snell, MD* Medical Examiner, Mecklenburg County Medical Examiner's Office, Charlotte, NC; Keith C. Kocis, MD, MS, Associate Professor of Pediatrics, Department of Pediatrics, University of North Carolina at Chapel Hill, Chapel Hill, NC; and Deborah L. Radisch, MD, MPH, Associate State Medical Examiner, Office of the Chief Medical Examiner, Chapel Hill, NC

The goals of this presentation are to educate the forensic community to the role of hyponatremia in both drowning and water intoxication.

Drowning is defined as death following an episode of submersion. Water intoxication is defined as the intake of a sufficient quantity of fluid to cause symptomatic hyponatremia. The role of hyponatremia in both conditions will be reviewed. The case of a 4-year-old boy that drowned and his twin brother that survived the incident will be presented. At initial exam, both boys were unresponsive and documented to have hyponatremia; however, no seizure activity or cerebral edema was documented. The theory of acute water intoxication has been proposed as an alternative explanation for the events surrounding the incident.

Numerous studies have evaluated the role of serum electrolytes in the mechanism of death in drowning deaths. Serum sodium levels

routinely remain above 126 mEq/L; however, approximately 12% of the cases will have serum sodium levels below 120 mEq/L. The hyponatremia is a consequence of absorption of aspirated hypotonic fluid, which has been calculated to be less than 22 ml/kg in 85% of drowning deaths. The hyponatremia associated with fluid aspiration resolves without medical intervention and is not considered a life-threatening anomaly. Therefore, hyponatremia is not associated with the mechanism of death in drowning.

Acute water intoxication occurs over a short period during which the individual consumes sufficient quantities of low sodium-containing fluids to cause symptomatic hyponatremia. The hyponatremia does not spontaneously resolve and results in prolonged seizure activity secondary to cerebral edema. In three cases that resulted in death, children from 6 to 16 years old were forced to consume between 3 and 6 liters of water at one time as punishment. The volumes retained averaged 41 ml/kg/hour and the serum sodium ranged from 109 to 114 mEq/L. All three children developed seizures, and cerebral edema was noted at autopsy. The literature has numerous reports of infants less than 1-year-old that developed acute water intoxication during swimming lessons. Serum sodium levels ranged from 111 to 123 mEq/L and seizure activity was documented in all cases. All of these infants recovered with medical therapy aimed at treating the hyponatremia. A single case of acute water intoxication occurring in a 12-year-old boy lodged in a drainpipe of a swimming pool has been documented. After a complete recovery from a serum sodium level of 111 mEq/L, the boy recalled swallowing large quantities of water.

In conclusion, fresh water drowning is not routinely associated with hyponatremia, but a small percentage of cases do have documented hyponatremia. Acute water intoxication is associated with symptomatic hyponatremia and requires diagnosis-directed therapy. Most of these cases have been documented in infants undergoing swimming lessons or in child abuse cases.

Hyponatremia, Drowning, Acute Water Intoxication

G41 An Unusual Cause of Sudden Death in Infancy: Hypertrophic Cardiomegaly

Marie E. Cannon, MD, Office of the Chief Medical Examiner, 720 Albany Street, Boston, MA; Eva Patalas, MD, Massachusetts General Hospital, 55 Fruit Street, Boston, MA; and Alexander Chirkov, MD, PhD, Office of the Chief Medical Examiner, 720 Albany Street, Boston, MA*

Hypertrophic cardiomegaly in infancy may cause sudden death in infancy. This presentation discusses the clinicopathologic features, describes the gross and microscopic features, and addresses the differential diagnostic features.

Introduction: The number of cases of Sudden Infant Death Syndrome (SIDS) is decreased by an increasing number of cases that can be ascribed to specific medical conditions. A case of the sudden death of an infant is described that autopsy revealed was due to the unusual finding of hypertrophic cardiomegaly in a two-month-old.

Clinical History: The infant was a healthy, full-term two-month-old white male, who was found unresponsive in his crib following a morning nap. The father began CPR and called emergency personnel. The infant was transported to the hospital, where resuscitative efforts were unsuccessful, and the baby was pronounced dead.

The infant was born to a G2P2 30-year-old woman, who had a history of a motor vehicle accident that resulted in brain trauma. She

later underwent temporal lobe resection for control of seizures. During pregnancy, seizure activity required that she was started on levetiracetam (Keppra), beginning at approximately 20 weeks gestation at a dose of 1000 mg per day that was later increased to 1500 mg per day. Towards the end of the pregnancy, she was also started on gabapentin (Neurontin) at a dose of 5400 mg per day. Her pregnancy otherwise was uneventful. At 32 weeks gestation, a second level ultrasound showed no fetal abnormalities, and the heart was normal in size.

Autopsy Findings: At autopsy, the body was that of a well developed and well nourished two-month-old white male, weighing 11 pounds and measuring 23 inches in length. There were no signs of trauma. All internal organs were in their normal anatomic relationships. The heart, in the fresh state, weighed 72 grams (average weight for age was 30 grams) and was structurally unremarkable. Upon sectioning, the myocardium was red/brown, without fibrosis, hemorrhage, or distinct lesions. The interventricular septum was intact. The atria were unremarkable, and no interatrial defects were present. The coronary ostia were normally located, and the distribution showed right dominance with a circulation pattern within normal limits. The valves were thin and unremarkable.

Microscopic Examination: Hypertrophic cardiomyocytes found on H&E sections of the heart. No other microscopic abnormalities were found. Electron microscopy and special histochemical stains were performed.

Discussion: Hypertrophic cardiomegaly in many ways resembles hypertrophic cardiomyopathy. There is left and/or right ventricular hypertrophy that is usually asymmetric and involves the interventricular septum. The hallmark features are myocardial hypertrophy and structural derangement. In this case, the heart was approximately double the normal weight and size.

Neonatal cardiomegaly may resemble hypertrophic cardiomyopathy. However, at autopsy a variety of cardiovascular defects, such as aortic coarctation or malformation of the coronary arteries, are usually found. In addition, in some patients without cardiovascular defects, another cause for ventricular hypertrophy may be present, such as chronic renal failure or maternal diabetes. In this case, no other cardiovascular defects, besides left ventricular hypertrophy, were found, and no additional medical conditions were known.

The differential diagnosis in this case includes amyloidosis, glycogen storage disease, and Fabry disease. These conditions can be eliminated from consideration by microscopic examination of the heart. In this case, sections of the heart showed no abnormal intracellular accumulations.

The etiology of this infant's hypertrophic cardiomegaly is unknown. The parents were concerned that the anticonvulsant medications taken by the mother during pregnancy may have adversely affected the fetus. This question cannot be answered with certainty. Both levetiracetam and gabapentin are pregnancy risk category C drugs, meaning there are no adequate studies of the drugs in humans, although animal studies have shown an adverse effect on the fetus. Category C drugs may be useful in pregnant women despite their potential risk.

It is possible that there may be a familial component to this case. The infant's paternal grandfather has a history of hypertrophic cardiomyopathy.

Conclusion: Hypertrophic cardiomegaly is a rare finding in infants and may be a cause of unexpected sudden death. This condition should be considered in the differential diagnosis of SIDS. A careful examination of the cardiovascular system is warranted in each case. Microscopic and special studies may be used to rule out other causes of cardiomegaly in infants.

Infancy, Hypertrophic Cardiomegaly, Sudden Death

G42 Use of Expert Consultation in the Evaluation of Tissue Donors With a Postmortem Diagnosis of “Hepatitis” to Determine Eligibility For Transplantation

Stephen L. Sgan, MD*, and Shobha Sharma, MD, Department of Pathology and Laboratory Medicine, Emory University School of Medicine, 1364 Clifton Road, NE, Atlanta, GA; and Judith Woll, MD, and Lance D. Trainor, MD, Community Blood Center / Community Tissue Services, 349 South Main Street, Dayton, OH

The goals of this presentation are 1) to emphasize the importance of attempting to specifically determine and report infectious vs. non-infectious etiologies of hepatitis in cadaveric donors of tissue for allotransplantation, 2) to emphasize that correlation of morphology with viral serologic testing results is integral to establishing the initial diagnosis of viral hepatitis, and 3) to assess the utility of expert consultation in making this determination.

Introduction and Hypothesis: Chronic hepatitis is a clinical-pathologic syndrome which may result from a number of causes including viral infections, autoimmune or metabolic diseases, drugs (medications), or other unknown etiology (cryptogenic). Chronic hepatitis is defined clinically as inflammatory liver disease continuing for at least 6 months. However, patients with chronic hepatitis may have asymptomatic clinical phases, for example in hepatitis C and autoimmune hepatitis. Patients with viral hepatitis, especially infections due to hepatitis C virus (HCV) or to hepatitis B virus (HBV) with or without hepatitis D virus (HDV) superinfection, are at significantly increased risk for developing hepatic cirrhosis and hepatocellular carcinoma. Chronic hepatitis due to viral infection is a clear contraindication for blood donation and is likewise a contraindication for allogeneic organ and tissue donation. The Federal Drug Administration (FDA) and American Association of Tissue Banks (AATB) standards require tissue donors to be screened by medical / social history for risk factors for viral hepatitis and to have negative laboratory tests for hepatitis B surface antigen (HBsAg), Hepatitis B core antibody (anti-HBc), hepatitis C virus antibody (anti-HCV), and human immunodeficiency virus, types 1 and 2 (anti-HIV-1/2). Cadaveric donation of tissue (e.g. bone, skin, fascia, tendons, heart valves, and corneas) may also be preceded or followed by postmortem examination of the donor, including liver biopsy. Since chronic hepatitis is a clinical-pathologic syndrome resulting from both infectious and non-infectious causes, it was hypothesized that many potential tissue donors with a postmortem diagnosis of “hepatitis” without reference to etiology made initially at autopsy, but with otherwise acceptable AATB donor criteria, would have minimal liver inflammation resulting from non-specific or non-infectious causes and would therefore be acceptable donors.

Methods: Seven potential cadaveric donors ranging in age from 16 to 72 years were referred to a regional tissue bank by either hospital (n=4) or medical examiner's office (n=3) staff. The causes of death included cardiac events (n=3; 1 acute myocardial infarction, 1 hypertensive cardiovascular disease, and 1 hemopericardium with cardiac tamponade), vascular rupture (n=2; 1 abdominal aortic aneurysm and 1 porta hepatis), and head trauma (n=2; 1 gunshot and 1 blunt injury). Based on initial screening criteria, including a detailed medical / social history obtained from next-of-kin and an external physical examination, the donors were approved as being suitable for tissue donation. After informed consent was obtained from next-of-kin, donor tissues including skin, saphenous and femoral veins, heart (for valves), ilia, fascia lata, long bones and achilles tendons of the lower extremities were procured

under aseptic conditions within 24 hours of asystole. In all cases, a post-mortem examination was performed either before or after the tissue procurement by a pathologist from the referring institution. Infectious disease testing was performed on ante- or postmortem plasma or serum samples meeting acceptable plasma dilution criteria with FDA-approved cadaveric test systems for HBsAg, anti-HBc, anti-HCV, anti-HIV-1/2, HIV p24 Ag, and HIV DNA by PCR. These seven donors, each with an autopsy diagnosis of “hepatitis” without reference to specific etiology, were re-evaluated after procurement of tissues. These cases, with complete clinical and laboratory findings including routine histological sections of liver from autopsy and results of infectious disease tests, were subsequently referred to independent expert gastrointestinal / liver pathologist consultants for a formal second opinion regarding the possible diagnosis of viral / infectious hepatitis. Tissues of donors with clinical and histological findings determined by the expert to be insignificant, non-specific or non-infectious were processed to a variety of grafts at an AATB-certified processing facility and released for transplantation. Clinical follow-up was obtained.

Results: For all seven potential donors, screening criteria from the medical / social history, including risk factors for infectious hepatitis, and the physical examination were acceptable on re-evaluation. In each case, all infectious disease laboratory test results for viral hepatitis markers were also acceptable. In addition to other findings, each autopsy report from the referring institution listed “hepatitis” as a significant postmortem finding. As these reports did not specify either an infectious or non-infectious etiology of hepatitis, histological sections of liver from autopsy were obtained in order to assess the suitability of grafts derived from each donor for transplantation. Preliminary review in all cases showed only minimal to mild, patchy inflammation limited to portal areas. The histological sections, along with clinical and laboratory results, were forwarded to independent expert gastrointestinal / hepatic pathologist consultants for a formal opinion of the possibility of hepatitis of infectious cause. In all seven cases, in the opinion of the expert, the findings were either a) unremarkable hepatic parenchyma (n=2), b) non-specific portal triaditis (n=4), or c) non-diagnostic of chronic hepatitis of viral etiology (n=1). Based upon these opinions, the donors were approved as suitable for transplantation and tissues from the seven donors were processed into a total of 254 surgical allografts, potentially benefiting an equivalent number of recipient patients. At the time of this writing (12.5 to 47.5-month follow-up from date of procurement), no cases of infectious hepatitis have been reported in the graft recipients.

Conclusion: Chronic hepatitis of viral etiology is a contraindication for cadaveric tissue donation. In contrast, hepatic inflammation due to non-infectious etiologies may not be prohibitive for donation. Thus, at postmortem examination of decedents who have donated tissues for transplantation, efforts should be made to accurately diagnose hepatitis and, if possible, to further determine the specific etiology (infectious or non-infectious) of hepatic inflammation. Correlation of morphology with viral laboratory testing is often integral to establishing the diagnosis. Typical histological findings of hepatitis of varying etiologies will be discussed. Microscopic findings of only mild, patchy portal triaditis should be interpreted as “hepatitis” with caution when viral serologic tests are negative or in the absence of such tests. The use of consultation by expert gastrointestinal/hepatic pathologists may assist hospital autopsy pathologists, forensic pathologists and/or tissue bank medical directors in making this determination and may result in an increase in the supply of acceptable tissue for transplantation to many patients needing surgical allografts.

Hepatitis, Tissue, Allograft

G43 Determining the Cause of Death and Contributing Factors in Fatal Recreational SCUBA Diving Accidents

James L. Caruso, MD, Office of the Armed Forces Medical Examiner, The Armed Forces Institute of Pathology, Washington, DC*

The goals of this presentation are to provide the forensic community with epidemiological data on diving fatalities and offer guidance and resources for investigating such deaths.

Diving with SCUBA (self-contained underwater breathing apparatus) equipment while breathing compressed air is a popular pastime in the U.S. An average of 90 to 100 recreational diving deaths occur in the U.S. or involve U.S. citizens diving abroad each year. Few medical examiner offices have enough experience with diving related deaths to adequately investigate such cases and errors in reporting the cause of death and contributing factors frequently occur. The goal of this presentation is to provide background data on the epidemiology of fatalities involving recreational divers and to arm the forensic community with some tools and guidance in properly determining the cause of death in such cases.

The Divers Alert Network (DAN) is a diving safety organization affiliated with Duke University Medical Center and located in Durham, North Carolina. DAN collects data on all recreational diving accidents and fatalities that occur in the U.S. or that involve U.S. citizens diving abroad. The information collected includes autopsy reports, investigational reports from law enforcement agencies and the U.S. Coast Guard, witness accounts, newspaper articles, and any other information from contributors involved in the case (e.g., medical treatment personnel, other divers, rescue personnel). Each case is reviewed by DAN staff, which includes individuals with technical diving expertise as well as a physician trained in both diving medicine and pathology. The Divers Alert Network publishes the data, including case reports, in an Annual Review of Diving Accidents and Fatalities. DAN also provides formal consultative services, free of charge, to any medical examiner office or government agency.

The Divers Alert Network fatality database was queried to obtain information on recreational diving deaths that occurred during the period 1989-1998. During that time there were 911 total diving deaths, over 70% involving male divers. Nearly half of all diving related fatalities involved divers age 30 to 49. Autopsies were performed in most, but not all, of the fatalities and in some cases a body was never recovered.

Not surprisingly, the most common cause of death was drowning (59%), though this should be considered a final common pathway in recreational water sports and the circumstances resulting in drowning are far more meaningful from a public health aspect. Other significant causes of death included cardiac events (11%) and arterial gas embolism (9%). Significant contributing factors that resulted in death while diving included running out of air at depth (17.2%), entrapment in a cave or other structure (10.7%), and having a medical problem during the dive (e.g., cardiac event (19%), asthma attack, etc.).

Diving experience varied but many were novices. Nearly half of the deaths involved divers who had made 20 or fewer lifetime dives, though a small, but significant, percentage occurred when the diver was under instruction in a formal training class. A large number of deaths involved divers who were involved in more challenging types of diving, such as cave exploration, wreck penetration, and deep diving. Of the divers who died while involved in these specialty types of dives, only a third had any documented formal training in that type of diving. Many divers in the fatality database were infrequent divers, making only a few dives each year. Diving dogma dictates that one always dives with another diver (the dive buddy). For the fatalities in the database, 40% became separated from their dive buddy during the dive; 14% chose to dive alone and had no assistance available when a problem occurred in the water.

Deaths that involve recreational divers are infrequent but can occur in almost any jurisdiction. For the ten-year period of data used in this report, nearly a third of the fatalities occurred in the southeastern part of the U.S. The states with the greatest number of diving related deaths were Florida, California, and Hawaii. However, a significant number of diving fatalities occurred in New England, the states bordering the Great Lakes, and the Pacific Northwest.

The medical examiner or forensic investigator involved in the investigation of a diving related fatality should either have a solid foundation in diving techniques and underwater physiology or seek expert consultation. To correctly assign a cause and manner of the death, these cases require a thorough investigation of the scene, knowledge of the circumstances surrounding the death (including a detailed history of the dive, if available), professional evaluation of the diving equipment used, and a complete autopsy with proper toxicological studies. Some modification in the autopsy protocol to look for pneumothorax and air embolism are necessary and a carboxyhemoglobin should be part of the standard toxicology for these cases.

Despite being uncommon events, recreational diving fatalities often involve young people with a large number of years of productive life lost and the cases nearly always go to litigation. The importance of a thorough investigation and arriving at accurate conclusions cannot be overstated.

SCUBA Diving, Drowning, Air Embolism

G44 Sphenoid Sinus Petechiae: Incidence and Significance

Kathryn H. Haden, MD, and David Dolinak, MD, Southwestern Institute of Forensic Sciences and the University of Texas Southwestern Medical Center, Dallas, TX*

After attending this presentation, participants will gain insight as to the incidence and significance of sphenoid sinus petechiae.

Purpose: Petechial hemorrhages, while a non-specific finding, may be indicative of an asphyxial death. Many studies have reviewed the importance of petechiae in a variety of sites, such as the conjunctiva, skin or visceral surfaces, however information regarding petechiae of the sphenoid sinus mucosa is not often commented on. The consensus of many investigators suggests that the pathogenesis of petechiae is related to the combined effects of increased venous pressure and hypoxic damage to endothelial cells, although the latter has been discounted by some authors. It is surmised that petechiae of the sphenoid sinus occur by the same mechanisms. The following investigation aims to demonstrate the significance of petechiae discovered in the sphenoid sinus, as well as to correlate their presence in conjunction with petechiae at other sites on the head.

Materials and Methods: The Southwestern Institute of Forensic Sciences in Dallas, Texas conducts approximately 3500 autopsies per year. Over a 30-day period, a series of autopsies were prospectively examined for the presence or absence of petechiae of the sphenoid sinus. Near the conclusion of the autopsy, i.e., after all organs had been eviscerated, the roof of the sphenoid sinus was removed via a triangular shaped opening made with a Stryker saw. Cuts were made through the lesser wing of the sphenoid bone on each side of the sphenoid sinus and just anterior to the sella turcica. Once the piece of bone was removed, the sphenoid sinus mucosa was examined with the aid of a halogen lamp or penlight. Petechiae were described as none, few or many; the latter equating to too numerous to count. Other variables documented in each case were: age, race, sex, cause and manner of death, the presence or absence of facial or conjunctival petechiae, body position at the time of death and whether or not cardiopulmonary resuscitation was attempted.

Results: As with petechiae identified in other sites, the presence or absence of sphenoid sinus petechiae neither confirms nor disputes the cause of death. However, they are seen in certain types of deaths with a

higher frequency than others. In cases where autopsy findings are subtle or vague, such as in drowning deaths or certain asphyxial deaths, the presence of sphenoid sinus petechiae can be useful corroborative evidence to support a particular cause of death. The position of the body at the time of death is important information when interpreting the usefulness of sphenoid sinus petechiae, as they are seen with increased frequency in specific body positions. While not specific for any particular cause of death, sphenoid sinus petechiae can provide pathologists yet another piece of information in certain settings, and when interpreted in the total case context, help support a particular cause of death.

Sphenoid Sinus, Petechial Hemorrhages, Incidence

G45 Homicide in the Elderly— Paris and Its Suburbs, 1996-2001

M. Berrouche, MD, Paul Fornes, MD, PhD, and Dominique Lecomte, MD, Forensic Institute of Paris, Medical School Cochin Port Royal, Paris, France*

Be it intra or extrafamilial, violence against the elderly has become an important source of concern. Surveys suggest that domestic violence and elder abuse and neglect are underestimated. The present study examined the circumstances surrounding homicides in the elderly, and autopsy findings.

As the population of the industrialized countries ages, the problems associated with the care of the elderly increase. Of those, violence against the elderly is an important source of concern. Most surveys indicate that the frequency with which elderly persons are assaulted or abused is likely to be underestimated. Among other forms of violence, domestic elder abuse and neglect has been suggested to be perhaps the most underreported crime. Homicide might be the extreme and most tragic form of abuse and neglect, and therefore may represent an accurate indicator of violence against the elderly. However, medicolegal autopsy-based studies and international comparisons are infrequent.

The aims of this study were to examine the circumstances, demographics, and autopsy findings in homicides involving persons aged 65 years or older, in Paris and its suburbs, between 1996 and 2001.

Results: 99 homicides occurred during the 6-year study period, 23 in 1996, 11 in 1997, 21 in 1998, 15 in 1999, 11 in 2000, and 18 in 2001. There were 59 female victims. The mean age of victims was 77 years, 79 in females (range, 65-97) and 74.5 in males (range, 65-87). There were 18, 24, and 17 females in the 65-74, 75-84, and ≥85 age groups, respectively, and 25, 9, 6 males in these age groups, respectively. 76% of victims were killed in their home. In 43 cases, the perpetrator was unknown to the victim. The murderer was a family member in 28 cases and an acquaintance in 28 cases. The most common motive for homicide was robbery, 40 cases. 30 of those occurred in the victim's home. 7 women were raped. There were 12 homicide-suicides. Disputes involving acquaintances or relatives accounted for approximately 25% of cases. In 12 cases, the perpetrator and motive could not be determined. Among the 99 homicides, 28 were domestic, including 20 intimate partner homicides, with the husband being the perpetrator in 14 cases. Guns were used in 14 of the 99 cases, 12 of which involved intimate partner homicides. Guns were never used in rapes or robberies. Stab wounds were found in 15 cases. Fifty-six persons died of blunt force injuries. In 39 cases, asphyxia was the cause of the death, with 25 of these in combination with blunt force. In 5 of the robbery cases, a cardiac disease, in addition to blunt force, contributed to the death.

Conclusion: During the 6-year study period, the number of elderly homicide victims, older than 65 years, in Paris and its suburbs has been approximately 16 per year. Males were at highest risk in the 65-74 age group, whereas females accounted for 75% of victims in the ≥85 age group. The elderly homicide victim was most likely to die from blunt force injuries. Domestic violence accounted for less than 30 % of homicides, whereas robbery was the most frequent motive for homicide,

accounting for 40 % of cases. Frailty and social isolation that come with illness or advanced age render the elderly more vulnerable to crime and make it impossible for some elderly individuals to protect themselves.

Elderly, Homicide, Forensic Sciences

G46 Abuse and Neglect: A 10-Year Review of Mortality in Elders

*Lisa B.E. Shields, MD *, and Donna M. Hunsaker, MD, Office of the Chief Medical Examiner, University of Louisville School of Medicine, Louisville, KY; and John C. Hunsaker III, MD, JD, Office of the Associate Chief Medical Examiner, University of Kentucky College of Medicine, Frankfort and Lexington, KY*

The goals of this paper are to present the prevalence and pertinent findings of elder abuse and neglect in a major metropolitan city in Kentucky.

Methodology: to analyze data representative of or suspicious for elder abuse from a ten-year (1992-2001) retrospective case review of morbidity and mortality among elders (greater than or equal to 60 years old) at a State Medical Examiner's Office serving a major metropolitan city in Kentucky conducting both medicolegal autopsies and examining living cases pursuant to a Clinical Forensic Medicine Program.

Elder abuse refers to an act or omission, which results in harm, including death, or threatened harm to the health or welfare of an elderly person. Between one to two million Americans experience elder abuse and neglect per year. Elder abuse may be divided into six discrete, but often overlapping, categories: physical, sexual, and psychological abuse; neglect; financial exploitation; and violation of rights. While elder neglect is the most commonly discovered and investigated form of elder abuse, it represents the least well-defined and most controversial form of maltreatment. The abused elder often is over the age of 75, lives in social isolation with few social contacts, and suffers from poor health and cognitive impairment. The abuser frequently lives with the elder, has a history of mental illness and/or substance abuse, commits violence, displays antisocial behavior in relationships, and is financially and/or emotionally dependent on the elder.

The 10-year retrospective study included 74 postmortem examinations and 22 living patients evaluated at a clinical forensic center in Louisville, KY. The authors present the 74 postmortem cases of victims age 60 and older, in which 52 deaths were attributed to a homicidal act and 22 deaths were suspicious for neglect. The homicidal causes of death included gunshot, beating, stabbing, and asphyxia. The primary cause of death in neglect cases was bronchopneumonia. Distinctive factors among this elderly cohort, such as the frequency of cancer and Alzheimer's disease, were uniformly evaluated.

Forensic pathologists or emergency room physicians and forensic nurses through the Clinical Forensic Medicine Program evaluated 22 living individuals greater than or equal to 60 years old. Among these clinical investigations, 19 cases constituted physical and/or sexual assault and 3 victims suffered from neglect.

The authors summarize the characteristic features of elder abuse in both postmortem and living cases and underscore the necessity for multi-agency collaboration in order to reach an accurate conclusion in case work. Policies gleaned from a well-established elder abuse task force enable the interaction necessary to formulate criteria for future prevention. In the majority of physical and sexual assaults evaluated in the Clinical Forensics Program and at autopsy, which appear to be inflicted by "unknown perpetrators," further in-depth investigative work must be done. These initially termed "unknown perpetrators" may represent acquaintances, family members, and people who live or work in the vicinity of the victim. With the ongoing communication between agencies, assailant identification and clarification of the circumstances will increase the likelihood that the case is brought to litigation.

Elder Abuse, Elder Neglect, Clinical Forensic Medicine

G47 Elderly Neglect/Abuse

Kanthi von Guenthner, MD*, Chief Medical Examiner, Department of the Medical Examiner, City and County of Honolulu, 835 Iwilei Road, Honolulu, HI

This presentation is designed to bring awareness to the forensic community of elderly neglect/abuse which is a widespread problem possibly affecting hundreds of thousands of elderly across the country. It is still underreported due to a variety of reasons. This will discuss in detail what constitutes elderly neglect/abuse, medical, investigative, and autopsy assessment with presentation of several case reports from the State of Hawaii.

On June 18, 2002, the U.S. Congress heard detailed accounts of case reports of elderly neglect/abuse by a panel of experts and a report issued by the National Research Council stating, "Based on the available estimates, between one to two million Americans 65 and older have been injured, exploited, or otherwise mistreated by someone on whom they depended for care and protection." The overall national response to elder mistreatment currently remains weak and incomplete. Information on neglect/abuse cases and policies on how to deal with it vary from state to state. Therefore, they requested that someone at the Federal level take charge of the situation, gather statistics, and try to find a way to deal with the problem that will only grow worse as the population ages.

The National Center on Elder Abuse has defined three major categories of abuse/neglect as domestic, institutional, and self-neglect. The types of abuse are physical abuse, sexual abuse, psychological abuse, financial exploitation, and neglect. If not considered in the differential diagnosis, like a disease, elderly neglect may not be diagnosed. Inconsistent statements by the caretakers, evaluation of the environment, medications, nutritional evaluation, and statements in regard to the explanation of injuries/ulcers should be considered in investigating deaths due to the neglect/abuse. Medical and autopsy assessments should indicate the nature and extent of injuries, evaluation of hydration and metabolic status, detailed documentation of decubitus ulcers with the size, extent, and appearance with reference to staging, determination of the cause of death with evaluation of the duration of specific conditions, and documentation for legal proceedings.

Preventive measures include public awareness through education and early identification, intervention, and treatment for elders and their caregivers in high-risk situations, increasing the staff in the care homes, and even criminal prosecution of caregivers.

Elderly, Abuse, Neglect

G48 Morphological Considerations of the Hyoid Bone

Joanne L. Devlin, PhD*, Department of Anthropology, University of Tennessee, 250 South Stadium Hall, University of Tennessee, Knoxville, TN

This presentation will demonstrate the tremendous variation that characterizes the hyoid bone

Combining the anthropological focus upon skeletal variation with the pathological interest in trauma, this study reveals the immense variation and complexity in laryngeal structures, and dispels the common notion of a causal relationship between advancing age and fusion of the hyoid bone.

Fractures of the laryngeal structures are frequently associated with manual and ligature strangulation, although external manifestation of such trauma is not always evident. Often, assessment of the condition of the hyoid bone may merely involve palpation of the laryngeal tissues at autopsy. Unfortunately, such interpretations are plagued by the unquestioned acceptance that the skeletal elements of the hyoid bone unite with

advancing age. Understandably, this erroneous consideration of the development of the laryngeal skeleton is frequently assumed in forensic interpretations.

The hyoid bone is comprised of several distinct skeletal components, the body and pairs of greater and lesser horns. However, throughout the anatomical and scientific literature the hyoid bone is traditionally described as a "U" shaped bone of a consistent form; a form that develops and fuses with advancing age. This interpretation, therefore, biases the potential anatomical, pathological, and clinical evidence that can be gleaned through examination of the components of the hyoid bone. Although the literature produced within these disciplines contains a wide variety of references to hyoid conditions, these reports suffer from a failure to recognize the variability that characterizes the human hyoid bone. Clearly, a thorough appreciation of the range of variation inherent in this structure is crucial for the accurate assessment of the hyoid in both antemortem and postmortem situations.

Toward this end 1,814 hyoid bones from individuals ranging in age from 2 months to 101 years, maintained in the Department of Anthropology at The University of Tennessee, were examined. Specimens were assessed for fusion and categorized as unfused, unilaterally fused, or bilaterally fused. Additionally, a series of measurements were performed to quantify overall size and shape. The structure of the hyoid, as revealed by the extent of fusion and overall size measurements was then compared against known age, sex, and ancestry data.

Results indicate that the hyoid is sexually dimorphic, though no significant differences exist between males and females with regard to fusion. However, age is a factor when considering a union between the body and greater horns in that among the young (0-9 and 10-19) no union occurs. There is minimal evidence for the occurrence of fusion between the body and greater horns during the third and fourth decades of life. Although an increase in the frequency of union occurs during succeeding decades, this study demonstrates that advanced age cannot be equated with fusion between the body and greater horns.

This enhanced awareness of the variability that truly characterizes the hyoid will enable more accurate pathological, anthropological, anatomical, and clinical descriptions of the hyoid in forensic settings.

Hyoid Bone, Laryngeal Trauma, Morphological Variation

G49 Relevance of the Autopsy as a Medical Tool: A Large Database of Physician Attitudes

Jody E. Hooper, MD*, U.S. Navy, General Medical Officer, Branch Medical Clinic, Naval Air Station, North Island, Coronado, CA

The goals of this presentation are: 1) to examine a large data base of physician attitudes about the value of the autopsy, 2) to attempt to correlate physician opinions about autopsy to their levels of experience with and knowledge of the procedure, and 3) to determine whether there is sufficient interest in the autopsy to make revitalizing it worthwhile as a contributor to medical practice.

Background: Autopsy rates for patients dying in hospitals have declined from approximately 50% in the 1950s to at or below 10% of similar patients today. A previous pilot study survey distributed to attending physicians in a large, urban, university hospital center suggested that in spite of this decline, physicians believed strongly in the usefulness of the autopsy. Most disagreed that diagnostic procedures were so accurate that autopsies had become irrelevant, and most disagreed that concern over litigation affected their desire to request autopsies. Given the results in this pilot survey, physicians' positive opinions about the value of the autopsy appeared to contradict their apparent declining requests for the procedure. It became important, then, to confirm that these attitudes hold true in a larger and more varied sample, perhaps more indicative of the population of physicians in general.

Methods: This study uses essentially the same survey on autopsy knowledge and opinions that was distributed in the pilot study. A slightly revised survey was distributed to all attending physicians in a second large, university-affiliated medical center and a large military-affiliated medical center. The database of physician responses now includes three major hospitals, two university-affiliated (one private and one public) and one military, as well as one east coast and two west coast hospitals. Including the pilot study, the 10-question survey has now been distributed to 723 full-time attending physicians. The survey was an anonymous, one-page, multiple choice format questionnaire, that could be completed in under five minutes. Clinicians first identified their department, years of practice, and the number of autopsies they had observed or participated in as a student, resident, or attending physician. They then estimated their departmental autopsy rate and opined on the sufficiency of that rate to meet departmental goals for education and research. The remaining questions examined, among other topics, physician belief in the value of the autopsy for confirming diagnostic results, its potential affect on medical practice, the effects of possible litigation on autopsy requests, and how prepared physicians felt to discuss autopsy with families of patients.

Results: A total of 113 military physicians and 94 university physicians provided 207 (29%) total responses to the survey. Departmental response rates varied from 13% to 80%, with response rates slightly higher on average at the military facility. Attendance was fairly evenly spread in years of practice from less than 5 to over 20 years. Physicians at the military center had been in practice somewhat longer than their civilian counterparts and, as a result, seemed to have had slightly more exposure to autopsy. However, overall exposure to autopsy by observation or participation was low, with 52% of physicians being involved in fewer than 5 cases (11% responded 0 cases) and only 21% indicating involvement in more than 20 cases over their careers. Respondents in nearly equal percentages (35% and 40%) agreed and disagreed that their departmental autopsy rates were sufficient to meet departmental goals, with this bimodality probably traceable to 46% indicating no knowledge of the rate. Fully 36% (the largest response category by far for this question) could not say whether or not results were reported in a timely fashion. The pattern of responses of military-affiliated physicians did not appear to be statistically different from those of university-based physicians on opinion-based (non-demographic) questions, so the two groups were combined for much of this analysis. Physicians across years of practice, autopsy experience and knowledge, and departments agreed (72%) that autopsy results could affect their medical practice and disagreed (74%) that the accuracy of modern diagnostic procedures makes autopsy obsolete. Interestingly, one of the largest concentration of responses in the survey (77%) disagreed that litigation concerns played a role in the request and use of autopsy. This result directly contradicts one of the principal conclusions in the literature offered to explain declining autopsy rates. Also, in spite of the apparent collective lack of experience with autopsies indicated by responses to the demographic questions, physicians mostly (79%) claimed to be comfortable with discussing the autopsy with family members. However, the most resounding result from the 207 physician responses to the survey appears to be that both military and civilian physicians feel that the autopsy is a relevant clinical instrument and medical tool, even when they have experienced, requested, discussed, or personally used very few of them.

Conclusions: The expanded survey data confirms that physicians highly value the autopsy as a clinical tool, in spite of declining rates and decreasing exposure to autopsy over their professional lives. These opinions do not appear to vary significantly across types of institution or years of experience. The survey data does not support (in fact, seems to refute) causes of the decline in the use of autopsy often cited in the literature, i.e., delayed reporting of results, concern over litigation arising from findings, or belief in the accuracy of current diagnostic procedures. The next step of this research will be to model the effects of

implementing changes in autopsy education and procedures on physician request rate and use. The anticipated changes would include, at minimum, more widespread exposure to autopsies at each stage of medical education, better pathologist to clinician communication, and prompt and relevant reporting. The autopsy, a procedure that physicians claim to value so highly, should not be allowed to become only a forensic tool and slip out of existence as a contributor to medical knowledge.

Autopsy Rates, Autopsy Relevance, Physician Attitudes

G50 Analysis of Five Thousand Forensic Medical Expert Opinions

Istvan F. Szentmariay, MD, DMJ, Marta Hubay, MD, and Gyorgy Dunay, MD, Institute of Forensic Medicine, Semmelweis University, Budapest, Hungary, Ullói Street 93, Budapest, Budapest, Hungary*

The goals of this presentation are to describe and characterize the major types of forensic expert medical opinions done by forensic pathologists in Hungary and explore strategies that may help improve service.

Methods: In majority of European forensic institutions, forensic pathologists play an important role to formulate expert medical opinion, additional to their regular medico legal autopsy workload. In many places these expert opinions even outnumber the forensic autopsies performed. At the Institute of Forensic Medicine, nearly 15,000 written opinions have been prepared (non-autopsy cases) during the last four years on wide variety of cases. Although majority of these involved forensic psychiatrists and psychologists, approximately 5,000 cases were clearly completed by the Institute's forensic pathologists.

Results: Cases include medical malpractice but also homicides, accidents, disability, worker's compensation, fight injuries, interpreting toxicological results, etc. Results of expert opinions will be provided based on the type of case and authorities' requests (civil or criminal court, police, DA's office, other institutions). The major categories of cases will further be broken down and scrutinized from many aspects. Preparing the expert opinion does not necessarily require complete patient examination; the percentage of giving opinion from documentation and charts only varies widely (i.e. in 6% of civil cases and in 23% of criminal cases no patient examination was involved). The increasing number of suspected mistakes in medical treatment allowed the authors to point out recurrent mistakes, and to categorize and statistically analyze the causes of claims. (i.e., misguided allegations, error of judgment, incompetent care, failure of communications, lack of expertise, etc.). Dealing with medical malpractice cases by forensic expert sometimes require input from clinicians to overcome the gap between academic approach (theory) and the care and treatment of an individual patient (practice). The authors will present personal experiences on why and when clinicians are asked to participate in formulating an expert opinion.

Disability evaluation is an important part of forensic medical evaluation in caseloads. The Institute represents a 3rd level forum. All patients were examined twice before a civil court, specializing in disability issues, referred them to the Institute for a final opinion. Further details will be provided on cases involving temporary and permanent injuries (what is done, how is it accomplished). Additionally, the number of questions submitted and the most often asked relevant questions, which an expert opinion should answer in each of the expert opinion categories, will be discussed.

Finally, challenging the forensic medical opinion in court of law works in Hungary will be explained. A very important index of the Hungarian forensic expert's work is the acceptance rate of expert opinion in the court, which will be presented.

Forensic Expert Medical Opinion, Medical Malpractice, Disability Evaluation

G51 The Happy Land Homicides: 87 Deaths Due to Smoke Inhalation

Lara B. Goldfeder, BS, MD*, James R. Gill, MD, and Marina Stajic, PhD, Office of the Chief Medical Examiner, 520 First Avenue, New York, NY

After attending this presentation, the participant will understand the roles of carbon monoxide, cyanide, ethanol, and hydrochloric acid in fatal smoke inhalation.

On March 25, 1990, eighty-seven people died of smoke inhalation at the "Happy Land Social Club" in New York City. A 36-year-old man, who earlier had been ejected from the unlicensed club after a verbal altercation with his former girlfriend who worked at the club entrance, intentionally started the fire. He went to a nearby service station, filled a plastic container with a dollar's worth of gasoline, and returned to the club. He threw the gasoline and lit matches into the only entrance of the two story social club. Smoke quickly filled the club. Although the fire was extinguished within minutes, all but five of the occupants of the building were found dead within the building.

Within 36 hours the New York City Office of Chief Medical Examiner performed 87 autopsies on this group of healthy, young people, all of whom quickly died from smoke inhalation from a common fire source. All decedents were visually identified and all had soot in the airway extending to the major bronchi. Only 30% of the decedents had thermal injuries and most were partial thickness burns involving less than 20% body surface area.

Carboxyhemoglobin (COHb) concentrations ranged from 37% to 93% with a mean of 76.5%. The vast majority (92%) of the decedents had COHb concentrations over 60%. Ethanol was detected in 72% of decedents with a range of 0.01 to 0.29 g% and a mean blood concentration of 0.11 g%. Of the 24 decedents with no ethanol detected at autopsy, the average COHb concentration was 79%. The 15 decedents with blood ethanol concentrations of 0.15 g% or higher had an average COHb concentration of 73%. Cyanide concentrations ranged from 0 to 5.5 mg/L with a mean of 2.2 mg/L. Nine decedents had no cyanide detected and seven had cyanide concentrations of less than 1 mg/L. The tracheal pH ranged from 5 to 7 (mean 6.4).

Since all decedents in this instance died from smoke inhalation in the same smoke filled environment, if cyanide was a reliable indicator of smoke inhalation, then all the decedents would have detectable cyanide. The fact that nine of the decedents had no cyanide detected and another 7 had less than 1 mg/L demonstrate that cyanide did not play any role in several deaths. In fire deaths, cyanide concentrations do not provide helpful, interpretable information and need not be performed on suspected smoke inhalation deaths. Alcohol does not appear to cause death at a lower COHb concentration as the mean COHb concentrations in the intoxicated (BAC >0.14g%) and sober groups were similar (73% vs. 79%). Hydrogen chloride inhalation, as judged by comparison of the pH of tracheal mucosa to controls, was not a factor. The cause of all deaths was smoke inhalation and the manner was homicide.

Forensic Science, Carbon Monoxide, Smoke Inhalation

G52 Documenting Patterns of Injury in Fire Victims

O'Brian C. Smith, MD*, Regional Forensic Center of the University of Tennessee, 1060 Madison Avenue, Memphis, TN; and Elayne J. Pope, MA, University of Arkansas, 330 Old Main, Fayetteville, AR

The goals of this presentation are to review 1) problems associated with documenting burned human remains, 2) recording patterns from fire trauma, 3) identifying features that may indicate body position and fire dynamics, and 4) suggestions for charting victims of mass disaster fatalities.

Dynamic burning processes affecting a human body produce one of the most complex alterations of form by distortion into the pugilistic posture. Additionally, further obfuscation occurs from superficial thermal changes to skin (charring, blistering, and splitting) and as damage progresses, exposure and destruction to deeper layers of subcutaneous tissue, musculature, viscera, and bones. Adequate records and documentation of burning changes are vital since it is known that the sequence of tissue changes correlates with heat source, origin, and body position especially if the expected pugilistic posture is not attained. The ability to use pathological examination of the body in this manner allows results to be integrated with independent investigation by anthropologists, fire marshals, and arson investigators. In such instances mere dictation of the findings fail to capture all the salient features and would otherwise be long and cumbersome. Borrowing on the ancient wisdom of a picture is worth a thousand words, a graphic presentation seems to be in order; however, accomplishing that in a constructive way is challenging.

One of the most difficult tasks in forensics is the ability to produce records for public consumption that are also useful as a court document and effectively convey the necessary information to communicate the same concepts understood by the examiner. Even more difficult is documentation limited by two-dimensional representation of a complex three-dimensional process. The emphasis on mass disaster preparedness compels experts to improve the entire process for all types of fatalities but this seems more so in the burn victim. These fatalities are virtually always out of the anatomical position, and usually have various layers of tissues or organs exposed. Photographs are very useful but hardly fit for public release and if overly graphic, may even be considered too inflammatory in the autopsy protocol and render it unsuitable for jury use unless redacted.

At the University of Tennessee, Memphis physicians have undertaken several methods to achieve a permanent record of observations that retains a continuity of interpretation readily discernable after the passage of time and serves as an effective basis of communication to investigators and juries alike. Taking advantage of this active research in the burning process the authors are now sufficiently aware of the expected sequence of the changes to the body to identify what parameters are more useful to record. The manner in which they are recorded may vary with the case and several examples are presented.

With the advent of the digital age it is possible to take photographs of any sort and convert them into digital images (if not so originally) and digitally redact them to the point of abstraction with a subsequent loss of inflammatory content. Although this has not been subject to challenges in court, the digital images are not tendered as evidence so much as an aid to testimony. It is also important to be able to describe the process by which the redaction occurred. Most often the techniques used are to eliminate the color aspect and present the photo in grayscale (black and white) followed by use of computer filters to portray the edges of the image. At times retaining the color scheme does enhance clarity and is retained. It is then helpful to graphically add text to point out the various landmarks and interpret the image so orientation and understanding are not lost.

Another method goes back to the time honored process of diagramming various views of the body using charts depicting the skeleton outlined by the body contour. In this fashion changes in the skin, soft tissue, and skeletal elements are charted together, merging the pathology and anthropology findings into the same document. Charts depict the body in anatomic position since this is a reference standard, and allows for notation of any deviation from the expected pugilistic posture. Using either different colors or textured fills can document the stages of soft tissue changes. Once recorded, a comparison with diagrams depicting the expected pugilistic posture, patterns of soft tissue loss, exposure, and direction of skeletal exposure can be easily accomplished. This creates a permanent visual record to be utilized by other agencies or investigators as an adjunct to their investigation and serves as a non-inflammatory source document to educate the jury.

Skeletal Trauma, Anatomical Charting, Fire Investigation

G53 Suicide Attempt Using a Self-Made Rifle

Jean-Sebastien Raul, MD*, Antoine Tracqui, MD, PhD, and Bertrand Ludes, MD, PhD, Institut de Medecine Legale, 11 rue Humann, Strasbourg, France

The literature reports mainly the use of self-made guns but more seldom the use of self-made rifles. As a contribution to the understanding of this unusual firearm, the author presents a case involving a suicidal gunshot wound to the head from a self-made rifle that fortunately did not result in the death of the victim.

The use of self-made guns is quite unusual because of the general public's ready access to professionally manufactured handguns or rifles, especially in the U.S. In France, the policy is very different and it is difficult to purchase a handgun or even a rifle for hunting purpose. Nevertheless, the use of self-made guns is rare in France and the experience of pathologists with firearm injuries caused by such guns is fairly limited. The literature reports mainly the use of self-made guns but more seldom the use of self-made rifles. As a contribution to the understanding of this unusual firearm, the authors present a case involving a suicidal gunshot wound to the head from a self-made rifle that fortunately did not result in the death of the victim.

A 34-year-old, depressed man with medical history of suicide attempts was discovered in his bedroom with a rifle near him. Still alive, he was rapidly carried by helicopter to the hospital of Strasbourg and underwent cerebral CT-scan examination and skull radiography. The local prosecutor requested the authors examine the victim.

The victim was examined in the emergency unit. He was maintained artificially unconscious. Skin examination showed a medio-frontal contact gunshot wound located 10 cm above the glabella. No exit wounds were seen. The CT scan showed a right subdural hematoma and a fragmentation of the bullet through the entire right hemisphere. A major element of the bullet was found in contact with the right occipital lobe, under the skull. Skull X-Ray showed the fragmentation of the bullet following a horizontal direction. The direction of the bullet was from front to back, slightly from left to right, and quite horizontally. The maximum distance between the frontal wound and the right or left second finger was 76 cm. The victim was known to be right handed.

The prosecutor informed examining physicians that the distance between the muzzle of the rifle and the trigger was of 84 cm. This was inconsistent with a suicide. Therefore a decision was made to review the scene and rifle.

The rifle was a self-made weapon with a broken trigger, and the only manufactured part was the barrel. The needle was broken and the butt was missing. A striker had been made with a plain pipe sliding within a boiler tube. The posterior part of the plain tube was pointed. On the scene ground and the walls were examined for a crack. A 12 cm vertical recent crack was found on a wall, starting 173 cm from the ground. The victim was 176 cm tall. He had certainly put the muzzle of the rifle on his forehead and fired the weapon by hitting the wall with the posterior part of the rifle. This could explain the direction of the bullet within the skull and the location of the entrance wound. This could also explain how the rifle had been fired making any consideration regarding the distance between the trigger and the muzzle irrelevant.

Epilogue: the victim survived with a left hemiplegia, and confirmed a few months later exactly what the authors had supposed on the scene.

Self-made Rifle, Suicide, Zip Gun

G54 Suicidal Jumping

Istvan Szentmariay, MD, DMJ*, and Gyorgy Dunay, MD, Institute of Forensic Medicine, Semmelweis University, Budapest, Hungary, Ullo Street 93, Budapest, Budapest, Hungary

The study was undertaken to investigate the pattern of injuries, the survival times, and the demographics of people who committed suicide by jumping from a height.

The authors reviewed 495 forensic autopsies performed at the Institute of Forensic Medicine, Semmelweis University, Budapest, Hungary between 1996 and 2001 in which the manner of death was suicidal falling from height (all jumps resulted from suicidal intent). During this period suicidal jumping was responsible for 16 % of all suicides in males and 18% in females. In the case of suicidal jumping the male/female (m/f) ratio was 1.35; the overall suicide m/f ratio was 1.6.

Important to note is that 78% of the males and 82% of the female victims immediately upon impact in a public place. The hospital was listed in the authors' database as the place of death in 13% of the males and 14% of females, although a fraction of these people actually committed suicide by jumping while being treated in a hospital. Statistical data pertaining to what department and why the jumper was hospitalized will be provided. Of the remote suicides, 4% of males and 2.4% of females could not reach the hospital and died during EMS transportation.

Demographic analysis shows that age distribution curves run fairly together for males and females after the age of 40. In younger age groups a strong male predominance was present (m/f ratio was 10 under 20 years of age, 2.7 in age group between ages 21-30 y).

The most important aspect of this work evaluates the injuries sustained during landing. All victims sustained wide range of multiple injuries. The frequencies of bone injuries (upper, lower limbs, pelvis, vertebrae, chest, and cranium) and soft tissue injuries (chest, abdominal organs, and aorta) were collected and analyzed statistically. The most common injury patterns were fractures of lower extremities and the spine. The Injury Severity Score was used to grade injuries for quantitative comparison with the height of falling. Most suicides (two-thirds) had serious mental illness. The blood alcohol level in toxicological reports on all victims was also reviewed. Overall 19% had positive results, although alcohol was present in blood of 38% in the youngest age group (16-20 years of age) and it was present in only 8 % in the oldest victims (age 71 and over). Positive alcohol tests revealed alcohol levels less than 0.15% in 62% of the jumpers and 17% of positive cases showed blood alcohol levels higher than 0.25%.

Monthly periodicity revealed the highest number of cases occurred in June and the lowest number of cases occurred in February in both sexes. Weekday analysis revealed that Monday is a critical day for males and Tuesday for female suicidal jumpers.

Falling From Height, Injury Severity Score, Survival Time

G55 Suicide in Eastern Crete

Katerina Kanaki, MD*, Researcher, Department of Forensic Sciences, University of Crete, Heraklion, Greece; Ersi Abaci Kalfoglu, PhD, Professor, Institute of Forensic Sciences, University of Istanbul, Istanbul, Turkey; and Manolis Michalodimitrakis, MD, Professor, Department of Forensic Sciences, University of Crete, Heraklion, Greece

The goals of this paper are to present data on suicide cases from autopsy records of the Forensic Sciences Department of the University of Crete, during the years 1997-2001 and to inform the forensic community of the variation extent of parameters like sex, age, time, and method of suicide.

Introduction: When pain exceeds pain-coping resources, suicidal feelings are the result. Suicide prevention programs try to lower the incidence of the event but it is still a serious public health problem. It is well known that geographic variation and ethnic composition are very important parameters affecting suicide. This study is an attempt to provide detailed information of the present situation in Eastern Crete and try to find the slope of the relationship between the suicide cases in this area and the rest of the country.

Methods/Results: Data collection involved medico-legal records of completed suicide cases from January 1, 1997 to December 31, 2001. A total of 139 records were reviewed. Results indicated that 25.18% of the victims in successful suicides were females and 74.82% were males. Spring was the period of the year with the most elevated numbers and the highest month recorded was May. Of the cases reviewed, 15.82% of suicides were under the influence of alcohol and 8.63% under the influence of illegal drugs. Only one case under the age of 20 years old was observed, whereas in the U.S. approximately three fourths of all deaths among persons aged 10-24 years result from only four causes: motor vehicle crashes, other unintentional injuries, or homicide and suicide. Suicide rates among elderly were found to be low. A finding that is quite contradictory with the rest of Europe where the suicide cases in elderly are approximately equal to the youth levels. Suicide methods were mostly violent. The most frequent method was hanging, seen in the 36.69% of the all cases followed by fatal poisoning with an incidence of 29.5%. Poisoning was generally the result of pesticide ingestion and was very widely used by females. The use of firearms forms 13.67% of the cases and is used exclusively by males. Although some studies indicate that rural men of all ages are twice as likely to commit suicides as their urban counterparts, the authors' study showed that 79.14% of suicides occurred in Heraklion the mostly populated city of Crete.

Conclusion: Suicidal events are initiated in order to change the contents of awareness of personal existence. Potential victims regard their lives as having unacceptable values because their understanding of meanings converges on a self defined criteria for which death is preferable. As this convergence approaches congruence, the wish to return to an earlier more satisfying state is approximated by a wish to die. The facts of termination and the occurrence of a physical death are expected to change distressing awareness without causing cessation of all awareness. Even those who deny life after death will imply that nothing will feel better than the present situation. However, there is always a window of opportunity to introduce prevention efforts. The authors believe that reliable and valid data of the present situation in an area will be beneficial in combating this very serious problem and establishing prevention programs.

Suicide, Crete, Autopsy

G56 Postmortem Findings in 22 Victims Due to Two Grain Silo Explosions in France

Sophie Gromb, MD, JD, PhD, and Koffi Bott, Service of Forensic Sciences, University of Bordeaux, Bordeaux, France; and Alain Miras, MD, University of Lyon, IML Avenue Rockefeller, Lyon, France*

The goals of this presentation are to describe and recognize the injuries and types of wounds resulting from explosions.

Silos located on industrial sites in Metz and Blaye, France and containing barley grain exploded; the first on October 18, 1992 in Metz and the second on August 20, 1997 in Blaye. In total there were 25 victims including 23 deaths (12 in Metz, 11 in Blaye) and one survivor in each case. This retrospective study concerns 22 cases, 11 at each site.

All 22 victims had multiple lesions due to the explosion and its consequences. The lesions demonstrated the effect of the blast associated with falling and projection of concrete fragments, heat, intoxication, and asphyxia. Death was instantaneous for all victims except one in whom the autopsy findings and complementary tests suggested an extremely

short period of survival. The role of the forensic doctor is therefore essential and should be included in emergency plans in order to facilitate the initial assessment, shorten the time taken to identify the victims, and improve thanatological procedures. Although dust explosions in agro-business plants, particularly cereal units, are becoming more and more frequent, postmortem data are rare in the literature.

Explosion, Postmortem Findings, Injury

G57 Injuries of an Armored Vehicle Occupant During Armed Robbery: A Case Report

Giancarlo Di Vella, MD, PhD, Rosa Falamingo, MD, PhD, Maura Belviso, MD, PhD, and Francesco Vinci, MD, Section of Legal Medicine - University of Bari - Italy, Policlinico, piazza G Cesare, 70124 – Bari, Italy*

The goal of this case report is to illustrate, by means of text and photographs, peculiar passenger injuries related to gunshot damage of the parts of an armored vehicle.

Armour plating is a system of reinforcement of a vehicle designed to protect passengers from attacks perpetrated from the outside for various purposes (robbery of valuables, homicide, abduction, car theft, etc.). The vehicle is usually built in such a way as to resist penetration by bullets from firearms. However, hi-powered military guns can damage the vehicle's structural parts and may cause high velocity fragments (secondary bullets) to be projected, which can seriously wound passengers. The authors report the results of an investigation carried out to establish the dynamics of the wounding of a policeman seated in a valuable transport van during a robbery.

In June 2002, along a main road in the district of Bari, a Fiat Ducato armored van was assaulted by unknown muggers and was robbed of a large sum of money. After the robbery, 25 cartridge shells were found lying in the road belonging to three different military weapons (a .223 Remington automatic rifle and two 7.62x39 Kalashnikov assault rifles). One of the members of the crew inside the van was wounded in the right buttock, diagnosed at the hospital E.R. as a firearm injury with retention of the bullet. The victim underwent surgery to extract the foreign body, a steel rod with an irregular circular section of about 7 mm in diameter and 3 mm in thickness with a concave surface while the other convex side was lined by thin parallel longitudinal stripes. These features excluded the possibility that this metal fragment could be a component of a firearm cartridge. Inspection of the van revealed no less than 29 points of bullet damage; 7 of these had struck glass surfaces (the windscreen and left back window) without breaking them, and the others had pierced the metal bodywork of the vehicle; 7 in the posterior part; 5 in the anterior part; and 10 in the left lateral part (including the driver's door). The 7 holes discovered in the rear of the vehicle were regular in shape, almost perfectly circular, with clean borders and a diameter of around 6 mm; all the other holes had different characteristics (irregular shape, 8-9 mm diameter, etc.). Further examination of the rear part of the vehicle showed that two bullets had reached and penetrated the armor plating protecting the cabin, perforating the backs of the anterior seats; the right one was completely pierced and blood stains were found on the anterior covering. The two seats were removed and disassembled; in the back of the left seat two very small metallic fragments were recovered. Nothing was found in the back of the right seat. The above data enabled the authors to conclude that one of the .223 Remington bullet had penetrated the rear part of the vehicle, with a horizontal trajectory, and detached the fragment of armor plating that had wounded the victim.

The recommended strategies for accurately determining causes of injury are discussed, including ballistic and medical data that have to be considered and evaluated in order to gain an overview of the mechanisms underlying injury of armored vehicle occupants.

Armed Robbery Assault, Armored Vehicle, Occupant Injuries

G58 Roll-Over Automobile Accident Survived By the Author as a Passenger

Gordon K. Murphy, MD, 814 Hathaway Road, Dayton, OH*

The attendee to this presentation will learn that most transportation accidents are multifactorial and that 3-point restraints are very effective in preventing serious injuries and deaths in vehicular accidents.

Trained investigators and attorneys recognize that most, if not all, transportation accidents are multifactorial. Rarely does a survivor of a vehicular accident such as this have both the desire, and the opportunity to document the scene of the accident and the condition of the vehicle soon after the event. Images of vehicle and scene will be presented.

In England, four friends took a day trip by automobile in late winter. The owner and driver of the 1992 Toyota Carina 4DS was a 76-year-old male. Three friends accompanied him, the author in the left rear seat. The owner-driver drove about 184 miles with several stops on two-lane roads in cold wind and rain. The destination was reached in late afternoon. The return trip was begun at about 7:30 p.m. on two-lane roads and in pitch-dark and rain.

Nearing the driver's home and on a straight, smooth, two-lane asphalt road, he allowed both left-side wheels to suddenly fall onto the shoulder. He quickly over-corrected with the car sliding right and into the center of the road. Over-correcting again to the left, the driver narrowly avoided a telephone pole on the left shoulder as the car left the road and traveled obliquely down a 2-3 foot steep bank turning onto its right side. The right front nosed down into a muddy field, the car then overturning in its longitudinal axis and coming to rest on its top facing the direction of travel. Each occupant was belted; each escaped through his/her window. Three occupants each sustained minor injuries.

The next afternoon, the author obtained the driver's permission to take Kodachromes for teaching purposes. The windshield was extensively cracked, and was detached at its crown. The roof was indented back to the center posts, but passenger space was otherwise preserved. The accident scene was also documented.

Analysis - This accident was clearly multifactorial: 1) an elderly driver with chronic disease, 2) poor weather, 3) driver fatigue, 4) a slick, newly paved road at the accident site, and 5) the driver, once in trouble, over-correcting twice.

Ameliorating factors: 1) speed slowed by braking before leaving the road, 2) no other traffic, 3) driver avoiding the telephone pole, 4) rain-soaked field absorbing roll-over impact, and 5) all passengers were restrained.

Conclusion: A potentially serious multifactorial accident in which the restrained occupants were nonetheless fortunate to survive.

Automobile Accident, Multifactorial, Restraint Systems

G59 Intracranial Internal Carotid Laceration at the Site of an Atherosclerotic Plaque: A Case Report

Kristin Gilmore, MD, Department of Pathology, Kings County Hospital, Brooklyn, NY; David Kindleberger, MD, SUNNY Health Science Center College of Medicine, Brooklyn, NY; and Charles A. Catanese, MD, Office of the Chief Medical Examiner, Brooklyn, NY*

The goals of this paper are to present to the forensic community an unusual injury and an analysis of its mechanism with respect to both trauma and natural disease.

This is a case of a 35-year-old man who received a blow to the face that abruptly and forcefully hyper-extended and rotated his head to the left. Autopsy revealed an intracranial right internal carotid artery laceration extending from a calcified atherosclerotic plaque, with an

associated basilar subarachnoid hematoma. This injury is unusual both because of its intracranial location and because of the presence of the atherosclerotic plaque.

Hyperextension of the head can cause injury to the vessels at the base of the brain. Generally, the extracranial portions of the vessels are affected, and laceration is believed to be caused by the sudden stretching of these vessels due to the abrupt movement of the head. In this case, the intracranial internal carotid is affected, which can be partially explained both by the rotational acceleration of the brain within the cranium as the head moves in response to the blow, and the abrupt increase in intravascular pressure caused by vessel stretching. During hyperextension or rotation of the head, the brain oscillates in the cranium due to its inertia, and this oscillation is opposite to the movement of the head, exposing tethered vessels within the head to shear forces. The quick and exaggerated movement of the head also stretches vessels, particularly those present in the neck, causing an abrupt increase in intravascular pressure that is transmitted to the intracranial portions of the vessels.

The atherosclerotic plaque found at the site of the laceration may also have contributed to the injury. Atherosclerosis has been documented to alter the structural integrity of vessel walls by destroying and altering tissue. Additionally, atherosclerosis changes the elastic property of arterial vessels and therefore lessens their ability to respond to abrupt or large changes in pressure load, with the response being more impaired the greater the pressures applied. Synergistically, the effects of atherosclerosis may have made the intracranial carotid more vulnerable to trauma than a healthy, non-atherosclerotic vessel might have been.

In order to delineate the roles of trauma and natural disease in the formation of this unusual lesion, photographs of the case are shown, and several published references on both traumatic injury to the head and neck vessels and atherosclerosis are reviewed and cited.

Hyperextension, Atherosclerosis, Subarachnoid Hemorrhage

G60 An Unusual Case of Crossbow Homicide

Sabina Di Donato, MD, Marianna Di Padua, MD, Floriana Monciotti, MD, Francesco Maria Morreale, MD, Margherita Neri, MD, and Cristoforo Pomara, MD, Department of Forensic Pathology, University of Foggia, Viale Pinto 1, Foggia, Italy*

The goals of this paper are to present a case of homicide due to a cranial encephalic wound provoked by an unusual lethal means identified also through experimental investigation.

A homicide is presented. A male is first rendered defenseless, blinded by a caustic substance and suffered head and chest wounds by a penetrating weapon missing from the scene of the crime. The peculiarity of the wounds and the scarcity of circumstantial evidence made additional investigation necessary in order to identify the weapon, including firing tests on experimental cranial models, for comparison.

A 52-year-old Caucasian male, a farmer missing from his home for two days, was found in a comatose state by the police in a forest in the Tuscan countryside. No weapon was found at the scene of the crime. The subject was revived in intensive care where wounds from a caustic substance were revealed on the face, eyes, shoulders, and back. In the left occipital region there was a round wound 1 cm in diameter and on the left hemithorax an oval wound 0.8 x 0.3 cm in diameter. The CT cranium revealed a large area of hemorrhage (25-30 cm) in the left temporal-mesial capsular nucleus, with hemo ventricle and shift to the right of the median line, the encephalic trunk appeared compressed with an obliteration of the pons mesencephalic cistern; the CT chest revealed integrity of the pulmonary and cardiac structures. The subject died 98 hours after he was found. The autopic macroscopic exam confirmed the presence of wounds due to liquid burns on the face, eyes, shoulders, and back. The chest revealed, on the cutaneous level, an oval shaped wound,

with the dimensions of 0.8x 0.3 cm. On the skull, in the left occipital region, the scalp revealed an oval shaped wound, 0.8x 0.3 cm in diameter that continued into the soft tissues provoking a small semicircular sternal bone erosion, 0.3 cm in diameter. On the cranium, in the left occipital region, the scalp presented an oval shaped wound, on the main traversal axis, 1x 0.3 cm in diameter, surrounded by traces of reddish color; in correspondence to this wound the left occipital bone revealed a round wound with clean cut outlines, 1 cm in diameter. The frontal left bone presented, on its external surface, an area of irregularly shaped estrous flexions of the bone 1.3 x 1 cm in diameter and, on the internal surface, a round wound with clean cut outlines, not along the entire depth, 0.5 cm in diameter. The brain was sectioned with coronal cuts according to the Pitres technique. The left occipital pole presented a round wound 1cm in diameter along all of the encephalic lining, from the base upwards, crossing the hypothalamic region, the anterior horn of the lateral left ventricle until reaching the left frontal pole, where a round wound, 0.8 cm in diameter, was present. The entire distance from the left occipital region to the frontal left bone measures 23 cm. The histological findings of the brain revealed subarachnoid and intraparenchymatous hemorrhage, "red neurons," diffuses axonal damage, confirmed by the positive results to the immunohistochemical dye for amyloid precursor protein (BAPP). According to the findings from the sectioning table it was possible to conclude that judging from the position and extension of the caustic wounds, acid was used to render the subject defenseless and successively strike him with greater ease. The chest wound was attributed to the use of a weapon with a pointed apex and scarce penetrating potential (2-3cm). In the cranium, the penetrating weapon once perforating the left occipital bone completely penetrated the brain and terminated in correspondence with the frontal bone, where it did not have the necessary force to completely perforate it. These findings permitted the authors to direct the investigation towards identifying a long penetrating object, 1cm in diameter and not less than 15 cm in length. It must have been animated by a weapon supplying the necessary force to penetrate the bone surface in such a clean cut manner and the cerebral substance so deeply; also it must allow a manual extraction of the arrow or dart, or one via automatic mechanisms of return, incorporated in the weapon utilized. The hypothetical weapon compatible with similar penetrating means must be capable of firing a manually extractable dart (crossbow, bow, spear gun, etc) similar to the pistols used for animal slaughtering with captive bolt. In order to establish the lethal weapon, firing tests were effected utilizing both mechanisms and, in particular, a Bernet "Wildcat II" model crossbow with a 150 pound bow, loaded with a 38 cm long, 1cm in diameter aluminum arrow with a conical head of the same diameter and a captive bolt pistol with a 20 cm long, 1 cm in diameter stylus loaded with caliber 22 ammunition, a model conventionally utilized in many Italian slaughterhouses. Experimental models of human craniums were constructed using plaster to simulate the bone structure and filled with a synthetic spongy material, easily penetrable, but minimally resistant, in order to reproduce the brain. The test with the crossbow, from a distance of 12 cm, produced a wound perfectly compatible with the postmortem data. The test with a captive bolt pistol resulted compatible with the wounds observed in the postmortem examination only if a modified weapon was utilized (a. with a prolonged external stylus, b. removal of the blocks that limit the internal path of the stylus) producing a 23cm wound, much longer than the 7-9 cm normally produced by common pistols used for slaughtering animals. The wounds produced in the experimental models with both types of weapon have characteristics compatible with those observed in the cranium of the subject, however the captive bolt pistol created a wound superior to 21 cm only when subject to difficult handmade modifications of the weapon, possible but extremely complicated. These data led the authors to consider as feasible the hypothesis of a manually extracted dart. Thanks to this technical support and to testimonial evidence some months after the homicide, the investigation led to the arrest of an individual. A search of his property produced a

crossbow and modified metal crossbow arrows (removal of the head and filing of the penetrating extremity, positioning of the distal extremity of a device that facilitates manual extraction of the arrow). According to the postmortem findings and observation of experimental data, the sequestered crossbow and arrows proved to be the most probable scientific hypothesis of the weapon utilized for the crime. Only few cases of wounds due to crossbow mostly accidental or suicidal and rarely homicidal are reported, therefore, this rare case of homicide due to crossbow seems even more unique if the combined use of caustic substances to render the victim defenseless and the penetrating device (arrow) was not found on the scene of the crime was considered.

Homicide, Crossbow, Caustics

G61 Body Found in the Waterway of Lille—Accident, Suicide, or Homicide?

Gilles Tournel, MD, Sandrine Gaulon, Anne Becart-Robert, DDS, Valéry Hedouin, MD, and Didier Gosset, MD, PhD, Forensic Department, Institut de Médecine Légale de Lille, Lille, France*

The authors report the case of a man found in a waterway and discuss the differential diagnosis for bodies found in water. These data are compared to those of the literature.

History: On June 20, 2002, a 42-year-old man is found floating face down in the waterway of Lille, France. At 8:00 p.m., a forensic pathologist performs a first examination at the edge of the waterway. He observes several wounds on the face with fracture to the skull and a peri-orbital bruise. The lesions are recent and could be attributed to a boat's propellers. This waterway is used as a barge crossing. There is a large brown bruise at right thoracic area. There is no suicide letter found and the man has no history of depression. An Autopsy is performed the next day and time of the death is estimated during preceding night.

Autopsy findings: The cadaver is not putrefied and is easily identified. The lesions on the face are not parallel. Some are small and blood flows out the wounds. The lesions have vital characteristics. Two hypotheses are considered: 1) the barge's propellers created the face lesions while he was still alive or 2) he was thrown in the waterway dead. The skull examination confirmed the second hypothesis. The brain was contuse with lesions. A round wound is observed. An entrance wound is present on the right temporal area and an exit wound is seen on left parietal area. This case was classified as a homicide. On X-Ray, no foreign bodies are found. All lesions on the face were penetrating. The cause of death is a hemorrhage of the brain with bruises.. After investigation by the police, the aggressor was found. He is a 40-year-old man. He reported that he used a large tool to strike the decedent in the head and face in a garage.

Discussion: A body recovered from water presents many challenges to the forensic pathologist. Drowning is a diagnosis based upon the circumstances surrounding the death with exclusion of other causes of death. Often, identification of subjects is complicated by decomposition. As in this case, the determination of cause and manner of death can be a daunting challenge. Moreover, many of the essential questions surrounding water deaths are answered after performing an autopsy. Was the individual alive prior to entering water is the essential question.

This case is a good illustration. The diagnosis of drowning is one of exclusion. Most of drowning deaths are accidental. This case was compared to suicides by drowning. The characteristics are studied to point out the difference between homicide and suicide during the crime scene investigation. The importance of crime scene investigations is reviewed. This case illustrates the difficulties in obtaining forensic evidence to conclude a homicide or suicide. Characteristics of skull bones lesions were compared to discover the important time of immersion with lesions as in this case. The characteristics of these lesions are important to when reviewing a subject without putrefactive changes.

Homicide, Drowning, Autopsy

G62 Pink Teeth in a Series of Bodies Recovered From a Single Shipwreck

Carlo Pietro Campobasso, MD, PhD, Giancarlo Di Vella, MD, PhD, and Antonio De Donno, MD, Section of Legal Medicine, University of Bari, Piazza Giulio Cesare, Bari, Italy; Giorgia Girone, DDS, and Gianfranco Favia, MD, School of Dentistry, University of Bari, Piazza Giulio Cesare, Bari, Italy; and Francesco Intronà, MD, Section of Legal Medicine, University of Bari, Piazza Giulio Cesare, Bari, Italy*

The goals of this presentation are to review the causes and distribution of the phenomenon of pink teeth among a series of bodies.

Pink staining of the teeth is more common in victims where sudden death occurred because the blood can remain liquid due to increased fibrinolytic activity. Hemoglobin is the most likely pigment responsible for this postmortem process that can be considered analogous to postmortem lividity. In fact, there is general agreement that the first requirement for the occurrence of pink teeth is an increase of blood in the pulp. All the reports on pink teeth indicate that the diffusion of the blood in the pulp into the dentinal tubules causes the red discoloration of the teeth; this seems to be favored mainly by blood accumulation in the head either due to congestion (as observed in prefinal insufficiency of the right heart) or a postmortem head-down position (as in cadavers floating with their head in a downward position).

Pink teeth have most often been observed in victims of drowning but have also been reported in subjects who died suddenly and unnaturally by strangulation, hanging, knifing, and carbon monoxide poisoning. Since there is no obvious connection between the occurrence of pink teeth and the cause of death, the condition of the surroundings (especially humidity and temperature) must certainly play an important role in the development of pink teeth. This is supported by the fact that the majority of the cases described in the literature were exposed to a wet or moist environment, most having been recovered directly from the sea. The existence of water or a high concentration of aqueous solution intimately surrounding the teeth is one of the most important requirements for this postmortem phenomenon. Further prerequisites are hemolysis either by autolysis or by osmosis leading to subsequent diffusion of hemoglobin into the dentinal tubules.

Since in some of the retrospective studies not all jaws and/or teeth may have been examined thoroughly, the real frequency and distribution of the phenomenon remains unknown. In fact, forensic pathologists must have observed that the distribution of pink teeth can vary in a mouth and not all teeth are necessarily involved. The purpose of the present investigation is to study the frequency and distribution of postmortem pink coloration of the teeth among a representative sample of 52 cadavers. All bodies were victims of a single shipwreck, which occurred on March 13, 1997 in the middle of the Otranto Canal (Mediterranean Sea). An Albanian ship trying to land clandestinely on the Southern Italian coast sank following a collision with an Italian Navy warship patrolling the border. All the passengers in the four holds died as the ship was engulfed and settled on the bottom of the sea at a depth of 800 meters. The bodies were recovered from the seawater on October 21,

1997 after approximately seven months. All the cadavers shared the same cause of death (drowning), the same storage time in water (7 months) and identical environmental conditions (the temperature of the water at 800 meters depth was 4°C). A team of forensic pathologists carried out the pathological examinations while two forensic odontologists performed all odontological examinations separately and at different times. Sex, age, degree of decomposition, and dental examination were registered for each cadaver. A distinct pink coloration of the teeth was found in only 23 cadavers (17 females and 6 males) of ages ranging between 13 and 60-years. The average age of the deceased was 27 years in accordance with the fact that the phenomenon is more pronounced in younger individuals because the dentinal tubules become narrower or are obliterated with age and are less penetrable by the pigment responsible for postmortem pink staining. It was also possible to confirm another common observation that the pigmentation is more prominent on the anterior teeth with single roots than in the posterior teeth with multiple roots. Using histochemical methods the causative pigment was also identified as hemoglobin and/or its derivatives.

Pink Teeth, Postmortem Staining, Marine Environment

G63 Calcified Primary and Metastatic Pancreatic Carcinoma Discovered in Skeletonized Remains

Joseph P. O'Hara, MD, and Debra Komar, PhD, University of New Mexico Health Sciences Center, Office of the Medical Investigator, Albuquerque, NM*

The goals of this presentation are to report a case of interest detailing the unexpected discovery of calcified masses during reduction of a body to bone for anthropologic study

Calcification in adenocarcinoma is not unusual and is reported to occur in many types of gastrointestinal neoplasia. Calcification associated with pancreatic carcinoma has been reported in the context of both discrete calculi formation and diffuse calcifications. Calculi are usually described within pancreatic ducts proximal to the tumor mass, presumably as a function of obstruction. However, stone formation has also been reported to precede identifiable carcinoma, making the causal and temporal relationship a topic of debate. Diffuse calcification of a tumor mass, surmised to be a type of calcinosis, is described in both primary and metastatic sites. Diffuse calcification in pancreatic neoplasia is described largely as either peripheral plaques or central, irregular nodules. This is a report of an archival case of calcified pancreatic cancer that is unusual with regards to the nature of the calcified masses and the circumstances in which they were discovered and obtained. Two relatively large, previously undetected finely trabeculated hard masses representing the calcified remains of the primary tumor and a hepatic metastatic focus were retrieved after the rendering of retained remains to bone for the purpose of anthropologic study.

A 76-year-old female first reported acute symptoms of weight loss, epigastric pain and nausea to her family physician in April of 1978. A diagnosis of cholelithiasis was made at that time. She was temporarily lost to follow up for one year and was eventually admitted for work-up and evaluation of her progressive epigastric pain. During her admission history she reported marked weight loss over several years that she attributed to poor diet. A history of pancreatitis was denied. Abnormal findings upon physical exam included a pelvic mass, hypokalemia, anemia, and malnutrition. There is no record of abnormal calcium metabolism or radiologically identified abnormal calcifications. An exploratory laparotomy was performed that revealed an inoperable carcinoma of the head of the pancreas resulting in palliative care. Her clinical course deteriorated until she was found to be unresponsive. An autopsy was not performed.

Since the body was not claimed, New Mexico State law provided for the retention of the remains for medical education purposes via the Department of Anthropology, Forensic Division, The University of New Mexico. In August 1979, the process of reduction to skeletal remains began. During the cut-down procedure, the initial harvesting of bones from the decomposed remains, previously undetected hard masses were found in the pancreas and liver. These were retained for continued enzymatic flesh removal. Subsequently, two calcified masses and a smaller dense stone were recovered. Current study of the archived stones revealed a 19.8-gram ovoid, white, trabecular, hard mass measuring 5.6 x 4.3 x 3.9 cm and a smaller, similar curved mass that measured 2.7 x 2.1 x 2.0 cm and weighed 4.5 grams. Chemical analysis of the masses revealed a composition of calcium carbonate. The small dense gallstone was rough, ovoid, light brown and measured 1.9 x 1.4 x 1.2 cm.

The calcifications in this case are unique in that they are apparently completely calcified primary and metastatic tumor masses that were not detected during medical evaluation. The masses consist of calcium carbonate in a lattice-like pattern recapitulating the extra-cellular space of the tumor. In the literature, calcifications in pancreatic neoplasia are commonly described as discrete nodular calcifications or peripheral plaques. The architectural complexity of the calcifications in this case is noteworthy. Since an autopsy was not performed, the discovery of hard hepatic and pancreatic masses during the initial bone harvest was unexpected. Although, there was a 5-month interval between death and discovery of the masses, it is unlikely that this represents some type of post-mortem calcification. It is probable that evidence of the existing calcifications was either lost or not collected. Viewed from the standpoint of forensic anthropology, this case begs a different type of question. It can be speculated whether a positive identification would have been made if this were a case of discovered skeletal remains including the two calcified masses, given the above medical history of a missing person.

Pancreatic Cancer, Skeletal Remains, Forensic Science

G64 Undefeated by Surgery: The Utility of Post-Surgical Foot and Ankle Radiographs for Identification: Focus on the Ankle

Dorothy E. Dean, MD*, Franklin County Coroner's Office, Columbus, OH; Nancy E. Tatarek, PhD, Ohio University, Athens, OH; Jeremy Rich, DPM, Brigham and Women's Hospital, Boston, MA; Robert H. Powers, PhD, Hamilton County Coroner's Office, Cincinnati, OH; B.G. Brogdon, MD, University of South Alabama Medical Center, Mobile, AL; and Bradley J. Lewis, MD, Franklin County Coroner's Office., Columbuzs, OH

After attending this presentation, the participant will 1) understand that radiographic comparisons of the ankle for positive identification can reliably be made even if there has been an alteration in the anatomy, 2) be able to quantitatively evaluate the "matchability" of such an identification, and 3) be able to recognize when such a comparison may be limited and more information is required before an opinion can be rendered.

Foot and ankle radiographs can be utilized as a basis of identification in forensic investigations. This type of information may be especially useful when examining fragmented, mutilated, and decomposed remains. The process of radiographic comparison is usually binary in nature, yielding a "yes" or "no" answer to the question: within a reasonable degree of medical certainty, did these radiographs come from the same individual? The authors have previously outlined, with respect to the foot, a quantitative method of reporting results, allowing for a systematic approach to the identification process. The same method had been applied in this study. This study focuses on the bones of the ankle joint; specifically, the talus and the distal segments of the tibia and fibula.

Experimentally, 53 sets of pre-surgical (antemortem) and post-surgical (simulating postmortem) radiographs of the foot and ankle were obtained from a tertiary care medical center. Up to four different radiographic views were considered: lateral, medial oblique (MO), ankle mortise, and antero-posterior (AP) projections. As in the previous study, the radiographs were not actual antemortem and postmortem radiographs, rather a simulation utilizing radiographs taken in the course of routine medical care. Sets of radiographs were selected by one of the authors, and included both legitimate matches and actual mismatches to simulate forensic context. The time lapse between the antemortem and simulated postmortem radiographs included a surgical procedure on the foot and / or ankle, and ranged from 2 months to 48 months allowing for alteration in anatomy by surgical repair and subsequent healing. As in the previous study, the authors wished to evaluate and grade, by a numeric system, the reliability of the match results. Radiograph sets were compared by two of the authors (NET and DED). Ten characteristic skeletal features were considered in the simulated postmortem radiographs. The antemortem radiographs were then evaluated for the same features. The results were scored as follows:

- (+1): If the feature was present and matched.
- (0): If the feature was either not present or its presence could not be determined.
- (-1): If the feature was present, but did not match, or (-1) if the trait was present in either the pre- or post-surgical radiograph but not both.

The radiographic sets were then independently evaluated, considering only the ankle joint, according to the medicolegal standard, "with a reasonable degree of medical certainty, these radiographs came from or did not come from the same person". Additionally, it was noted if there was not enough data visible in the ankle joint portion of these radiographs to determine a positive identification. Spearman correlation coefficients, to measure how the two methods of evaluating correlate, were calculated from the raw data.

Results were consistent with previous studies, and indicate that surgical intervention with subsequent healing does not preclude positive identification in foot and ankle radiographic comparisons. However, because the ankle joint is structurally less complex than the foot it contains fewer features that may provide the basis for identification.

Forensic Pathology, Human Identification, Ankle

G65 To Rave or Not to Rave: A Report of Three Fatal GHB Poisonings

John R. Fernandes, MDCM*, Regional Forensic Unit, 237 Barton Street East, Hamilton, Ontario, Canada; Marcella F. Fierro, MD, Office of Chief Medical Examiner, 400 East Jackson Street, Richmond, VA; and James Cairns, DRCOG, Office of Chief Coroner, 26 Brevoire Street, Toronto, Ontario, Canada

Gamma-hydroxybutyrate (GHB) has surfaced in the "rave" and "club" scene as a recreational drug, which is believed by users to be safe. There are increasing reports of near fatal and the occasional fatal outcomes of the use of this drug. It is simple to make, has euphoric effects, and has associated amnesiac effects, which make it an ideal candidate for use in the arena of date rape.

This report is of three deaths where GHB was the primary or sole toxic agent. In one case, death resulted from a suicidal consumption of drug where polypharmacology played a role. In the second case, hypothermia was a significant contributor to the cause of death. The third fatal case represents an accidental, isolated drug poisoning.

All blood samples obtained and analyzed were autopsy or admission blood and stored in sodium fluoride (NaF). Analyses were by liquid chromatography in the laboratory of Hospital for Sick Children in Toronto for Cases 1 and 2 and in the Virginia Division of Forensic Sciences in Case 3.

Results identified the levels of GHB to be: Case 1: 690 mg/L, Case 2: 55 mg/L, Case 3: 269 mg/L.

While GHB may be produced postmortem and may also be identified as a normal metabolite especially in the central nervous system, levels detected in these three decedents were well into the fatal ranges. The overlap with survivable intoxication is large. Why some individuals die with lower concentrations is unclear. Combination with other drugs or environmental conditions as in Case 1 and 2 respectively may have resulted in enhanced toxicity.

While GHB compared to other illicit drugs such as cocaine, opiates, or alcohol appears to be less serious to users, the clinical presentation of toxicity including death needs to be recognized by clinicians involved in the care of these patients. Pathologists performing forensic autopsies need to be aware of the use of this drug by this group of at risk individuals.

Samples from autopsy with subsequent testing of well preserved blood (in NaF), urine, and tissue needs to be processed in a laboratory geared to the identification of this drug. Interpretation of results must bear in mind the natural production of GHB for correct conclusions to be reached.

Lastly the dangers and legal implications of the use of GHB in date rape situations need to be remembered.

GHB, Fatality, Rave

G66 Methadone-Related Deaths in Palm Beach County

Barbara C. Wolf, MD, Palm Beach County Medical Examiner's Office, 6065 Ellis Lane, Loxahatchee, FL; Wendy A. Lavezzi, MD, Albany Medical College, 47 New Scotland Avenue, Albany, NY; and Lisa M. Flannagan, MD, Palm Beach County Medical Examiner's Office, 3126 Gun Club Road, West Palm Beach, FL*

The goals of this presentation are to examine the role of methadone in drug-related deaths in Palm Beach County from 1998 to 2002.

Methadone is a long acting oral opioid agonist used therapeutically to treat opiate dependency and in the management of chronic pain. Recent media accounts of an increase in the number of deaths attributed to methadone toxicity in Palm Beach County, FL, particularly among teenagers, have raised public concern over the illicit use of the drug. The authors examined cases investigated by the Palm Beach County Medical Examiner's Office over the period from 1998 to 2002 in which post-mortem toxicologic studies indicated the presence of methadone, to examine the role of the drug in these deaths. The reports of the post-mortem examinations and toxicologic studies and the investigative reports were reviewed.

Identified were 70 methadone-positive cases. There was a dramatic increase in the number of cases during the period, from 2 cases in 1998 to 37 cases in 2001 and 18 cases in the first quarter of 2002. The cases included 57 males and 13 females. Ages ranged from 16 to 72 years (mean 37.1 years). All decedents were white except for one black male. Methadone had been prescribed for chronic pain to 16 of the decedents. There were no cases in which the decedent was known to be enrolled in a methadone maintenance program.

The methadone-positive cases included 57 in which the death was classified as an accident due to drug toxicity. In 12 of these cases the cause of death was attributed to methadone toxicity alone and in 35 cases methadone was identified as contributing in combined drug toxicity. Non-toxic levels of other drugs were present in 9 of the methadone toxicity cases. Cocaine and/or cocaine metabolites were identified in 27 of the 36 cases of combined drug toxicity, morphine in 9 (5/9 with 6-MAM), oxycodone in 8 and ethanol in 8, with blood alcohol levels

ranging from 0.024-0.183 G/dL (mean 0.095 G/dL). In 23 deaths methadone was detected but was considered to be an incidental finding. These included 9 deaths attributed to other drugs and 13 to non-drug related causes (5 natural, 3 suicide, 4 accident due to trauma, and 1 undetermined gunshot wound). Methadone was detected only in the urine in six cases.

There was considerable overlap in the postmortem blood methadone levels among the groups. Levels ranged from .114-.984 mg/L (mean .430 mg/L) in cases where death was attributed to methadone toxicity; trace-1.243 mg/L (mean .331 mg/L) in cases of combined drug toxicity; .069-.664 (mean .242 mg/L) in deaths attributed to other drugs; and .072-.782 mg/L (mean .303 mg/L) among non-drug related deaths.

Data indicates that most deaths in which methadone plays a role are due to the use of the drug in conjunction with other prescription or illicit drugs. Establishing the role of methadone in these cases can be difficult in light of the other drugs present. The levels of methadone detected in these cases indicate that it may not be possible to determine what constitutes a lethal methadone range since the majority of cases involved drug interactions and since individuals may have different levels of susceptibility and/or tolerance. However, the data demonstrate that death can occur at methadone levels below the previously reported lethal ranges. Determination of the cause of death in methadone-positive cases necessitates correlation of the postmortem toxicologic results with autopsy results and investigative findings.

It is possible that the increase in methadone-related deaths may be in part due to more physicians prescribing the drug in light of the recent recognition of the hazards of other analgesics such as oxycodone. Street users of methadone may be unaware of its long half-life, with frequent use resulting in its accumulation to dangerous levels.

Methadone, Death, Drug Levels

G67 Comparison of the Distribution of Fentanyl in Deaths Related to Use and Abuse of the Duragesic® Patch and Intravenous Administration of Patch Contents

Jaime L. Oeberst, MD, and Timothy P. Rohrig, PhD, Sedgwick County Regional Forensic Science Center, 1109 North Minneapolis, Wichita, KS*

The goals of this presentation are to provide the audience post-mortem distribution data of fentanyl relating to its route of administration

Fentanyl is a synthetic narcotic analgesic of high potency and short duration that has been in clinical use since 1963. Initially the drug was used as an adjunct to surgical anesthesia. The transdermal fentanyl system, under the trade name of Duragesic®, was developed for chronic pain control. The product labeling for the patch states that it is a schedule II controlled substance that can produce drug dependence similar to that produced by morphine. The transdermal system allows for the maintenance of a relatively even steady state blood concentration. The patches are available in three dosage forms: 25, 50, and 100 mcg/hr. Because of its relatively short half live of 3 ½ hours and high potency, an addicted individual is likely to constantly seek a source (supply) of the drug. The Sedgwick County Regional Forensic Science Center has seen increasing numbers of cases where death was due to or related to use and abuse of the Duragesic® patch.

The 6 individuals in this series, 3 males and 3 females, ranged in ages from 30 to 53 years of age. All were Caucasian. Five of the decedents were reported to have chronic pain syndrome: fibromyalgia, lower

back pain, chronic headaches, Crohn's disease, and pain due to remote blunt force injuries from a traffic accident. Three of the individuals had been prescribed the Duragesic® patch as part of their pain management therapy. The patch had been obtained by 2 individuals without a prescription. The prescription history of the last individual was not known. Found dead in bed were 2 decedents, 1 of the decedents was found obtunded in bed and died a short time later, and the 3 remaining decedents were found dead either seated or lying on a couch or chair.

On external examination, 2 individuals had transdermal patches on their trunk, 1 of the individuals, a 45-year-old white male had 6 100 mcg/hr patches on his lower chest/upper abdomen, 1 decedent from another county had the patch removed at the scene of death, and 3 of the decedents had injected the patch contents intravenously.

At autopsy, 4 of the individuals had bilateral pulmonary congestion; 3 had aspirated gastric contents. All the decedents had mild to moderate cardiomegaly with heart weights ranging from 370 g to 470 g. In one case, coronary artery atherosclerosis was listed as a contributory cause of death. All of the individuals with a history of intravenous injection of the patch contents had extensive amounts of polarizable material in the lungs on histologic examination.

Toxic effects of fentanyl were listed as the cause of death in 3 of the cases. The cause of death for the remainder of the cases was mixed drug intoxication. Toxicological analyses revealed multiple prescription medications in 5 of the 6 cases. Toxicological analysis in one case revealed the presence of benzoylecognine, fentanyl and amphetamine. The presence of ethanol was detected in only one case.

The analysis of fentanyl (identification and quantitation) was accomplished by gas chromatography-mass spectrometry in the selective ion-monitoring (SIM) mode.

The average postmortem blood/tissue distribution of the "patch" cases were as follows: heart blood, 13.3 ng/ml (range 4-25); femoral blood, 10.3 ng/ml (range 4-18); vitreous, 10.0 ng/ml (range 3-14); brain, 32.0 ng/g (range 12-52); and liver, 35.6 ng/g (range 28-42). The average postmortem blood/tissue distribution of the "IV" cases were as follows: heart blood, 11.3 ng/ml (range 5-17); femoral blood, 4.0 ng.ml (range 2-7); vitreous, 3.3 ng/ml (range <2-5); brain, 26.6 ng/g (range 21-34; and liver, 25.6 ng/g (range 11-38).

Fentanyl concentrations did exhibit site dependency. The average heart/femoral blood concentration in the "patch" cases was 1.2 (range 1-1.3); whereas the "IV" cases demonstrated a greater concentration, averaging 3.3.

The data from these case studies demonstrates that the distribution of the fentanyl is similar, irrespective of the two common routes of administration: transdermal absorption or intravenous injection of the patch contents.

Duragesic®, Fentanyl, Postmortem Distribution

G68 Sufentanil Toxicity in Healthcare Professionals

Douglas Posey, MD, Joye M. Carter, MD, and Jessie Adame, MD, Harris County Medical Examiner Office, 1885 Old Spanish Trail, Houston, TX; and Ashraf Mozayani, PharmD, PhD, Autopsy and Pathology Services, Inc., P.O. Box 920903, Houston, TX*

The goals of this paper are to present to the forensic community an awareness of two recent cases of sufentanil toxicity involving healthcare professionals.

This presentation demonstrates two autopsy cases from the Harris County Medical Examiner's Office involving sufentanil toxicity among healthcare professionals. Sufentanil citrate is available under its generic name of sufentanil and is often used in the surgical suite by anesthesiologists as an adjunct to general anesthesia. Sufentanil is available in Dosette ampules of 50-mcg/1 ml, 100-mcg/2 ml, and 250-mcg/5 ml. It is a Class II controlled synthetic narcotic, which is about 5 to 7 times as potent as fentanyl and 500 to 800 times as potent as morphine. The usual adult dose is 1 to 2 mcg/kg. Supplemental doses of 10 to 25 mcg may be given as needed. Profound analgesia is achieved with doses of 2 to 8 mcg/kg. Deep general anesthesia is achieved with doses of 8 to 30 mcg/kg. Sufentanil easily crosses the blood-brain barrier and is quickly routed to body tissues. After 24 hours, approximately 80% of the drug dose is excreted in the urine. Sufentanil is metabolized into N-desmethylsufentanil and O-desmethylsufentanil. Approximately 30% of a dose metabolizes as conjugates in both urine and feces. Sufentanil has a number of toxic effects including respiratory depression, acute respiratory arrest, seizures, hypotension (also sudden hypotension), euphoria, dizziness, muscle rigidity, drowsiness, nausea, vomiting, bradycardia, and irregular heartbeat. The literature reports 2 deaths in adults after self intravenous administration of sufentanil indicating blood levels of 1.1 and 7.0 mcg/L and liver levels of 1.8 and 3.4 mcg/L. It is not clear if these adults were healthcare professionals.

The following are details of two cases involving sufentanil toxicity that have occurred in less than a two-month period. Case one is a 41-year-old Caucasian male anesthesiologist who was found, in the bathroom, sitting on the toilet with his pants on and unresponsive. An empty syringe was found inside a dry beer can. A small vial of sufentanil 50 mcg, ¾ empty, was found in the bathroom. The autopsy findings included: a recent injection site in the left antecubital fossa with a 3/8 inch hematoma, cardiomegaly (450 grams) with moderate atherosclerotic cardiovascular disease, bilateral pulmonary edema and congestion, hepatomegaly (2550 grams), and erosions of the gastric mucosa.

Case two is a 34-year-old Caucasian male registered nurse who was found at work in the ladies bathroom face down on the floor with his pants and underwear down around his ankles. In addition to the 1 opened ampule of sufentanil, 15 different ampules, vials, and bottles of medications were found in the bathroom. In addition, 1 previously used syringe with needle and cap was found at the scene. The autopsy findings included: bilateral injection sites on the medial thighs, cardiomegaly (550 grams) with right ventricular dilatation and concentric left ventricular hypertrophy, and hepatomegaly (2400 grams).

Sufentanil can be assessed in the laboratory by multiple methods including gas chromatography with nitrogen specific detection, radioimmunoassay, and gas chromatography-mass spectrometry (GC-MS). The blood analysis for sufentanil was identified and quantitated by GC-MS method. Biological specimens were made alkaline (pH 13) using 2N, NaOH. Sufentanil was extracted using a mixture of hexane:ethanol (19:1). D5-fentanyl was used as an internal standard. The dried extracts samples were injected onto the GC-MS and the ions 250, target ions, 194, 195, 151 for D5-fentanyl and 250 (target ion), 290, 291, 140 for sufentanil were monitored. Postmortem blood in case one was positive for ethanol 0.12 g/dL and sufentanil 2.95 mcg/L. The syringe wash was also positive for sufentanil. No other drugs were identified. In case 2, sufentanil was the only compound in concentration of 2.63 mcg/L. The cause of death of death was sufentanil toxicity for both cases. The manner of death was ruled as accidental for both cases.

In conclusion, these 2 deaths resulting from sufentanil toxicity in Harris County Medical Examiner Office in less than 2 months are warning signs of the popularity of this potent, narcotic substance among healthcare professionals with substance abuse problem.

Sufentanil, Harris County Medical Examiner Office, Healthcare Professionals

G69 Acute Fatal Propafenone Toxicity: Drug Concentration, Distribution, and Clinical Features in Two Suicides

Dwayne A. Wolf, MD, PhD*, and Ashraf Mozayani, PharmD, PhD, Harris County Medical Examiner's Office, Joseph A. Jachimczyk Forensic Center, 1885 Old Spanish Trail, Houston, TX; and Christopher LaVergne, MD, North Houston Heart Center, 800 Peakwood, Suite 8A, Houston, TX

The goals of this presentation are to illustrate clinical and toxicological features of deaths due to acute propafenone toxicity.

Propafenone is a class 1C antiarrhythmic agent, an agent that reduces the upstroke velocity of the cardiac muscle cell action potential by inhibiting the fast inward sodium channel. Propafenone is indicated in the treatment of paroxysmal atrial fibrillation/flutter and supraventricular tachycardia in patients without structural heart disease, and non-sustained ventricular arrhythmias. Potential proarrhythmogenic effects of propafenone are recognized. However, few cases of fatal propafenone toxicity are reported in the literature. This presentation reports two autopsy cases of acute propafenone toxicity, including history, and postmortem propafenone concentration and distribution.

The first case is a 29-year-old white female with a long medical history of benign conditions including an ankle injury with multiple orthopedic surgeries and borderline diabetes mellitus. She had a complaint of cardiac palpitations; Holter monitor evaluation in 1999 demonstrated episodes of atrial fibrillation/flutter. No structural defects were identified by echocardiogram. Treatment with propafenone was begun. Her clinical course was uneventful with regard to cardiac complaints, until approximately 2 years later when she presented with a complaint of chest pain of four days duration. Evaluation at that time, including electrolytes, chest X-Ray, and V/Q scan were normal; an EKG had first degree atrioventricular block, and nonspecific T wave changes. Following spontaneous symptomatic relief she was discharged home. She returned to the same hospital approximately 16 hours later, with migration of pain to the epigastric region. Additional laboratory studies included a normal gallbladder ultrasound. An EKG at that time indicated a first-degree atrioventricular block with slight prolongation of the QRS interval. During a four-hour period of observation, she was administered lidocaine, compazine and ketorolac, with symptomatic relief and was discharged home. EKG prior to discharge revealed slight narrowing of the QRS interval compared to what was seen in the previous EKG. The QTc interval was not appreciably prolonged in any EKG. Propafenone is known to cause some prolongation of PR and QRS intervals, but has no effect on QTc intervals. She returned to the hospital by ambulance eight hours later, after collapsing with seizure-like activity at home. An agonal arrhythmia was documented during unsuccessful attempts at resuscitation. At autopsy, the mildly obese female had hesitation scars on the left wrist, and contusions and lacerations of the tongue. Her lungs were congested. The heart and brain had no structural anomalies. Complete toxicology analysis revealed blood temazepam (0.17 mg/L), lorazepam (0.01 mg/L), oxazepam (< 0.01 mg/L), venlafaxine (<0.25 mg/L), and nortriptyline (0.28 mg/L; liver nortriptyline 4.0 mg/Kg). Lidocaine was also detected. Unexpectedly, the post-mortem blood level of propafenone was 5.4 mg/L. Total amount of propafenone in gastric contents was 70 mg. The blood level of propafenone indicated intentional overdose (the plasma therapeutic range of propafenone is 0.06 – 3.2 mg/L). Hesitation scars, and the presence of other psychiatric medications provided further support for a suicidal manner.

The second case is a 32-year-old Hispanic male with no previous medical history who checked into a motel room with a female companion. The female subsequently left the room; the male was discovered dead on the floor of the bathroom 13 hours later. A brief suicide note was under the body. A bottle of propafenone, 150 mg tablets, prescribed

to the female companion, was in the room, with approximately 68 tablets missing. At autopsy, the lungs were edematous and congested. Blood and vitreous ethanol were 0.20 g/dL and 0.28 g/dL, respectively. Less than 0.1 mg/L cocaine and cocaethylene were detected in the blood, along with 0.65 mg/L benzoylecgonine. Blood propafenone was 9.1 mg/L, and liver propafenone was 230 mg/Kg. A total of 135 mg of propafenone was in the gastric contents.

These two cases provide data on suicidal intoxication with the antiarrhythmic drug propafenone, including data on drug distribution, and evolution of EKG changes.

Class 1C Arrhythmic Agents, Propafenone, Suicide

G70 Flecainide: A Suicidal Pharmacist's Choice

Dwayne A. Wolf, MD, PhD*, and Ashraf Mozayani, PharmD, PhD, Harris County Medical Examiner Office, Joseph A. Jachimczyk Forensic Center, 1885 Old Spanish Trail, Houston, TX

The goals of this presentation are to illustrate scene findings and toxicologic analysis of an unusual death of a pharmacist involving flecainide toxicity.

Flecainide is a class 1C antiarrhythmic agent that reduces upstroke velocity of the cardiac muscle cell action potential by inhibiting the fast inward sodium channel. Class 1C agents are approved for treatment of nonsustained ventricular arrhythmias. Proarrhythmogenic properties of flecainide and other class 1C agents are known. The authors report a case of suicidal ingestion of flecainide, with additional unusual toxicology findings and bizarre scene findings. The toxicologic findings and pharmacokinetic considerations are discussed in the context of the scene findings.

A 44-year-old black male pharmacist had no significant medical or psychiatric history. He was an avid diver; a dive logbook found in the apartment indicated over 255 dives. He had recently been depressed because of a busy work schedule, and having been denied vacation time for his annual dive trip. A coworker became concerned when he did not show for work for two days. On the third day, police were summoned and gained entry into the secure apartment where they found him deceased, supine in the bathtub. He was clad only in a pair of swim trunks. The tub was partially filled with water, the water was off, and the drain was plugged. At the time of discovery, water did not completely cover the face, and the nose and mouth were above water level. Two partially submerged, full, sealed 5-gallon water bottles were on the decedent's left abdomen and right chest. Several pieces of clear plastic wrap were adjacent to the decedent, on the edge of the tub, on the nearby toilet seat, and on the bathroom counter top. An open box of plastic wrap was on the floor just outside the tub. Complete toxicology analysis revealed flecainide with the following distribution: blood 11 mg/L, liver 324 mg/L, and gastric 367 mg. A large amount of flurazepam (1 g) was also in the stomach, although flurazepam was not detected in the blood. Blood and vitreous ethanol were 0.02 g/dL and 0.03 g/dL, respectively.

The high blood level of flecainide indicated a suicidal manner of death (the reported therapeutic serum concentration of flecainide is 0.2 – 1 mg/L.). Moreover, the decedent did not have a prescription for flecainide; in fact, he had no preexisting arrhythmia or other known cardiac problem, suggesting that he sought out a medication specifically for the purpose of ending his life. As a pharmacist, he had access to a variety of agents and had knowledge of pharmacologic mechanisms and pharmacokinetics. Perhaps flecainide was chosen because the mechanism of death was considered to be similar to a myocardial infarct, potentially less violent than other means. Perhaps he thought the unusual nature of the drug would preclude its detection on routine postmortem toxicology.

The large amount of flurazepam in the gastric contents further supports a suicidal manner, and the lack of flurazepam in the blood indicates preterminal ingestion.

The complex scene findings and unusual toxicology suggest purposeful activity by this decedent; several aspects remain puzzling. For example: why would flurazepam have been added? What was he doing with the plastic wrap? Why was he holding bottles of water on his chest and abdomen? Is his extensive knowledge of diving relevant? These aspects will be discussed during the presentation.

Class 1C arrhythmic Agents, Flecainide, Suicide

G71 The Use of Lidocaine to Commit Homicide: A Case Report and Review of the Literature

Brian C. Hunter, MD, 1215 East Michigan Avenue, Lansing, MI; John H. Trestrail III, BS, RPh, Regional Poison Center, Grand Rapids, MI; and Stephen D. Cohle, MD, Spectrum Health East Campus, Pathology Department, Grand Rapids, MI*

The goals of this presentation are to report the first case of Lidocaine being used to commit homicide outside a hospital setting, to pull known cases of iatrogenic homicidal Lidocaine poisoning into the forensic sciences literature, to review and compare the two groups highlighting similarities and differences, and to distinguish those situations where an elevated Lidocaine level should trigger a more extensive investigation.

Lidocaine is a drug that is commonly used during the course of resuscitating critically ill patients. It is most effective at treating ventricular tachycardia associated with a myocardial infarct. It is therefore a common finding on the toxicology reports of medical examiner cases. It is so common one could even say that it has become part of the "normal flora" of drugs found in people who die suddenly and unexpectedly along with Cotinine and Caffeine. It is also not uncommon for Lidocaine levels to be elevated, even above the "potentially toxic" level because of the grave situations in which the drug is administered. As a result, medical examiners/forensic pathologists can become desensitized to the dangers of this drug. Above therapeutic levels, it can cause severe cardiovascular and neurologic effects including immediate asystole, apnea, and convulsions. It lowers seizure thresholds and may increase the risk of bradycardia and asystole. Yet, the common assumption about Lidocaine is that if it is found in a patient's blood, the careful hand of a physician or paramedic with the goal of saving the patient's life administered it. The cases presented here illustrate that this is not always true. One case illustrates how Lidocaine was used as a tool to commit homicide by a non-professional while the other three show that when used in the medical setting, it is not always with a therapeutic intent. The former case is the first reported of its kind.

In this paper, the cases of iatrogenic homicide are briefly reviewed, characterizing the perpetrators, the victims, the motives, and the keys to recognizing the deaths as homicides. The majority of the focus is on the case involving the homicidal Lidocaine poisoning outside the hospital. Similarities and differences between that case and the hospital-based homicides are highlighted with the goal of raising awareness as to when an elevated Lidocaine level should trigger a more extensive investigation.

The majority of known Lidocaine homicides have been committed by so called "Medical Murderers." These are health care providers of one form or another who made Lidocaine their weapon of choice. Robert Diaz was a 46-year-old nurse who killed 12 patients (and possibly 50 more) by Lidocaine injection while he worked as a nurse at two California Hospitals. His motive stemmed from his desire to appear to

have a "doctor's" knowledge of how sick patients were and to "predict" when they would die. Joseph Dewey Akin was convicted of killing a quadriplegic patient by injecting him with Lidocaine for the "fun of watching him die". He committed this crime in Birmingham AL but was suspected to have killed 17 others while working at a hospital in Atlanta GA. And finally Randy Powers was a 26-year-old respiratory therapist who was never convicted of murder but was convicted of "assault with a deadly weapon" and "practicing medicine without a license." He gave an eleven-month-old child an intramuscular injection of Lidocaine inducing a high fever and seizure activity. He participated in the resuscitation and was originally thought to be a hero. Physicians however identified a needle puncture wound on the child's thigh and toxicology revealed elevated Lidocaine. Powers was suspected to have been involved in many other unexplained deaths. However, the bodies that were exhumed failed to show needle puncture wounds or elevated Lidocaine levels.

The case of homicidal Lidocaine poisoning outside a hospital involved the husband of a 69-year-old female with a past medical history most significant for Alzheimer's disease, schizophrenia, and macular degeneration. He was her sole caretaker but was also an active volunteer at the Red Cross and a local Michigan hospital. On the day of her death, he found her lying on her bed around 8:00 a.m. She was unresponsive and this prompted him to notify emergency medical personnel. On arrival, paramedics determined that she had been dead for some time and pronounced her dead at the scene. Her husband reported that she was in her usual state of health and had no complaints when he put her to bed on the prior evening (around 11:00 p.m.). The police and the medical examiner investigator found the scene secured with no evidence of a struggle. She was lying on top of the bedding in her nightshirt with a pillow lying over her right leg. There was no evidence of injury to the body. At autopsy the diagnosis of Alzheimer's disease was confirmed and there was no evidence of injury or needle injection marks. Two EKG leads were the only evidence of therapy. She was a normally developed female and had moderate atherosclerotic cardiovascular disease. Postmortem urine toxicology revealed Lidocaine, Tocainide, Meperidine, Salicylate, and Caffeine. A postmortem blood drug screen (subclavian blood) revealed Lidocaine 12.4 mcg/ml (potentially toxic >8 mcg/ml) and Salicylate (non-toxic levels). Discussions with MEI personnel confirmed that EKG monitoring was the only resuscitative procedure performed on the decedent and that there was no evidence of accidental ingestion of topical anesthetics. A police investigation was started and revealed information that suggested her husband would have the knowledge to administer the drug and may have been involved in previous attempts to kill her. Follow up testing (including DNA analysis) confirmed the presence of Lidocaine and ruled out the possibility of specimen mix-up at the laboratory. Based on this information the cause of death was determined to be Lidocaine poisoning and the manner of death was homicide.

This paper is valuable for multiple reasons. It first pulls cases of homicidal Lidocaine poisoning into the forensic literature. Secondly, it highlights how the deaths of elderly people and the severely ill are not infrequently treated with benign neglect despite the fact that they are precisely the people most likely to be the victims of homicidal poisoning. It highlights how elevated Lidocaine levels are treated with similar benign neglect. This is clearly illustrated in the comment by one forensic pathologist who was asked to evaluate the toxicology report knowing only that it was a case of an elderly person who died at home. He quickly stated, "There is nothing here" automatically attributing the elevated lidocaine level to "an artifact of resuscitation." This paper illustrates how the hobby or profession of the assailant/caregiver can give important clues as to the cause of death and to the poison used. And finally it illustrates how doing a thorough scene investigation including a detailed medical and social history of the decedent and the family can alert you to a situation perfect for homicidal poisoning.

Lidocaine, Homicide, Forensic Science

G72 The Normal Heart Weight: Diagnostic Criteria for Cardiomyopathies

Paul Fornes, PhD*, and Dominique Lecomte, MD, Forensic Institute of Paris, Medical School Cochin Port Royal, Paris, France

The definition of normal heart weight is discussed. Various features and causes of cardiac hypertrophy are examined and illustrated. Criteria for the diagnosis of cardiomyopathy are discussed.

In medicolegal practice it is not uncommon that the cause of a death cannot be determined by autopsy, histology, and toxicology. Among other questions, the following deserve special attention: Was the heart weight normal? Can an isolated cardiac hypertrophy be a cause of death? What can be expected from cardiac histology?

In the first part of this presentation, the definition of the normal heart weight is discussed on the basis of a personal series of normal hearts and the literature. For this purpose, the weights of 973 hearts from adults with normal hearts who died of violent death were measured in order to determine the upper limit of the normal heart weight as a function of sex, age, body weight, body height, and body area. In the second part, gross and histologic findings in 38 hypertrophic hearts were examined. The meaning of myocyte disarray is discussed. Diagnostic criteria for the diagnosis of primitive hypertrophic cardiomyopathy are examined. Contribution of cardiac histology to the assessment of the diagnosis of cardiomyopathy is also analyzed.

Heart, Hypertrophy, Cardiomyopathy

G73 Normal Fat in the Right Ventricle vs. Arrhythmogenic Right Ventricular Cardiomyopathy/Dysplasia

Paul Fornes, PhD*, and Dominique Lecomte, MD, Forensic Institute of Paris, Medical School Cochin Port Royal, Paris, France

Fat is a normal component of the right ventricle. In this presentation, the diagnostic criteria for right ventricular cardiomyopathy are examined. The role of fat *per se* in sudden death is discussed.

Fat is a normal component of the right ventricle. However, in some hearts the proportion of fat is dramatically increased. The question of whether fat infiltration of the right myocardium *per se* can be responsible for sudden death has not yet been answered. In a previous series of sudden cardiac deaths related to arrhythmogenic right ventricular cardiomyopathy, the authors showed that in this disease, fat was constantly associated with fibrosis^[1]. The significance of fat infiltration without fibrosis in the right ventricle was not discussed. In a first part of the present study, the authors examined 30 right ventricles with an increased amount of fat, which was semi-quantitatively evaluated using a score of severity ranging from 1 (minimal increase) to 4 (transmural involvement). These hearts were obtained from persons who died of violent or natural death, but sudden cardiac deaths were excluded. The hearts were compared in blind conditions to those from the authors' previous sudden death series. In the non-sudden death group, the mean age was 62 years (range, 42-97), 80% of victims were female and 20% of right ventricles had grade 4, 45%, grade 3, 30%, grade 2 and 5%, grade 1. Fibrosis was never observed. In a second part of the study, case-reports of the literature were analyzed, in which fat infiltration *per se* was considered the cause of sudden cardiac death. A personal case-report is also reported in which sudden cardiac death occurred in a person who had only fatty replacement of the right ventricle.

Conclusion. Fat is a normal component of the right ventricle, and may be increased in certain persons, especially obese and/or old women. Sudden cardiac death is most likely to occur when fat is associated with fibrosis. Sudden cardiac deaths have rarely been reported to have occurred despite absence of fibrosis. In such cases, additional factors may contribute to the arrhythmogenicity.

Arrhythmogenic Right Ventricular Dysplasia, Sudden Death, Cardiomyopathy

G74 Isolated Noncompaction of the Left Ventricle: A Rare Cause of Sudden Death

Kendell V. Crowns, MD*, and Adrienne Segovia, MD, Cook County Medical Examiner's Office, 2121 West Harrison Street, Chicago, IL

This presentation will review the literature and the autopsy findings of Isolated Noncompaction of the Left Ventricle, a rare congenital cardiomyopathy.

A 44-year-old black female with no known medical history was witnessed to collapse suddenly at work. Upon arrival, paramedics found an initial rhythm of ventricular fibrillation; their initial efforts resulted in conversion to sinus tachycardia, which quickly deteriorated into ventricular fibrillation. The patient was taken to a nearby hospital where she was pronounced dead in the emergency room.

Autopsy examination showed a well developed, well nourished black female weighing 158 pounds and measuring 5' 2" in height. Internal examination revealed a 409 gram heart with no evidence of coronary artery disease. The left ventricle measured 1.3 centimeters in thickness, the right ventricle measured 0.5 centimeters, and the septum ranged in thickness from 0.5 to 1.3 centimeters. On cut surface, the left ventricle had a sponge-like appearance. Filling the left ventricle, from the apex to the level of the mitral valve were extensive trabeculations with deep intertrabecular recesses. An area of scarring and hemorrhage was present along the anterior third of the septum. Autopsy also showed pulmonary edema and congestion, emphysematous changes of the apex of the upper lobes of the lungs bilaterally, and nephrosclerosis. Histologically sections from the heart showed trabeculations lined by ventricular endocardial endothelium, which was continuous with the ventricular endocardium. The trabeculations showed areas of endocardial thickening and ischemic changes with myocyte necrosis and hypertrophy of the surrounding myocytes. Sections from the lung showed chronic congestion. Toxicology tests were negative.

Isolated noncompaction of the ventricle (INLV) is a rare congenital cardiomyopathy thought to be caused by an arrest of compaction of the loose meshwork of myocardial fibers during embryogenesis. Noncompaction results in the formation of muscular trabeculations that fill one or both ventricles imparting a spongy appearance. The overall incidence in the adult population is 0.05 percent. Genetic studies have shown an X-linked recessive inheritance pattern with mutations in the gene G 4.5 on the Xq28 chromosomal region associated with INLV. However, the occurrence of INLV in women suggests a possible non-X-linked inheritance pattern.

Patients have been identified ranging in age from 1 week to 71 years. The onset of symptoms, commonly related to depressed left ventricular function, frequently develops during adulthood. The diagnosis in adults is often delayed because the symptoms, which are nonspecific, are similar to more frequently diagnosed conditions such as congestive heart failure. Patients can also present with various arrhythmias. The arrhythmias can be associated with Wolf Parkinson White Syndrome, bundle branch blocks, or ventricular arrhythmias. Some patients present with embolic events that include transient ischemic attacks, stroke, and pulmonary embolism. INLV has specific echocardiographic findings, and it is not until this test is performed that the diagnosis is confirmed.

Isolated noncompaction of the left ventricle is a rare congenital cardiomyopathy affecting both sexes through a wide range of ages, has non-specific clinical manifestations, and can result in sudden death.

Isolated Noncompaction of the Left Ventricle, Spongy Myocardium, Congenital Cardiomyopathy

G75 Trauma-Related Hemorrhage vs. Spontaneous Rupture of Vascular Malformation: Three Case Reports Illustrating Medico-Legal Aspects

Dominique Lecomte, MD*, and Paul Fornes, PhD, Forensic Institute of Paris, Medical School Cochin Port Royal, Paris, France

In medicolegal practice, cutaneous and visceral hematomas are often caused by trauma. In some cases spontaneous rupture of a hemangioma can mimic trauma-related hemorrhage. Three case-reports illustrate this issue.

In medicolegal practice, cutaneous and visceral hematomas are often caused by traumas. However, in some cases, a hemangiomas/vascular malformations can be involved. These can be overlooked if histology is not performed. The matter is further complicated by the fact that rupture of hemangioma can be provoked by slight trauma. Three autopsy case-reports are presented to illustrate medicolegal aspects of this issue.

Case 1: A 6-month-old boy was found dead in his bed by his parents. The GP who examined the body found the child's anus enlarged and considered the death suspicious. At autopsy, the anus was considered normal, but there was an ecchymotic area at the surface of the left ventricular epicardium, 2 cm in diameter. No resuscitation attempts had been performed. There were no rib fractures or any other cutaneous or visceral hemorrhages. Histology revealed a small hemangioma in the anterior left ventricular wall. Such vascular malformations have been reported to cause sudden cardiac death in infants and older children.

Case 2: A 5-year-old boy was found dead in his bed by his parents. The cause of death was found to have been a tamponade due to a hemopericardium. The right atrium was found ruptured. There were no rib fractures or any other hemorrhages. Histology showed a ruptured hemangioma in the right atrial wall. Such vascular malformations have been reported to cause death in infants and older children. This localization has been reported to be the most frequent.

Case 3: An 18-year-old man was found dead in jail. During the days prior to the death, he had complained of various neurological symptoms, including headache and difficulty in standing and walking. He reported that these symptoms developed in the days following a dispute, when he had been punched to the face. Neurological examination showed no objective abnormalities. At autopsy there was a meningeal hemorrhage surrounding the cerebellum and the upper part of the brain stem. Edema in the underlying parenchyma caused death. Histologically, there was a ruptured hemangioma in the cerebellum.

In conclusion, hemangiomas are rare causes of hemorrhages. Rupture can be spontaneous (cases 1 and 2). However, in medicolegal practice, the question often arises of whether a slight trauma may have facilitated the rupture (case 3). Histology is essential in revealing the hemangioma and dating lesions.

Hemangioma, Heart, Brain

G76 Esophageal and Pharyngeal Injury Associated With the Esophageal-Tracheal Combitube®

Robert Stoppacher, MD, MS, BS*, Milwaukee County Medical Examiner's Office 933 West Highland Avenue, Milwaukee, WI

The goals of this paper are to present a series of cases of esophageal and pharyngeal laceration associated with the use of the Combitube®.

The esophageal-tracheal combination tube or Combitube® is a ventilatory device used for the intubation of patients in a number of different clinical settings. Its basic design consists of a twin lumen tube with proximal and distal inflatable cuffs. This design allows for placement of

the device in either the trachea, or more commonly, the esophagus, and through appropriate inflation of the proximal and/or distal cuffs provides a conduit for ventilation. The major benefit of the Combitube® is that its design and function allow for non-laryngoscope-assisted or blind insertion into the oropharynx. Therefore, it is frequently used in emergency situations such as cardiopulmonary resuscitation in both the hospital and pre-hospital setting. As with any invasive procedure, intubation using the Combitube® is not without complications. The majority of complications is relatively minor and includes sore throat, dysphagia, upper airway hematoma, and a more pronounced hemodynamic stress response. A rare and serious complication reported primarily in the anesthesiology literature is rupture of the esophagus. However, this reportedly rare injury is increasingly seen by medical examiners/coroners in the forensic setting.

A series of three cases of esophageal rupture and a single case of laceration of the hypopharynx associated with the use of the Combitube® that were identified at the time of medico-legal autopsy at the Milwaukee County Medical Examiner's Office between 1997 and 2002 will be presented. The cases involved patients between the ages of 15 and 78. The cause of death in three of the cases was determined to be sudden cardiac death due to atherosclerotic and hypertensive cardiovascular disease while acute asthmatic attack was the cause of death in one case. All individuals were intubated in the field by emergency medical personnel during cardiopulmonary resuscitation. The Combitube® was inserted in the esophagus in the three cases of esophageal rupture and in the hypopharynx in the case of pharyngeal laceration and placement of each was confirmed at postmortem examination.

A review of select literature is also presented. This includes a review of the development of the Combitube®, its design and function, and the manufacturer's recommendations for its use. Case reports from the anesthesiology literature are also provided. In addition, the presentation will review information regarding possible mechanisms of injury focusing on recent reports that investigate the importance of anatomic location, cuff volume, esophageal and tracheal distortion, and mucosal pressures in the development of esophageal rupture.

By providing this information, it is hoped the awareness of the forensic community to the esophageal and pharyngeal injuries associated with use of the Combitube® and how they occur is raised. The authors stress the importance of thorough investigation of the perimortem events including review of resuscitation records/reports as they aid in defining the extent to which the injury contributes to the cause and manner of death. In addition, this work demonstrates the vital role the medical examiner/coroner plays in identifying existing or potential problems with current or emerging medical devices. By fulfilling this role, the medical examiner/coroner can provide clinicians and emergency medical personnel information that can be used to prevent similar injuries in the future.

Esophageal Rupture, Combitube®, Complications

G77 Determination of Time Since Death—Cardiac Troponin I

Alberto J. Sabucedo*, PhD, and Kenneth G. Furton, PhD, Department of Chemistry and International Forensic Research Institute, Florida International University, University Park, Miami, FL

This presentation will describe the development and utility of cardiac Troponin I (cTnI) as a time since death marker. Estimates of time since death in the early postmortem interval 0–7 days are currently performed using different temperature based methods and other physical parameters that lack the desired forensic reliability. The qualitative and semi-quantitative analysis of the degradation of cTnI as a time since death marker will be discussed using a bovine tissue model followed by postmortem human cardiac tissue samples.

The importance of determining the time since death is crucial to criminal, civil and forensic cases. Time since death markers have lagged behind the advances in technology of the past century. Knight explains, ‘regrettably, the accuracy of estimating the postmortem interval (PMI) has by no means kept pace with the enormous strides made in technological sophistication.’ Early documented works on time since death focused on temperature measurements postmortem and possible algorithms to model the behavior of postmortem cooling of the body. Current technology is based on postmortem temperature methods similar to those described back in the 1800s. Marshall, an expert in this area, best summarizes the general issues with temperature measurements as follows, ‘It would seem that the timing of death by means of temperature can never be more than an approximation.’ Biochemical markers investigated to estimate time since death include protein fractions, urea, creatinine, glucose, iron, potassium, calcium, enzymes, immunohistochemical detection of insulin in pancreatic β -cells, myo-albumin fraction and Strontium-90 calcium analogue levels. Postmortem muscle proteolysis has been researched to explain the muscle relaxation following rigor mortis. Temperature, as a time since death marker, remains a leading marker after many years of investigations and limitations.

Cardiac Troponin I emerged as the leading serum marker for myocardial infarction (heart attack) in both the U.S. and Europe in the mid 1990s. It has become the gold standard serum marker for cardiac damage. This research is focused on a technique exploiting the postmortem tissue degradation of cardiac Troponin I to determine the time since death.

The technique consists of isolating and separating troponin I and its proteolytic fragments from cardiac muscle tissue (myocardium). This is accomplished by using magnetic microparticles that capture this protein from a 1.0 g cardiac tissue homogenate extracted with a buffer that inhibits proteolytic activity. The capture microparticles are incubated for 1 hour and washed several times with extraction buffer. The proteins bound are eluted from the microparticles using a low pH buffer. The proteins are separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and transferred to paper using a semi-dry Western blot protocol. The proteins transferred are probed with monoclonal antibodies specific for cardiac Troponin I. The blot is then incubated with goat anti-mouse antibody labeled with alkaline phosphatase (GAM-ALP). The blot is developed after incubating with a precipitating colored substrate. The bands of cTnI and most of its proteolytic degradation products that retain the antibody-binding region (epitope) are visualized by this technique. Digitization of the Western blot is performed using a scanner and software that can integrate the area of the peaks for qualitative and semi-quantitative analysis.

Cardiac troponin I exists as an intact protein when sampled from fresh human cardiac tissue. The experiments focused on a model of bovine cardiac tissue followed by human cardiac tissue with known time since death. The samples were frozen until the analysis was performed to avoid proteolysis during storage. The results indicate a consistent cTnI banding pattern amongst different human cadavers and a pseudo-linear relationship between percent cTnI degraded and the log of the time since death with a coefficient of correlation, $r > 0.95$. The unknown time since death degradation pattern can be qualitatively compared to a “reference heart” incubated under controlled conditions. The analysis matches the cTnI degradation pattern of the cadaver in question to the “reference heart” degradation pattern incubated at different time points. Thus, the extent of cTnI degradation serves to estimate time since death. Overall, this technique offers advantages over current methods such as wider postmortem interval, measurable degradation pattern and a temporal semi-quantitative relationship. In addition, at lower temperatures the postmortem prediction interval can be extended to provide a wider range. The degradation pattern of tissue cTnI is useful in the determination of the early postmortem interval (0 to 7 days), which is difficult to estimate with current technology.

Cardiac Troponin I, Time Since Death Marker, Postmortem Interval

G78 Quantitative Measurement of Ribonucleic Acid Degradation as a Possible Indicator of Postmortem Interval

Ira Gramlich, Dieter Patzelt, MD, and Martin Bauer, MD, Institute of legal Medicine, University of Wuerzburg, Versbacher Str. 3, Wuerzburg, Germany*

After attending this presentation the participant will understand that RNA degradation is time-dependent, can be quantified by reverse transcription and polymerase chain reaction and may serve as indicator of postmortem interval.

Ribonucleic acid (RNA) research is a major topic in molecular biology and medicine. RNA is less stable than DNA in vivo and in vitro and therefore is believed to undergo rapid postmortem degradation. This may be the reason why RNA analysis did not obtain significant attention in forensic science up to now. However, due to the nucleic acid structure small amounts of mRNA can be amplified by polymerase chain reaction after synthesis of complementary DNA (cDNA) by reverse transcription (RT-PCR). The poly-A-structure at the 3'-end of most mRNAs allows exact imaging of the mRNA pattern by oligo(dT)-primed reverse transcription including differences in fragment size due to degradation. Primers designed for sequences near the 5'-end of the mRNA should provide weaker amplification results than primers located near the 3'-end in degraded samples because the average mRNA size is expected to be smaller after RNA degradation so that less full-size transcripts will be generated during reverse transcription.

The objective of this study was to investigate whether quantitative measurement of RNA degradation could be helpful in determining the time of death in bodies. Blood taken from healthy volunteers was stored under various conditions and for variable time periods. Blood from bodies with exactly known time of death was taken from the femoral vein. After counting leucocytes RNA and DNA were extracted using standardized protocols. For estimation of the degree of degradation the 260/280 nm UV absorption ratio and the ratio of 28S to 18S ribosomal RNA of the RNA samples were determined. To assess the integrity of messenger RNA competitive RT-PCR using a synthetic competitor mRNA, one-step duplex RT-PCR with simultaneous amplification of a short and long fragment of the same mRNA (β -actin), multiplex RT-PCR with amplification of four fragments located between the 3' and 5'-end of the mRNA (fatty acid synthetase, FAS) and comparative RT-PCR of house-keeping genes (glycerin aldehyde-3-phosphate dehydrogenase) were performed. The amplification products were visualized with agarose gels or automated capillary electrophoresis. For quantification the staining intensity in ethidium-bromide stained agarose gels or the peak area in electropherograms generated with laser-induced fluorescent capillary electrophoresis were calculated.

The results show, that RNA degradation is gradually increasing up to 5-6 days postmortem depending on the ambient temperature. The in vitro as well as the postmortem assays demonstrate that the in vitro/postmortem time interval can be estimated by quantitative measurement of RNA degradation during the first week within a range of 1-2 days. Multiplex RT-PCR of the FAS-mRNA provided the most consistent results because the degradation of long (>4kb) mRNAs is measured showing a significant decrease of the amount of 5'-sequences that require full-size transcripts for detection relative to 3'-sequences which are close to the origin of reverse transcription.

Beside the forensic implications this study has high relevance for clinical and experimental RNA research because the exact time-course of postmortem or in-vitro RNA degradation is largely unknown. In forensic pathology quantitation of RNA degradation seems to close the gap between early postmortem interval (< 24 h) and the beginning of putrefaction. Further evaluation studies are currently performed with autopsy cases to enhance the significance of statistical calculations.

RNA Degradation, RT-PCR, Postmortem Interval

G79 Experimental Evaluation of Rigor Mortis: The Influence of the Breaking (Mechanical Solution) on the Development of Rigor Mortis

Thomas Krompecher, MD*, André Gilles, MD, Conxita Brandt-Casadevall, MD, and Patrice Mangin, MD, Institut universitaire de Médecine légale, Rue du Bugnon 21, 1005 Lausanne, Switzerland

The learning objective consists in presenting the influence of the breaking (mechanical solution) on the development of the intensity of rigor mortis.

Although little is still known about its development over time, rigor mortis is routinely used to estimate the time since death. In order to further knowledge on this phenomenon the authors have developed a method for the objective measurement of the intensity of cadaver rigidity in rats.

The principle of the method is to determine the force required to cause a movement of small amplitude (4 mm) in the limb under examination. Since the movement doesn't break rigor mortis, serial measurements can be conducted. The apparatus measures the resistance caused by rigor mortis in the knee and hip joints of rats. This method was formerly used to evaluate the influence of several antemortem and postmortem factors (i.e. body weight, muscular mass, age, physical exercise, ambient temperature, various causes of death, electrocution) on the development of rigor mortis. Present investigations address a very poorly known phenomenon in the development of rigor mortis, which consists in the return of the rigidity after mechanical solution. In fact, observations on human cadavers have shown that if early rigor mortis is "broken" (by forcing a limb to bend), it may reappear. However information based on standardized experiments is lacking concerning this phenomenon.

Experimentation: Question addressed:

- reappearance
- intensity after reappearance
- rapidity of reappearance
- time limit of reappearance
- rigor mortis time span after reappearance

Animals: male albinos rats, approx. 300 g
Method to break rigor mortis: the paw is vigorously pulled twice in order to completely straighten the limb.

Breaking time points: 1, 2, 4, and 6 hours p ostmortem.

Measurement time points: 10 min, 1h, 2h, 3h, 4h, 5h, 6h, 8h, 12h, 16h, and 24 h postmortem.

Results: The maximal values of the intensity of rigor mortis are reached between 4 and 5 hours postmortem in the control group with a plateau of the intensity between 4 and 8 hours postmortem. If the breaking takes place at 1 hour postmortem, the curve representing the intensity of rigor mortis has the same shape, i.e., maximal values are attained at the same time, but values are significantly lower. A breaking point at 2 hours postmortem gives similar results: maximal values are obtained at the same time as in the control group but values are significantly lower. If breaking occurs after 4 or 6 hours no significant rigidity reappears.

Conclusion: Rigor mortis may reappear if it is broken during the early phase of its development, but its intensity is significantly lower. The time course of rigidity after breaking is the same as in the controls. If the breaking intervenes after the full development of rigor mortis, it doesn't reappear. These results offer a better understanding of the phenomenon of rigor mortis and, further, of the estimation of time since death, a fundamental element in forensic medicine.

Rigor Mortis, Breaking of Rigor Mortis, Development of Rigor Mortis

G80 Evaluation of a Putative Snuff Film

William R. Oliver, MD*, Armed Forces Institute of Pathology, 1413 Research Boulevard, Rockville, MD; Peter G. Lawson, Naval Criminal Investigative Service, 620 John Paul Jones Circle, Portsmouth, VA; William C. Rodriguez III, PhD, Armed Forces Institute of Pathology, 1413 Research Boulevard, Rockville, MD; and Douglas Knittel, MD, Naval Medical Center, 630 John Paul Jones Circle, Portsmouth, VA

The attendee will understand how to critically evaluate computer animation from a medicolegal perspective.

So-called "snuff films" are films, which purport to show an actual killing as entertainment. The killing is done for the purpose of the film, as distinguished, for instance from compilations of executions and killings from news reports or taken by observers. The existence of "real" snuff films or whether they are an urban myth is an occasional source of debate.

This is a case report of a putative snuff film that was presented to investigators as evidence of a possible homicide. In this animation, a young woman was tied to a chair and shot. The investigators were skeptical, and before expending resources to search for a body asked for an evaluation of the imagery. This presentation will detail some of the findings, and provide an approach to the evaluation of such imagery.

A copy of the data was provided to the Digital Image Processing Laboratory, and the cine was evaluated on a frame-by-frame basis. Analysis focused on two primary areas:

1. Internal inconsistencies (features in the image that were not appropriately constant), such as inappropriate optical flow, evidence of image manipulation, etc.
2. Factual inconsistencies (features which did not fit natural laws), such as inappropriate bloodstain patterns.

In this particular instance, a number of internal inconsistencies were found in the imagery, including inconstant positioning of the entrance wound, inappropriate firing of the weapon, inaccurate bloodstain patterning, and others. A computer search was performed to determine the provenance of the animation, and was successful. The film was traced to its original release on the internet a few years ago and to the production house that made it. A Canadian special-effects company that specializes in "fantasy violence" had made the film as a publicity effort.

A number of points can be made from this analysis, including the importance of a multidisciplinary approach to integrating scene and medical information, the effects of image quality and compression method, and the use of the internet as a source and repository for these kinds of films and resource for their investigation. In this particular case, the use of JPEG compression placed severe limitations on the analysis of optical flow, since the details necessary for such evaluation were obscured by the JPEG blocking effect, which becomes increasingly problematic if contrast enhancement is used.

As digital imagery becomes increasingly integrated into the current culture, forensic pathologists and physical anthropologists should expect to receive more and more images for medicolegal evaluation. The evaluation of these images requires both an understanding of the medical aspects of the scene being analyzed but also a comprehension of how to approach imagery and how to handle digital evidence. In cases of digital imagery, the media containing the data may well be itself a piece of physical evidence to be analyzed separately than the data contained therein. A number of groups, including the Scientific Working Group on Digital Evidence are promulgating guidelines for handling evidence that is provided in digital format, while other groups, such as the Scientific Working Group on Imaging Technologies in the U.S. and similar groups in the international arena are developing guidelines for the acquisition and evaluation of digital data. A short discussion of the handling of digital evidence and the place of the medical examiner in handling such evidence will be provided.

In this particular instance, a determination that this image was not of an actual killing was made rather quickly, and a more intense examination

was not necessary. Possible further approaches to evaluation will be discussed.

A short review of the snuff-film urban legend and its variants, and an introduction into some of the material easily available through modern distribution methods of imagery, including the internet, will be provided.

Video Analysis, Image Analysis, Snuff Film

G81 Analysis of Electric Injury Patterns in Human Skin by Magnetic Resonance Microscopy

Michael Thali, MD, Office of the Armed Forces Medical Examiner, Rockville, MD, and Institute of Forensic Medicine, University of Berne, Berne, Switzerland; William R. Oliver, MD, and William C. Rodriguez III, PhD, Armed Forces Institute of Pathology, Rockville MD; Richard Dirnhofer, MD, Institute of Forensic Medicine, University of Berne, Berne, Switzerland; and Kimberlee Potter, PhD, Armed Forces Institute of Pathology, Rockville, MD*

The goals of this presentation are to gain a greater understanding of emerging diagnostic technologies; to develop correlations between magnetic resonance microscopy and light microscopy for electrical injuries; and to better recognize the histopathology and pathophysiology of electrical damage to the skin.

Introduction: The pattern observed for an electric injury depends on the strength and frequency of the electric field, the path of the current, and the histoarchitecture of the tissues. Tissue trauma results from (a) electric field effects and (b) Joule heating due to the passage of electricity. To characterize the electric injury pattern in skin a variety of techniques, ranging from histology to scanning electron microscopy, have been applied. These techniques give detailed information about changes to cell morphology in sections taken at the site of the entrance and exit wounds, but provide little information about the extent of tissue damage in peripheral and deep tissues. Clinical MRI studies can provide some information about vessel patency and muscle necrosis, but the injury pattern is lost due to limited spatial resolution. In this work, MRM was used for the first time to characterize the microanatomy of an electric injury pattern in human skin.

Materials and Methods: Skin specimens, with visible epidermal lesions, were dissected from the left and right foot of a human cadaver that had received a fatal electric shock. Fixed skin samples were rehydrated in phosphate buffered saline prior to imaging. All experiments were performed on a Bruker Biospec spectrometer (Bruker Instruments, Inc. Billerica, MA) coupled to horizontal magnet operating at 7T (300 MHz for protons). Quantitative 2-D images had a slice thickness of 2 mm and an in-plane resolution of 120 mm. 3-D images were acquired with a RARE imaging sequence. The microanatomy of the resulting electric injury pattern was characterized by MRM and images were validated against histologic sections taken through the wound site.

Results and Discussion: On gross inspection, electric lesions were found to be composed of three zones: a central zone, an intermediate zone, and a peripheral zone. In the central zone the epidermal layer was completely destroyed and the underlying dermis was thermally damaged. In the intermediate zone, dermal necrosis was observed under the detached epidermis and in the peripheral zone there was little evidence of damage to cutaneous tissues.

Three-dimensional MRM images of formalin-fixed skin specimens were found to provide a complete view of the damaged tissues at the site of an electric injury as well as in neighboring tissues, consistent with histologic reports. The signal intensity of the dermal layer in the central zone was reduced due to thermal damage and increased in the intermediate zone because of cellular necrosis caused by the electric field. A subjacent blood vessel with extensive intravascular thrombosis supports the hypothesis

that electricity traveled through the vascular system before arcing to ground. MRM images of intact skin samples confirm that the resulting electric injury pattern was comparable to that of a vascular lesion.

G82 Coins as Intermediate Targets: Reconstructive Analysis With Body Models

Michael Thali, MD, Office of the Armed Forces Medical Examiner, Armed Forces Institute of Pathology, Rockville, MD, and Institute of Forensic Medicine, University of Berne, Berne, Switzerland; Beat P. Kneubuehl, PhD, Institute of Forensic Medicine, University of Berne, Berne, Switzerland; William C. Rodriguez III, PhD, Office of the Armed Forces Medical Examiner, Armed Forces Institute of Pathology, Rockville, MD; James Smirniotopoulos, MD, Uniformed Services University of the Health Sciences, Bethesda, MD; A. Charles Richardson, DDS, National Naval Medical Center, Department of Radiology, Bethesda, MD; David R. Fowler, MD, Offices of the Medical Examiner of the State of Maryland, Baltimore, MD; Michael L. Godwin, BS, and Aaron Jurrus, Office of the Armed Forces Medical Examiner, Armed Forces Institute of Pathology, Rockville, MD; Doug Fletcher, PhD, National Naval Medical Center, Department of Radiology, Bethesda, MD; and Craig T. Mallak, MD, Office of the Armed Forces Medical Examiner, Armed Forces Institute of Pathology, Rockville, MD*

The attendee will learn about intermediate targets and body models in wound ballistics.

Introduction: The phenomenon of intermediate targets is well known in wound ballistics. Intermediate targets are materials that receive some kinetic energy from the striking bullet. The result is that the intermediate target may be set into motion and become a secondary projectile. The injury analysis involving intermediate targets is often difficult. Therefore in forensic science, models are used to reconstruct injury patterns to answer questions regarding the dynamic formation of unusual injuries. In ballistic research glycerin soap and ordnance gelatin have been well established as soft-tissue substitutes. Recently, based on previous experiences with artificial bone, a skull-brain model was developed. The goal of this study is to create and analyze a model-supported reconstruction of a real forensic case with a coin as an intermediate target. A man with multiple bullet wounds was admitted to the hospital, where they found, by computed topography of the head, two foreign bodies. The man died several hours after admission to the hospital. At autopsy two foreign bodies in the brain were identified: a .380 caliber Winchester Silvertip bullet and a deformed, 1970, Mexican 50-centavo coin. There was no evidence of close-range firing and a through-and-through gunshot wound at the base of the left index finger suggesting that the bullet passed first through the hand, picking up the coin as secondary projectile before entering the head. Since it wasn't clear exactly how this unusual injury pattern came about, a reconstruction was attempted.

Materials and Methods: Gunshot experiments were made at the "Ballistic Missile Trauma Laboratory and Range" of the Armed Forces Medical Examiner at the Armed Forces Institute of Pathology, Washington D.C. For the first experimental set-up 10% gelatin blocks were used (size 36 x 15 x 15 cm) at 4° C. For the reconstruction of the ballistic process, a gelatin block with a thickness of 1.5 cm was used to represent the left index finger of the victim; a gelatin block of 0.5 cm was used to simulate the skin of the head. In some gelatin block experiments "Lauan Plywood" with a thickness of 6 mm (Home Depot, USA) was used to simulate the bony skull, which was placed between the finger and skin simulants. For the second experimental the artificial skull-brain-model was used (Thali, et al. *Forensic Science International* 125 (2002) 178-189). The artificial

skull is a layered polyurethane sphere 19 cm outside diameter and 6 mm thick) constructed in a specially designed form with a inner table, outer table and a porous diploe sandwiched in between. The brain itself is simulated with ordnance gelatin. Ammunition (Winchester 380 Automatic (85 GR) Silvertip Hollow point – muzzle velocity 1000 fps) similar to the real case was used. The bullets were fired by a Llama .380 pistol. As intermediate target 1970, 50- centavo Mexican coins were used. The coin was positioned between the simulated finger and the body simulant.

First the authors fired directly into three gelatin blocks, then fired into two “finger-coin-gelatin-block”-models, then into five “finger-coin-wood-gelatin-block”-models and finally into two skull-brain models. The gunshots were documented with a high-speed digital black and white camera PHANTOM V4.0 (Photo-Sonics, Burbank, CA) frame speed of up to 32,000 pictures per second. All gelatin blocks were examined by a digital mobile C- arm unit Compat 7600 (OCE, Salt Lake City) at the Office of the Armed Forces Medical Examiner in Rockville, MD. The CT scans of the head models were done at the National Naval Medical Center in Bethesda, MD with a GE Light Speed multi-slice helical scanner (General Electric Medical Systems, Milwaukee, WI). Using this cross-sectional modality 3D volumetric data was acquired which gave the possibility to do further post-processing with 3D virtual reconstructions (VoxelView, Vital Images, Inc., USA). After the radiological examination the gelatin blocks and the head models were dissected to analyze the bullets and the coin as an intermediate target.

Results and Discussion: With this model of an intermediate target simulation it was possible not only to demonstrate the “bullet-body (finger) interaction”, but also to recreate the wound pattern found in the victim. It could be demonstrated that after the primary projectile has struck the simulation materials, that the bullet and the coin traveled through the tissue simulants.

This case demonstrates that using ballistic models and body-part substitutes can reproduce gunshot cases simply and economically, without conflicting with ethical guidelines.

Thus, model set ups with body-part substitutes, in many scenarios, are ideally suitable diagnostic aids for the purpose of solving reconstructive ballistic questions.

Forensic Science, Ballistic, Intermediate Target

G83 Two Gunshots to the Head: Suicide or Homicide? A Biomechanical Study

Jean-Sebastien Raul, MD*, Institut de Medecine Legale, 11 rue Humann, Strasbourg, France; C. Deck, and F. Meyer, Institut de Mécanique des fluides - ULP-CNRS 7507, Strasbourg, France; Annie Geraut, and Antoine Tracqui, MD, PhD, Institut de Medecine Legale, 11 rue Humann, Strasbourg, France; R. Willinger, Institut de Mecanique des Fluides, ULP-CNRS 7507, Strasbourg, France; and Bertrand Ludes, MD, PhD, Institut de Medecine Legale, 11 rue Humann, Strasbourg, France

This presentation will use of a finite element head model to demonstrate the lack of incapacitation following a shot with a .22 bullet, demonstrate the importance of crime scene elements, and discuss the consequence of three shots : one to the chest and two to the head.

A 20-year-old man was found dead in his bedroom by his younger brother, in the family house. Investigators found the body lying on the ground, near the bed, with a handgun and a box of bullets at his beside. Examination of the body showed three gunshot wounds: one to the chest and two to the head (between the eyes and above the right ear respectively). Entrance wounds were all contact wounds. The handgun was a single-shot revolver and the box of bullets contained “super x”, .22 caliber bullets. Both the box of bullets and the handgun belonged to the victim who used to practice shooting in a club. Investigators found blood spots

on the victim’s bed aiming towards the cupboard where the deceased used to store his gun. Prior to autopsy, X-Ray examination of the body showed that Bullet A was stuck in the dorsum sellae, Bullet B in the left temporal bone, and Bullet C in the spine.

Bullet A penetrated the skull through the ethmoid, crossed the sphenoid sinus and ended in the Dorsum Sellae, close to the external part of the dura mater. This shot was associated with hemorrhage surrounding the two optic nerves. Bullet B penetrated the right temporal bone, crossed the brain and ended in the left temporal bone. Bullet C penetrated the sternum, touched the right side of the heart, crossed the aorta and the 11th dorsal vertebrae and ended in the medulla. Bullet A caused a blindness of the victim. Bullet B led to an immediate incapacitation of the victim. Bullet C caused an internal hemorrhage and a paraplegia. The possibility of a suicide was discussed. Bullet B leading to immediate incapacitation was certainly the last fired. Bullet C was possibly fired just before. But did bullet A led to an incapacitation of the victim or could he still rearm his weapon and shoot twice? The bullet did not penetrate the neurocranium, therefore there was no crush or stretch mechanism involved that could lead to incapacitation. But was a commotio cerebri generated? Commotio cerebri is a matter of sudden acceleration of the skull, which by means of inertia of the brain, results in wounding at coup and contrecoup. The .22 bullet has a mass of 2.5g, measures 5mm diameter and has a muzzle velocity of approximately 230 m/s. This results in an ultra short time span during which the projectile is acting upon the skull. Because of inertia, the skull will not essentially move during transfer of impulse. A high transfer of momentum and energy will result in perforation of the skull without acceleration of the head. To confirm this theoretical approach, a biomechanical study using a finite element model of the head and brain was done. The authors used the ULP model a validated finite element model developed in Strasbourg. The geometry of the inner and outer surfaces of the skull was digitized in the Strasbourg laboratory from a human adult male skull. The data given in an anatomical atlas by Ferner, et al. 1985 was used to mesh the human head using the Hypermesh code. The ULP model includes the main anatomical features: skull, falx, tentorium, subarachnoid space, scalp, cerebrum, cerebellum, and brain stem. Falx and tentorium have a layer of shell elements, skull is simulated by three-layered composite shell and the others were constituted by brick elements. This skull modeling permits simulation of the bone fracture introducing material discontinuity and then to analyze its effects on the head response in case of head impacts involving skull fracture.

The finite element mesh is continuous and represents an adult human head. The subarachnoid space was modeled between the brain and the skull to simulate the cerebral-spinal fluid. This space is constituted by a layer of brick elements and surrounds entirely the brain. The tentorium separates the cerebrum and cerebellum and the falx separates two hemispheres. A layer of brick element simulating the cerebral-spinal fluid surrounds these membranes. The scalp was modeled by a layer of brick elements and surrounds the skull and facial bone. Globally, the present human head model consists of 11939 nodes and 13208 elements divided in 10395 bricks and 2813 shells. Its total mass is 4.5 kg.

This study shows a very slight movement of the head (less than 1mm) and no shearing injuries to the brain, providing no argument for an incapacitation of the victim following the shot of bullet A. The shot between the eyes could therefore have been the first, followed by a shot to the chest and a final shot to the head, the latter penetrating the two cerebral hemispheres and rapidly leading to death. The localization of blood spotting could be the consequence of a movement of the victim towards the cupboard to seek for his box of bullets to rearm his weapon. The victim was right handed. Important gunshot residues were found on both hands of the victim but mainly on the right hand. Investigators found that the victim was depressed because of personal and professional conflicts. The authors demonstrate that even if, initially, a homicide could be suspected, the possibility of a suicide cannot be excluded and is likely to be the manner of death in this case.

Head Model, Suicide, Incapacitation

G84 Application of Biomechanics to the Interpretation of Pathology Data

Robert O. Andres, PhD, Ergonomic Engineering, Inc., 20 Gulf Road, Pelham, MA; and Joseph H. Davis, MD*, 8905 Southwest 115 Terrace, Miami, FL*

The presentation will demonstrate how biomechanical analysis aids in the interpretation of pathology data resulting from a fatal fall.

A female university student was found dead in the early morning on the pavement four stories below her dormitory window. Both the university and the local police conducted investigations of the incident. An autopsy was performed. The autopsy report and photographs were provided to a consultant forensic pathologist in anticipation of wrongful death litigation. The complaint alleged that the student had accidentally fallen from a "loft" built by a third party and out of the bottom of the swung open window in the room. The "loft" was a bed raised upon two by fours, above the height of the window, to provide more floor space.

The body displayed multiple blunt trauma consistent with the fall, fractures of skull, spine, sternum and ribs with posterior displacement of the lumbar spine. Striated abrasions of the anterior inferior thorax and upper abdomen were prominent. The initial problem was how to correlate these injuries with egress from the window, the windowsill and a 30-inch concrete overhang located above the first story presumed by police as undisturbed.

A 3-dimensional mock-up of the loft and the window was created to investigate possible fall mechanisms. A subject with the same anthropometric characteristics as the deceased was labeled with reflective markers before testing began. Sagittal plane kinematic data were acquired and evaluated with a Peak Performance Technologies Motion Analysis System (Englewood, CO). The position of the whole body center of gravity (CG) was derived in the sagittal plane. There were no accidental fall scenarios that resulted in the CG extending beyond the window ledge; the only possible scenario involved the subject crawling over the ledge and out the opening. An evaluation of the fall trajectory was consistent with this latter scenario – there was no evidence of a push or other source of substantial horizontal velocity. The striated abrasions were consistent with the scenario supported by the biomechanical analysis. The fractures were also consistent with the fall distance.

In this case, the pathologist required further data than originally provided at autopsy to decipher the mechanisms of injury and death. The biomechanical analysis provided the necessary data to interpret the autopsy findings.

Biomechanical, Fall, Autopsy Interpretation

G85 Evaluation of Iron and Macrophages in Meninges of Infants Dying Suddenly and Unexpectedly

Ellen G.I. Clark, MD, 475 Kirman, Reno, NV; Kathy P. Raven, MD, King County Medical Examiner's Office, 325 Ninth Avenue, Box 359792, Seattle, WA; Daniel Anderson-Wooley, 475 Kirman, Reno, NV; and Richard C. Harruff, MD, PhD, 325 Ninth Avenue, Seattle, WA*

The goals of this research project are to assess the significance of iron and macrophages in the leptomeninges and dura of infants and young children dying without evidence of head injury.

As potential pathological markers for occult head injury, the presence of iron and macrophages in the meninges of infants and young children who died of various causes and without evidence of head injury were evaluated. This preliminary study was conducted in order to develop criteria for assessing whether these markers are reliable

indicators for head injury when identified microscopically in the leptomeninges and dura of infants dying suddenly and unexpectedly.

For this study the authors evaluated 18 deaths involving infants and young children ranging in age from 0 to 2 years old, with a mean age of 23 weeks. These included 4 deaths of Sudden Infant Death Syndrome (SIDS), 6 additional natural deaths, 2 unintentional deaths, 1 homicidal death, and 5 deaths due to undetermined causes. None of the cases had history or anatomic evidence of head injury. They selected 3 samples of leptomeninges from each infant and, in 12 of the 18 cases, one sample of dura. They examined tissue sections stained by hematoxylin and eosin (H&E), trichrome, an iron stain for hemosiderin, and an immunocytochemical stain for the macrophage marker, CD68. Under a 40x objective lens, they graded the microscopic features of each section semi-quantitatively for the presence and quantity of iron and macrophages. An "iron score" of 0 to 4 was ascribed to each section as follows: no staining for iron (score 0); occasional staining with most fields negative (score 1); focally abundant staining with most fields showing no staining (score 2); focally abundant staining with most fields showing positive staining (score 3); prominent staining throughout the section (score 4). Because there were 3 sections of leptomeninges examined, they calculated a "total leptomeningeal iron" score from 0 to 12 by simply adding the individual scores from each section of leptomeninges from the same case. As only one section of dura was examined, possible scores for the "total dural iron" ranged from 0 to 4. The "total macrophage" scores from both leptomeninges and dura were derived using the same procedures.

Eleven of the 18 cases showed a total leptomeningeal iron score of zero (of 12 possible); i.e., no iron was observed in any of the three sections. Four of the eighteen cases received a total iron score of 1/12; one case had a score of 2/12; one case had a score of 3/12; and one case had a score of 4/12. The dura (n=12) showed slightly higher total iron scores with only three of the 12 cases having total iron scores of 0 (0/4). Four of the cases had a score of 1/4; 3 cases had a score of 2/4; and one case each had scores of 3/4 and 4/4. All 18 cases had positive macrophage staining on all sections with individual section scores ranging from 2 to 4. The total leptomeningeal macrophage score was 8/12 on 2 of the 18 cases; 9/12 on 4 cases; 10/12 on 3 cases; 11/12 on 5 cases; and 12/12 on 4 cases. The dural macrophage score was also positive on all 12 cases, with scores ranging from 1 to 4. Three cases had a score of 1/4; 4 cases had a score of 2/4; 2 cases had a score of 3/4; and 3 case had a score of 4/4.

These data indicate that macrophages and small amounts of iron are a common finding in the leptomeninges and dura of infants and young children who have died suddenly and unexpectedly. However larger amounts of iron deposits may indicate either birth injury or occult traumatic brain injury. As a continuation of this preliminary study, we are evaluating additional cases of sudden infant deaths in order to establish a "normal" basis of iron and macrophages in the leptomeninges and dura of children with respect to age, birth history, and cause and manner of death. The ultimate outcome of these efforts is to develop objective criteria for markers of occult head injury.

Child Abuse, Traumatic Brain Injury, Meningeal Hemosiderin

G86 Extent and Distribution of Retinal Hemorrhages in Abusive and Non-Abusive Head Injury

M.G.F. Gilliland, MD, Brody School of Medicine East Carolina University Department of Pathology and Laboratory Medicine, Brody 7510, Greenville, NC*

The goals of this presentation are to present the differences between the extent and the distribution of retinal hemorrhages found in abusive compared with non-abusive head injury.

Outcome: Attendees may know differences in retinal findings which can be used to help distinguish between abusive and non-abusive head injuries.

Observations from ocular examination of 80 head-injured infants and children identified a statistically significant greater extent and different distribution of retinal hemorrhages in those with abusive head injury compared with those with non-abusive head injury.

A prospective ocular and systemic study of infants and children was undertaken at the Southwestern Institute of Forensic Sciences between 1981 and 1989. The study group included 169 infants and children. Death was attributed to head injury in 80 of the children. Review of investigations, medical records, and follow-up investigations was used with gross and microscopic findings from autopsy examinations which included ocular examinations. Most of the deaths were attributed to abusive head injury, 62 cases, while 18 of the deaths were attributed to non-abusive injury. The latter included five children involved in motor vehicle collisions. Five more were run over by motor vehicles. One was thrown from a motorcycle. Four children fell: one went out a second story window to a concrete patio, one fell from stairs to a conglomerate patio, the third was standing on a washing machine and fell onto his head, the fourth was standing on tall bed above a concrete floor and fell onto his head. One child was riding on a bicycle with an adult who fell on top of her when the bike hit an obstacle. A child's stroller rolled downhill and collided with a wall; a respiratory tract infection contributed to that death. The eighteenth child suffered a gunshot wound of the head and the ipsilateral eye was examined; no hemorrhages were seen in that eye.

Retinal hemorrhages were found in nine of the eighteen children with non-abusive injuries (50%) compared with 53 of the 62 children with abusive head injuries (85%). The Yates-corrected p value was 0.004 with Greenland, Robbins 95% confidence limits $1.07 < \text{Relative Risk} < 2.74$. Looking at the presence of retinal hemorrhages at the retinal periphery, hemorrhages were found in three of the 18 with non-abusive injuries (17%) compared with 47 of the 62 with abusive injuries (76%). The p value was <0.001 with confidence limits of $1.60 < \text{RR} < 12.90$. Hemorrhages at the macula were found in six of the eighteen children with non-abusive injuries (33%) while 48 of 62 with children abusive injuries (77%) had such hemorrhages. The p value was 0.001 with confidence limits of $1.19 < \text{RR} < 4.53$. Posterior hemorrhages near the optic disk were found in nine of eighteen children with non-abusive injuries (50%) and 50 of 62 with abusive injuries (77%). The p value was 0.02 with confidence limits of $1.00 < \text{RR} < 2.60$. Looking at the presence of hemorrhages in the superficial retina, hemorrhages were found in four of the 18 children with non-abusive head injuries (29%) while 47 of the 62 children with abusive head injuries (76%) had such hemorrhages. The p value was <0.001 with confidence limits of $1.42 < \text{RR} < 47.85$.

Microscopic grading of the extent of retinal hemorrhages allowed further differentiation between the two groups. Hemorrhages of 4+ markedly distorted the retinal architecture, 3+ slightly distorted the retinal architecture, 2+ were visible at low power (20x), and 1+ were only visible at high power (100x). The distribution of the hemorrhages was described with reference to the ora serrata, the equator, the macula, and the posterior retina including the disk at the nasal and temporal sides of pupil-optic nerve sections of the eye. The hemorrhages were also described with respect to the superficial and deep retina as well as subretinal hemorrhages.

Only one child among non-abusive head injury group had as much as a 3+ hemorrhage and that in one eye only. It was found at the subinternal limiting membrane (superficial retina) at the temporal equator. The child was unrestrained sitting on the lap of a back-seat passenger in a car broad-sided in a motor vehicle collision. The child also had 2+ hemorrhages at the macula, the posterior, and both sides of the ora serrata. Two had more extensive 2+ hemorrhages. One of these children had 2+ hemorrhages extending from the posterior retina to the equator in

one eye, the other eye was uninjured. A car rolled over this child's head at low speed. The other child with slightly more extensive hemorrhages had them present posteriorly and extending to the equators bilaterally; hemorrhages were also seen at the ora serrata in one eye. This child had an unwitnessed fall while playing on concrete stairs over a conglomerate patio. The patterned injuries from the conglomerate were helpful in reconstructing the event. All six of the other children with hemorrhages had 2+ hemorrhages in at least one area, usually the posterior or equatorial retina. The superficial retina was involved infrequently.

In contrast, children with abusive head injuries had more extensive retinal hemorrhages which more often were found in the superficial retina and the retinal periphery. Hemorrhages graded as 3+ and 4+ were found in 38 of the 62 children with abusive injuries (61%) as opposed to 1 of 18 of those with non-abusive injuries (6%). The children with at least 2+ hemorrhages tended to have them more widely distributed and to involve the superficial retina more than the children with non-abusive injuries. There was only one child with but a single microscopic 1+ posterior hemorrhage; nine had no hemorrhages.

The presence and extent of superficial and peripheral hemorrhages were good discriminators of abusive head injuries when present. No 4+ hemorrhages were seen in non-abusive head injuries in this population. Only one 3+ hemorrhage was seen in an uncontested non-abusive injury death. Only three children with non-abusive injuries had hemorrhages at the retinal periphery. Two were unrestrained back-seat passengers in motor vehicle collisions; the third fell from concrete stairs.

Extensive superficial and peripheral hemorrhages are part of the constellation of abusive head injuries. The absence of such hemorrhages increases the need to identify the other parts of the constellation before making a diagnosis of abusive head injuries.

Retinal Hemorrhages, Abusive Head Injury, Retinal Periphery

G87 Perimacular Retinal Folds and the Shaken Baby Syndrome: Critical Appraisal Testing of the Current Medical Literature

Patrick E. Lantz, MD, Wake Forest University Health Sciences, Medical Center Boulevard, Winston-Salem, NC*

The goals of this presentation are to discuss the limitations of the current medical literature regarding specificity and presumptive causal mechanism of perimacular retinal folds in Shaken Baby Syndrome.

Perimacular retinal folds accompanying retinal hemorrhages in childhood head trauma are considered virtually pathognomonic of Shaken Baby Syndrome by many ophthalmologists, pediatricians and forensic pathologists. The postulated mechanism is that these traumatic retinal findings result from vitreoretinal traction during cycles of acceleration-deceleration (shaking). Bilateral severe retinal hemorrhages and perimacular retinal folds observed clinically had been attributed to abusive head trauma in a 14-month-old child and a 7-month-old infant with severe acute intracranial injuries. Forensic autopsies confirmed the ocular findings but subsequent investigations concluded that the fatal injuries were non-intentional from static or quasi-static loading.

Design: Case reports, observational

Testing: Critical appraisal testing was performed on 35 medical journal articles and book chapters published from 1966-2001 that discussed presence, specificity and/or causal mechanism of perimacular retinal folds in abusive childhood head injuries.

Results: Publications discussing specificity or formative mechanism of perimacular retinal folds concomitant with retinal hemorrhages observed in childhood abusive head trauma consist of case reports (2), clinical and/or autopsy case series (8), unsystematic review articles (8),

and book chapters (2). Two case controlled studies were found; however, one exhibited bias in control selection and the other only discussed the postulated formative mechanism. The remainder of the publications indicated that perimacular retinal folds were present in some cases of childhood abusive head trauma.

Conclusions: Perimacular retinal folds accompanying retinal hemorrhages in childhood head trauma cannot be regarded as diagnostic of Shaken Baby Syndrome based on the current medical literature due to study type, design bias and lack of appropriately controlled studies. Well-designed clinical and autopsy studies with suitably matched controls must be done before causative mechanism and specificity can be assigned to perimacular retinal folds when observed in children with acute intra-cranial injuries.

Perimacular Retinal Folds, Shaken Baby Syndrome, Child Abuse

G88 Neuropathology of Abusive Head Injury

Mary E.S. Case, MD, Saint Louis University Health Sciences Center, 6039 Helen Avenue, St. Louis, MO*

The goals of this presentation are to 1) appreciate the differences between traumatic and hypoxic diffuse axonal injury; and 2) to understand the basis of traumatic unconsciousness.

This presentation will describe the neuropathology of a large series of abusive head injury in infants and young children as well as a group of control cases. The brains were examined by a forensic neuropathologist and subjected to a protocol for sectioning with sections from 16 sites including parasagittal white matter, 3 levels of corpus callosum, brain stem, cerebellum, distal optic nerves, and cervical spine. Sections were stained by H & E and β -amyloid precursor protein (β APP) and graded for the presence of β APP reactivity using a 4 grade classification. The abusive head injured children ranged from 3 weeks to 8 years old and the controls were of similar ages. Head injury is the most common cause of death in children dying from inflicted injuries. There is great interest in understanding the neuropathology in young children with abusive head injuries and correlating the pathology with the biomechanics of the injury. Clinically, these children most often present an immediate change in their level of consciousness following injury which may consist of impact, shaking, or a combination of the two mechanisms. These mechanisms have been proposed to cause rotational or angular acceleration injuries of the brain accounting for the presence of thin layers of subdural hemorrhage, retinal hemorrhages, and brain swelling in those who survive some period. The question of whether traumatic diffuse axonal injury is the basis of the loss of consciousness (traumatic unconsciousness) and other findings in these children is an important issue. A recent study by Geddes (Geddes et al, Brain 2001, 124:1299-1306) reported that severe traumatic axonal damage is rather rare in infant abusive head injury unless there is considerable impact and that the diffuse brain damage responsible for loss of consciousness in most cases is hypoxic rather than traumatic. This presentation will demonstrate findings from a large series of abusive child head injuries which finds that traumatic diffuse axonal injury occurs more frequently than reported by Geddes. It is important to recognize hypoxic brain damage and to distinguish those changes from traumatic diffuse axonal injury as frequently the two findings occur together and these distinctions will be discussed. The study also found differences in the appearances of acute traumatic DAI and older injury as demonstrated by β APP.

Abusive Head Injury, Traumatic Diffuse Axonal Injury, Child Abuse

G89 Pediatric Injury Evaluation: A Clinical Forensic Pathology Program in Georgia

Lora A. Darrisaw, MD, Julie P. Gardiner, BA, Geoffrey P. Smith, MD, and Kris L. Sperry, MD, Georgia Bureau of Investigation, 3121 Panthersville Road, Decatur, GA*

The goals of this presentation are to describe the authors' consultative experience in the evaluation of physical injury in children.

Child abuse is a common cause of physical injury in children. It is estimated to occur in one million children each year in the United States. The majority of cases of child abuse do not result in fatal injury. It frequently becomes the responsibility of a medical professional to recognize and accurately interpret the nature of injuries in suspected child abuse. An accurate diagnosis is critical in protecting the child and in providing medical-legal information. Thus, it is necessary to develop expertise in the field of child abuse through extensive experience or specific training in a forensic medicine program. The authors have established a child abuse investigative support center to address the critical need to accurately interpret injuries in children and to train more forensic pathologists in this field.

The Child Abuse Investigative Support Center (CAISC) is a clinical forensic medicine program at the Georgia Bureau of Investigation (GBI) Division of Forensic Sciences (DOFS) that was established in August 2000. The center was established to address the needs of agencies involved in investigations of child maltreatment. The center performs dual functions of providing consultative assistance and educational training throughout the state of Georgia. Physician members of the center consist of forensic pathologists of the GBI Medical Examiner's Office who possess expertise regarding injury causation. They are requested for expert consultation in suspected child abuse cases and are available for court testimony. An investigative division of the center provides consultations by criminal analysts who possess expertise in reference to crimes involving children. The center is also an integral part of the forensic pathology fellowship at the GBI and serves to train fellows in the field of child abuse and neglect. The center operates under state and federal grants and provides services free of charge to consulting agencies.

Since its inception, 103 cases (mean age 2.7 yrs; range 19 days to 16 yrs; 58M:45F) of pediatric, predominately non-fatal, injuries have been referred to the center for evaluation. Various law enforcement agencies presented the majority of the cases and the Department of Family and Children Services requested the center's service in 33% of the cases. The interpretation of injuries was based upon the evaluation of pertinent documents depicting and/or describing the injury. These included medical records, photographs, case files and radiographs. In four instances the object implicated as the source of the injury was evaluated and on two occasions the acutely injured child was evaluated while hospitalized.

A spectrum of injuries was represented in the cases we evaluated including bone fractures (35%), dermatologic injuries such as bruises and abrasions (31%), burns (24%) and cranial-cerebral injuries (22%). Only 3 cases involved injuries to regions involving or near the genitalia and were presented to evaluate for possible sexual abuse. Overall, 56% of the injuries were interpreted as abusive in nature. Nine cases were interpreted as representing discipline but not clearly abusive in nature and injury causation was inconclusive in eight cases. In the majority of cases a written consultation report was provided at the time of the evaluation. So far, courtroom testimony has been necessary in only three cases.

This review of the child abuse investigative center has yielded useful information. The authors identified that the service is particularly of value to rural areas that lack the resources and medical expertise that are typically available in large metropolitan areas. They recognized that

in many cases there is a long delay in the investigation and prosecution of child maltreatment. Their goal is to improve marketing of their services and to evaluate more acutely injured children. They have experienced difficulty in interpreting injuries on some occasions because of sub-optimal documentary material (i.e. photographs).

Overall, this study reveals that forensic consultative teams can perform several functions related to child abuse crimes: 1) provide expertise in evaluation of the injuries, 2) provide training opportunities in the field of child abuse, 3) provide expert court testimony.

Child Abuse, Clinical Forensic Medicine, Georgia Bureau of Investigation

G90 Physical Findings in Confessed Homicidal Suffocation of Children: A Case Series

Tracey S. Corey, MD, and Deirdre Schluckebier, MD, Office of the Chief Medical Examiner and University of Louisville School of Medicine, OCME, 810 Barret Avenue, Louisville, KY*

The goals of this presentation are to review the physical findings, and lack thereof, in homicidal suffocation of young children.

Investigation of death and injury in children requires attention to detail of subtle injury patterns and careful, thorough case history review and scene investigation. As seen in various individual anecdotal cases, intentional suffocation of children may have relatively few findings. To have a more comprehensive understanding of the physical findings in suffocation, the authors undertook a retrospective review of cases of confessed suffocations of children age 5 years or less in which the first author performed the post-mortem examination or a living forensic examination prior to the child's death. In all cases presented herein, a parent entered a guilty plea in criminal court. In four of the five events, the parent gave a formal confession to law enforcement, and later entered a guilty plea in criminal court. In the 5th event, the mother allegedly confessed to cellmates, and entered an Alford Plea in criminal court. The case series consists of 8 children age 5 or less who died at the hands of 5 perpetrators. In 2 of the events, multiple children were killed on the same night.

Event #1 - Fraternal twins, age 6 weeks were reportedly discovered dead in their crib by their parents one morning. Despite initial denial of the parents of use of the in-home apnea monitors, the investigators collected them at the time of the initial scene investigation. Post-mortem examination revealed no injuries whatsoever on the boy, and a small superficial abrasion on the eyelid of the girl. Downloading of the apnea monitors revealed a record of the double homicide. Confronted with the evidence, both parents confessed to suffocating the infants with pillows. The father told investigators that he did it because he "couldn't take" the continuous crying of both infants. Both entered guilty pleas and accepted "life" sentences. Interestingly, during a previous marriage five years earlier, the mother had "lost a baby to SIDS."

Event #2 - A previously healthy baby girl was admitted to the hospital for a reported apneic episode at 4 months of age. Over the next four months, she was repeatedly admitted to the hospital for recurrent apnea, and underwent a Nissn fundoplication in an attempt to alleviate GE reflux thought to be contributing to the apneic events. At eight months of age, the infant was admitted in full arrest following another in-home apneic event. At the request of the treating physicians and police, she was evaluated as a "forensic medicine" case at the time of the last admission. There were no injuries to the baby at the time of the final admission, and there had been no injuries documented on previous admissions for apnea. She did not recover, and died 2 weeks later. The immediate cause of death was hypoxic encephalopathy, but the underlying cause and manner remained unknown. Later, the mother

(a juvenile) spontaneously came forward and admitted to repeatedly suffocating the baby, who was the alleged result of an incestuous event. The case was resolved in juvenile court.

Event #3 - A four-month-old infant was brought to the OCME as a "suspected SIDS" case after being found dead on a couch. At autopsy, findings included a faint abrasion surrounding the ala nasa, erythematous areas over the neck, and a geographic pattern of cutaneous petechiae involving the head, neck, and right upper extremity. The investigators re-interviewed the mother following the preliminary autopsy findings report. The mother, a teenager, admitted to suffocating the baby against her chest and shoulder to stop his incessant crying. She avoided a jury trial by pleading guilty to reckless homicide, and was sentenced to five years.

Event #4 - A two-year-old boy with diagnoses of hyperactivity and probable autism was found dead following a nap. His position at body discovery was described as prone, with his head "face down" in the pillow. The child had no petechial hemorrhages, no intraoral trauma, and no identifiable injuries to any body surface. The preliminary autopsy report listed "no anatomic cause of death." Two days later, investigators received a call from a relative claiming to be an eyewitness to the child's homicidal suffocation. The father admitted to suffocating the child by holding his face into the pillow "until he went to sleep." The case was adjudicated without a trial.

Event #5 - Three young girls (ages 5 years, 28 months, and 17 months) were allegedly discovered dead together in a standard adult bed. Complete autopsies and detailed scene investigation and case history review failed to reveal any natural disease, environmental hazard, or toxicologic substance to explain their deaths. All facial trauma was mild, and increased with the age of the child. But even the 5 year old displayed only small maxillary gingival contusions and abrasions, rare bulbar conjunctival petechial hemorrhages. The girls' baby sister (age 2 weeks) had died 4 ½ months earlier - death in that case was initially attributed to SIDS, although a disclaimer had been included in the final opinion, stating that the age was not "typical." The three older girls' deaths were attributed to suffocation, with the manner ascribed to homicide. Fifteen months after the deaths, the mother pleaded guilty to four counts of murder by means of an Alford Plea.

In reviewing cases of pediatric death, all aspects of the investigation must be integrated to draw conclusions regarding cause and manner of death. The physical findings of asphyxia (accidental or homicidal) are often subtle, and may range from no evidence of injury to minor facial trauma. Additional clues to the cause of death may be found in a careful case history review and integrated scene investigation. These findings may initially seem to be small details that seem "out of kilter," and thus direct the investigation further. In many cases however, because of the paucity of findings in these cases, only admission by the perpetrator will allow determination of a homicide.

Child, Suffocation, Homicide

G91 Escalated Homicide: Cultural Changes Produce a New Type of Child Death

Chantal Ferraro, PhD, Long Island University at Brookville, Brookville, NY; and O'Brian C. Smith, MD, University of Tennessee at Memphis, 1060 Madison Avenue, Memphis, TN*

The goals of this presentation are to present results from a study of abuse related child deaths in Memphis, TN, using hospital records, Medical Examiner reports, homicide police investigation files, and court transcripts; to evaluate the validity of the battered child syndrome and the impulsive homicide as a framework of analysis for child abuse related fatalities; and to propose the additional analytical category of escalated homicide to the existing conceptual tools of analysis.

The clinical tableau of abuse leading to child death has traditionally been classified as either manifestations of the battered child syndrome, or as evidence of impulsive homicide. The battered child syndrome first described by Tardieu¹ in the 1860s in France, and again by Kempe² in the 1960s in the USA typically involves a long term pattern of physical abuse creating a series of injuries over time, often coupled with symptoms of deprivation and neglect. Impulse homicide is presented as a single event of lethal violence, most often from blunt trauma injuries, with little or no evidence of any sequence of severe prior injuries or deprivation³.

It is the contention of this paper that, although both types are valid and useful description of abuse, they do not provide an adequate explanation for all cases. As a result of the studies, the concept of escalated homicide is introduced as a tool for assessing, recognizing and describing the changing nature of patterns of child abuse.

Medical and forensic treatment of violence against children gives primacy to physical injuries, and is essential to the understanding, diagnosis and documentation of abuse. But looking at the tree should not hide the forest. Circumstances produce injuries, not vice versa. The physical injuries of child abuse occur in a social/cultural context, for the most part a household, or care facility, the structure, composition and function dependent upon larger social forces. They are places where complex and often dysfunctional interpersonal relationships are acted out. Unfortunately, these environments are also the first lines of failure under stress, and their weakest and most silent members often the first victims.

This study integrates the forensic and social findings in such a way as to allow for the discrimination of the social and cultural forces leading to the abusive event. Of the 30 cases reviewed as part of the initial study and drawn from a prior study of 1,451 child deaths investigated by the Medical Examiner in Memphis, TN, in the past ten years, 5 were categorized as impulse homicides, 6 as battered child cases, and 12 as escalated homicides. One case involving a 20 month-old girl abused separately by mother, showing battered child signs, and mother's boyfriend, killing the child as an escalated homicide was classified as a combination example. Finally 5 cases were atypical in regard to perpetrators and setting.

Of the 12 escalated homicides, eleven involved the victim being murdered by the victim's mother new paramour, and only in one case was the child killed by the biological father. Typically, the ultimate assault takes place within a fit of anger deceptively reminiscent of the impulsive homicide. The pathognomonic differences are definite. What differs is the fact that in all cases there were premonitory and warning signs of abuse, ranging from observed behavioral responses of the young victim towards the aggressor, to unexplained bruises, bite marks, black eyes, and even unexplained and/or unobserved broken bones were present. Although escalated homicides reveal patterns of injuries over time, the motivation leading to the production of injuries differs because the relationships of authority vary between abused and abuser.

In a battered syndrome context, relations of authority are legitimate, or perceived as legitimate, and articulated in terms of parental rights. Typically a father takes over the task of disciplining a child either for the general purpose of "showing him the way," or for a specific purpose such as toilet training. Most often, physical punishment is not secretive, and the level of external interference limited. In instances of escalated homicide, boyfriends do not possess any legitimate authority over their girlfriends' kids, and are often being reminded so. Here, physical abuse is hidden and excuses are made to explain the injuries and scars. Most importantly though, beating the child has nothing to do with disciplining him, or teaching him to become a man. In most cases, it is a venting of anger, frustration, and resentment over the current living situation, and ill feelings towards their partners. This gradual escalation of frustration and anger, generated by household dynamics leads to repetitive acts of increasing violence eventually culminating in a deadly blow.

Recognizing variation in the behaviors that create child abuse is the first step in establishing profiles of perpetrators of violence against children. The forest is made up of a variety of trees.

Battered Child Syndrome, Impulsive Homicide, Escalated Homicide

G92 Magnetic Resonance Microscopy as an Adjunct in The Evaluation of Infant Rib Fractures

Andrew M. Baker, MD, Office of The Hennepin County Medical Examiner, 530 Chicago Avenue, Minneapolis, MN; and Kimberlee Potter, PhD and William R. Oliver, MD, Armed Forces Institute of Pathology, 14th and Alaska Avenue, Northwest, Washington, DC*

The purpose of this presentation is to explore the use of magnetic resonance microscopy in the evaluation of infant rib fractures, and to compare the findings with traditional anterior-posterior radiography, axial radiography, and histologic evaluation.

Following the second infant death in a family, the autopsy findings in the first infant death were reviewed at the request of the Naval Criminal Investigative Service (NCIS). Original autopsy radiographs from the first infant revealed multiple healing fractures that had previously been overlooked. Exhumation was recommended, and permission for exhumation ultimately granted. Re-interview of the mother, coordinated with the timing of the exhumation, prompted a confession as to how the children were killed.

The body of the first infant was exhumed, and healing posterior rib fractures were resected *en bloc* with the adjacent vertebral body and contralateral normal rib. Axial radiographs of each vertebra-rib pair were obtained. Magnetic resonance microscopy (MRM) was performed on each sample. Specimens were whole-mounted and cut in the axial plane for histology.

MRM provides microanatomic images of both hard and soft tissue. Images were acquired on a Bruker-Biospec system operating at 7 Tesla (300 MHz for ¹H). The 3-D images were acquired with a fast spin echo imaging sequence. The datasets were processed for visualization using the AVS/Express development environment, and 3-D images were rendered using a direct composite algorithm.

The ability to view and rotate the fractures in 3-D space allowed visualization of fracture morphology in ways unobtainable by standard radiography or histology. Fracture dimensions, the fracture line, the uninjured bony cortex, and the trabecular bony architecture were readily discernable by MRM. Histologic examination provided details of various aspects of bony healing that were not readily visible by MRM.

While MRM is currently an expensive imaging modality, limited to a few institutions and restricted to specimens of small size, it has great potential as an adjunct in the evaluation of healing fractures. With continued advances in technology and computing power, MRM will likely become widely available as an adjunct to, or perhaps a replacement for, histologic examination of some specimen types.

Infant, Magnetic Resonance Microscopy, Fracture

G93 Mother/Infant Co-Sleeping/Bed-Sharing and Sudden Infant Death Syndrome

James J. McKenna, PhD, University of Notre Dame, 613 Flanner, South Bend, IN; and Joseph A. Prahlow, MD*, South Bend Medical Foundation & Indiana University School of Medicine, 530 North Lafayette, South Bend, IN*

The goals of this presentation are to present to the forensic community a review of mother-infant co-sleeping and bed-sharing practices; to differentiate "safe" from "unsafe" co-sleeping conditions; to understand that, when done safely, bed-sharing/co-sleeping may actually be protective against death due to SIDS.

Deaths which remain unexplained after a thorough medicolegal death investigation can be the source of great frustration for forensic pathologists. Several categories of unexplained deaths are known within the forensic community, but for many, no category of deaths is as frustrating as Sudden Infant Death Syndrome (SIDS) cases. SIDS remains one of the great mysteries within the world of medicolegal death investigation. As such, theories as to the underlying cause or causes of SIDS have been and remain plentiful. Many risk factors have been identified, but most forensic pathologists know of several cases of SIDS occurring in infants with no identifiable risk factors. Whether or not a particular risk factor actually plays a role in SIDS can be controversial, and the implied blame that can accompany the identification of a particular risk factor can lead to feelings of guilt in the parents or other caregivers.

Within the forensic community, one of the most widely acknowledged potential causes of a SIDS-like death is overlay, an accidental asphyxial death related to another person lying on top of or wedged against the infant. Consequently, whenever an infant death occurs where the infant is sleeping with or next to another individual, it is important to consider the possibility of death by overlay. Depending on the forensic pathologist certifying such a death, a case where overlay is a possibility (but not necessarily proven) may be certified as a death due to overlay, SIDS, undetermined causes, or some other variation.

Because of the potential risk for overlay, there has recently been a national campaign against "co-sleeping/bed-sharing" with infants. Although the prevention of overlay deaths is an appropriate and worthwhile goal, the unconditional implication that any form of adult-infant co-sleeping is harmful is inappropriate, untrue, and not supported by scientific research. Part of the problem clearly stems from a lack of understanding of the terminology used in this debate. For example, "bed-sharing" is a form of co-sleeping, but there are other forms of co-sleeping that do not involve bed-sharing.

Another very important factor that is frequently overlooked is the nature of the maternal-infant relationship, including whether or not the mother is breastfeeding her infant. With respect to maternal-infant wake/sleep patterns, maternal and infant attentiveness and response, and similar parameters, it is inappropriate to consider the breastfeeding mother-infant night-time relationship equivalent to a nonbreastfeeding mother-infant relationship. Add to the latter relationship such factors as maternal drug or alcohol use and inappropriate sleeping conditions (such as a sofa) and it becomes clear that there are two ends of a spectrum when it comes to co-sleeping (and bed-sharing). At one end, there are the breastfeeding mothers who tend to be very attentive to their babies' needs, while at the other end, there are the mothers who are not so attentive and may, in fact, be careless. In other words, there are unsafe ways in which to co-sleep/bed-share, and there are safe ways in which to co-sleep/bed-share. A categorical condemnation of every form of co-sleeping/bed-sharing may indeed prevent accidental overlay deaths in certain infants; however, such a policy might also adversely affect infants who are otherwise a part of a safe co-sleeping/bed-sharing relationship. Data from previously-reported and ongoing studies of

mother-infant sleep patterns will be presented, showing that in otherwise safe sleeping conditions, co-sleeping/bed-sharing may actually protect against SIDS. As the debate continues within the forensic community about how to certify SIDS-like cases in the setting of co-sleeping/bed-sharing, it is important that forensic pathologists be aware of all available information regarding this topic.

Sudden Infant Death Syndrome, Co-Sleeping, Bed-Sharing

G94 Death Certification in Sudden Infant Death Syndrome and Related Infant Deaths

Joseph A. Prahlow, MD, South Bend Medical Foundation & Indiana University School of Medicine, 530 North Lafayette, South Bend, IN; and Randy L. Hanzlick, MD, Fulton County Medical Examiners Office, 430 Pryor Street, SW, Atlanta, GA*

Upon completion of this presentation, attendees will become familiar with a newly-proposed method for certifying SIDS and SIDS-like deaths and to become involved in the dialogue concerning certification of such deaths.

For an infant death to be considered due to "Sudden Infant Death Syndrome" (SIDS), a complete death investigation and autopsy, including toxicology, must be negative, and the infant must be less than 1-year-old. The "classic" SIDS scenario involves an infant, typically less than 6-months-old, who is found dead in his/her crib. Known risk factors include low socioeconomic status, parental smoking, prone sleeping position, formula-feeding, and a history of prematurity. Within the past 10 years, a campaign by public health agencies and pediatricians to advocate a supine sleeping position has purportedly resulted in fewer SIDS deaths. Amongst forensic pathologists, a trend has been noted that there are fewer and fewer "classic" SIDS cases. Whether this is related to the sleep position campaign, better information-gathering, different methods of death-certification, or a combination of these is not known. Be-that-as-it-may, many SIDS-like cases occur where certain known risk-factors are clearly identified. A potentially unsafe sleeping environment is a factor that is increasingly being recognized as a possible cause in some of these deaths. Ultimately, these and the other known risk factors for SIDS may cause potential interpretive difficulties for forensic pathologists, thus creating death certification dilemmas.

A recent proposal in the National Association of Medical Examiners' "A Guide For Manner of Death Classification" (in draft form) relates to the certification of SIDS and SIDS-like deaths. In this proposal, it is suggested that various items from the scene investigation/history which cause potential interpretive difficulties (such as bedsharing or being found face down on a soft pillow) should be listed in part II of the death certificate, with part I listing "Sudden Infant Death Syndrome" or "Findings consistent with SIDS." In this presentation, a series of cases will be presented, ranging from classic SIDS to accidental overlay, with many cases including one or more items causing interpretive difficulty. In each, the circumstances of death, the autopsy findings, and the death certification using the newly-proposed method will be presented. Discussion will include the potential controversies concerning which items/risk factors warrant inclusion in part II of death certificate; other options for relaying information about these items/risk factors will also be addressed. Through the presentation of a series of example cases, the authors hope to foster more discussion and dialogue about this very important issue.

Sudden Infant Death Syndrome, Death Certification, Cause of Death

G95 Pediatric Mortality in the Cook County Medical Examiner's Office, 1 to 4 Years: 2000-2001

Eupil Choi, MD, and Edmund R. Donoghue, MD, Office of the Medical Examiner, Cook County, 2121 West Harrison Street, Chicago, IL*

The goal of this presentation is to present statistical data on causes of death in the pediatric group between 1 and 4 years of age in the Cook County Medical Examiner's Office cases. The authors examined case records of the Cook County Medical Examiner's Office (CCMEO) over the two-year period from January 1, 2000 through December 31, 2001.

The number of deaths investigated by CCMEO between 1 to 4 years of age totaled 148 cases in the two-year period. Eighty-six cases involved males and sixty-two involved females. Specific causes of death were identified in 97% of all cases. Leading causes were accidental injuries, natural deaths and homicides. This report highlights the impact of violent death mortality in early age. Accidental injuries are related to automobile accidents, pedestrian injuries, drownings, asphyxias, house fires, falls and overdoses. In natural deaths, diseases of the heart and infection predominate. Infection includes bronchopneumonia, lobar pneumonia and sepsis. Homicides include blunt trauma injuries, gunshot wounds, stab wounds, drownings, suffocations, starvations and arson fires. The cause of death was undetermined in 3% (5/148) of the cases. By manner of death, there were 70 accidents, 42 naturals and 27 homicide cases, respectively. Undetermined manner is 6% (9/148) of all cases. Those that were of undetermined manner included two cases of fire and two cases of drowning, and 5 cases where the cause of death was undetermined.

Mortality, Cook County, Medical Examiner's Office

G96 Suicide in Children: A 12-Year Retrospective Study

Jeffrey M. Jentzen, MD, and Eileen Weller, RN, MHA, Milwaukee County Medical Examiner's Office, 933 West Highland Avenue, Milwaukee, WI; and Adam Ruck, University of Wisconsin-Milwaukee, 2465 Oakland Ave, Milwaukee, WI*

Suicide in pre-adolescent children (ages 6-12), although unusual, present unique causes, risk factors and potential prevention strategies which serve a specific public health need in the prevention of this unique form of violence.

Methodology: Case files for all deaths in children ages 6 to 12 ruled suicide or undetermined from the Milwaukee County Medical Examiner's computerized case records were reviewed from 1989 through June 2002. In addition, case files for all adolescent suicides reported in the corresponding time period were reviewed. Detailed demographic information, social history, behavioral history, and death scene investigation, autopsy findings, individual and family medical and psychiatric conditions and characteristics has been abstracted and analyzed. Review of the pertinent medical and psychiatric literature, including collaboration with a pediatric psychiatrist treating children and survivors of suicide attempts has been undertaken.

Results: The authors identified trends, frequently occurring factors and consistent findings within characteristics, and in doing so a way to observe the predictive indicators for suicide "prone-ness" in any or all cases. Specific factors will include behavioral factors such as previous suicide attempts, verbalization of suicidal ideation, the presence of depression, parental and family psychiatric history, impulse control history, history of abuse and other factors. Medical factors include: substance abuse disorders, attention deficit hyperactivity disorder, enuresis, parental and family medical history.

Discussion: The Milwaukee County Medical Examiner's office has identified an issue with suicide in children, ages 6-12 and has determined that this is a public health significance do to it being such an unusual phenomenon. Although suicide in the childhood age group is a rare phenomenon, it is encountered in normal practice of medical examiners and child psychiatrists. Characteristics of suicide in children are different than those found in the teenager age group. Identification of the risk factors, personality and behavioral characteristics in completed suicides will provide a framework for the development of prevention strategies. The barriers to consistent death certification and reporting across jurisdictions will also be evaluated, in an effort to develop strategies to increase consistency and improve data comparability and meta-analysis capacity across multiple jurisdictions.

Suicide, Childhood, Pediatric

Pathology/Biology

G1 Overview of Suicide Cases in Geneva, Switzerland During a Twenty-five Year Period (1971-1995)

Romano La Harpe, MD*, Institut Universitaire de Médecine Légale, Av. de Champel 9 (CMU), Genève 4, Switzerland

The goal of this research project is to provide demographic information regarding people who committed suicide in Genève.

The purpose of this study is to provide demographic information regarding people who committed suicide in Genève between January 1, 1971, and December 31, 1995.

In this period (25 years), the forensic institute of Genève, Switzerland examined all the cases of suicide (2,074) committed in Genève by individuals, who were between 13 and 97 years of age.

The average number of such cases per year is 83. The mean annual suicide rate is 22.52/100,000 population, and the rate has remained relatively stable over the years. The average age of the decedents is 48 years. The sex ratio is 1.5 : 1 (1,261 males and 813 females).

The most common cause of death is by firearms (19%). A high incidence of men (91%) could be explained by an easier access to weapons (In principle, every Swiss man must enrol in the army; furthermore, he is asked to keep his gun at home.) Entry wounds are most frequently localised within the cranium and the face (78%). Jumping from height is the second most common cause of death (18%). This method (43% of men) doesn't require any special material and is frequently chosen by the elderly. Hanging (17.5%) is chosen especially by men (73%). The weak proportion of women could be explained by a misunderstanding of the exact cause of death ("soft" death by vascular compression and not suffocation). Intoxication (16.5%) is a well-known cause of death predominant in women (only 42% of men), because it's a soft death and because women often have easier access to drugs such as benzodiazepines or anti-depressors. Drowning (16%) is chosen by men and women in the same proportion (50%), It's the principal means of suicide of women exiting a psychiatric hospital. Suicides by carbon monoxide poisoning is relatively rare (4.5%). In 1978, town gas, which contained carbon monoxide, was replaced by natural gas (methane without CO). Therefore, carbon monoxide poisoning, previously a suicide method of choice, has now become very rare and completed especially by men (72%) in their car. The other causes of death (train fatalities, asphyxias, electrocutions,) are very rare. Women predominantly commit attempts by cuts on wrists. Death by cuts on wrists (2%) are predominantly committed by men (73%).

In conclusion, we can say that the incidences of suicide cases in Genève, Switzerland, which are among the highest in Europe, are, of course, underrated since an unknown number of these cases are mistaken for deaths of another nature (mostly accidental and natural deaths).

Suicide, Death, Genève

G2 An Unusual Presentation of a Rare Entity: Exsanguination by Ruptured Left Subclavian Aneurysm

Reade A. Quinton, MD*, UT Southwestern Medical Center, Department of Pathology, 5323 Harry Hines Boulevard, Dallas, TX; and Joni L McClain, MD, Southwestern Institute of Forensic Sciences, 5230 Medical Center Drive, Dallas, TX

The goal of this research project is to present an unusual case of a ruptured left subclavian artery aneurysm with formation of a subclavian-esophageal fistula, and to review the associated literature.

The case presented represents an unusual entity with an even more unusual history. The decedent, an 88 year-old white male, lived at home with his wife of 70 years who suffered from severe Alzheimer's disease. The decedent's past medical history was only significant for hypertension. Police records indicated a number of calls to the residence in the recent past because the wife had mistaken her husband for a "prowler" in the yard. On this occasion, the wife left her residence to cross the street and tell her neighbor that she had seen the prowler and "hit" him. The decedent was found face down and unresponsive on his front porch. He was noted at the scene to have small incised wounds of the hands and wrists, but no other injuries were noted at that time. The neighbor called 911, and resuscitative efforts were initiated at the scene by EMS. On arrival to the emergency room, resuscitation was still in progress, but continued efforts were unsuccessful.

Scene investigation revealed the decedent's blood on the door handle leading into the residence. The wife told officers at the scene that she had tried to hit the "prowler" with a candy bowl, and that he had blocked it with his hands. A fragmented glass candy bowl was found at the scene, also with the decedent's blood. Questioning the neighbors revealed that a similar incident had occurred one week prior, but the incident had not been reported. At that time the wife had confronted the husband within the house with a kitchen knife, but he was apparently uninjured and the authorities were not notified.

At autopsy, the external examination confirmed superficial incised (defense) wounds of the hands and wrists. Also noted were scattered, healing superficial incised wounds of the left chest, presumed to be related to the previous unreported knife incident. Examination of the scalp, skull, and brain was unremarkable. Internal examination revealed moderate to severe atherosclerotic disease of the aorta and its main branches, as well as mild narrowing of the coronary arteries by atherosclerotic plaques. There was also marked narrowing of the vertebral, basilar, and internal carotid arteries. Examination of the heart showed a single focus of fibrosis in the posterior wall of the left ventricle which suggested a small remote infarct. The most notable finding was a mildly dilated left subclavian artery that contained a large intimal defect near the aortic arch. This defect opened into a saccular aneurysm, surrounded by thin adventitia and periaortic tissue. The aneurysm contained a large thrombus, which abutted the posterior aspect of the esophagus. Examination of the esophagus demonstrated an associated rupture site through an area of ulcerated mucosa, forming a subclavian-esophageal fistula. Greater than 1500 cc of clotted blood was discovered within the stomach, suggesting acute exsanguination into the gastrointestinal tract.

Aortic aneurysms as a complication of severe cardiovascular disease are frequently seen at autopsy, but aneurysms of the arch vessels exclusively are uncommon. Of the cases reported, the majority of subclavian-esophageal fistulae present as a complication of aberrant subclavian arteries. One of the few reported cases of subclavian-esophageal fistula associated with normal subclavian vessel distribution occurred as a result of an esophageal foreign body. In our case, the arch vessels were appropriately positioned, a history of previous trauma or surgery was not elicited, and no foreign bodies were discovered. This suggests that this case was exclusively related to the decedent's cardiovascular disease.

Under certain circumstances, the manner of death in a number of cases of myocardial infarction has been ruled a homicide. If we were to assume that in this case, the decedent's aneurysm finally ruptured due to an acute stressful event (the assault), then this case could be considered a rare case of homicide by subclavian aneurysm. Given the circumstances, the manner of death in this case was eventually called natural. We present this case and review the associated literature.

Subclavian Aneurysm, Subclavian-Esophageal Fistula, Atherosclerosis

G3 An Unusual Cause of Sudden Death in Infancy: Histiocytoid Cardiomyopathy, Report of an Autopsy Case

Frank Evangelista, MD*, Office of the Chief Medical Examiner, 720 Albany Street, Boston, MA; Melissa P. Upton, MD, Beth Israel Deaconess Medical Center-Department of Pathology, 330 Brookline Avenue, Boston, MA; Richard J. Evans, MD, Eva Patalas, MD, and Alexander M. Chirkov, MD, PhD, Office of the Chief Medical Examiner, 720 Albany Street, Boston, MA

The goals of this research project are to remind participants of the following: 1) be aware of an unusual form of cardiomyopathy which may cause sudden death in infancy or early childhood; 2) know the clinical features of histiocytoid cardiomyopathy; 3) recognize the gross and microscopic features of this rare cardiac disease; and 4) be able to select the appropriate special stains to differentiate this entity from glycogen storage disease and from infiltrates of inflammatory origin.

Methods: Report of sudden death, autopsy findings, and histopathologic examination, including special stains and immunoperoxidase studies.

Clinical History: An otherwise healthy, full-term 22 month old female was at home in her crib when she began to cry. Her father picked her up and noticed that she was having trouble breathing. She subsequently became unresponsive and stopped breathing. EMS was called and the father began CPR. Upon arrival of EMS, the child was found to be in agonal respirations and without pulse. A cardiac monitor was placed, and it showed ventricular fibrillation. She was intubated and transported to the hospital. CPR was continued, and upon arrival to the Emergency Department, she was pulseless and not breathing. The cardiac monitor showed agonal rhythm, and ACLS was begun. Despite medical intervention, she displayed extended periods of asystole without pulse, and her pupils were fixed and dilated. Resuscitative efforts were discontinued and she was pronounced dead.

Autopsy Findings: At autopsy, the body was that of a well developed and well nourished 22 month old white female, who weighed 27 pounds and measured 34 inches in length. Her growth and development were appropriate for age. There were no signs of trauma. All internal organs were in their normal anatomic relationship. The heart, in the fresh state, weighed 70 grams (average weight for age = 56 grams), and it was structurally unremarkable. Upon sectioning, the myocardium was red/brown, without fibrosis, hemorrhage or distinct lesions. The interventricular septum was intact. The atria were unremarkable, and no interatrial defects were present. The coronary ostia were normally located, and the distribution showed right dominance with a circulation pattern within normal limits. The valves were thin and unremarkable. Microscopic examination of hematoxylin and eosin (H+E) stained sections of the heart revealed multiple myocardial and subendocardial clusters of clear histiocytoid cells with an associated minimal chronic inflammatory cell infiltrate. Special stains and immunoperoxidase stains were performed, and the histiocytoid clusters showed focal PAS positivity, weak positivity for actin, and negative staining for the histiocyte marker CD68. Based on these results, a glycogen storage disease (which would show diffuse PAS positivity) and a histiocytic process (which would show CD68 immunopositivity), were ruled out. The positive immunohistochemical staining for muscle actin supported a myocytic origin of the clear cells. The remainder of the autopsy, including microscopic evaluation, was unremarkable.

The clinical data together with the results of the autopsy, including H+E, PAS, and immunohistochemical microscopic examination of the heart, support the diagnosis of histiocytoid cardiomyopathy.

Discussion: Histiocytoid myocardiopathy is a rare cardiac disorder of infants and young children, presenting under two years of age, and it generally affects females. The clinical presentation is characterized by severe and eventually fatal, cardiac arrhythmias. Less frequently, the

presenting feature is sudden death. Gross morphology of the heart shows hypertrophy, tan/yellow myocardial nodules, but it may be grossly unremarkable. In most cases the heart weight is increased for age. Characteristically, the microscopic examination reveals focal collections of rounded, pale, vacuolated, or granular cells with centrally placed, round nuclei. These cells can be found in a diffuse or focal pattern throughout the myocardium, but they have been described to follow the course of the conduction system. Ultrastructural studies in reported cases demonstrate myofibrils, consistent with cardiac muscle origin, and abundant mitochondria. In some reported cases, malformations of the nervous system have been described. These have included hydrocephalus, agenesis of corpus callosum, malformations of cerebellum, and microphthalmia. In extracardiac viscera, some patients have had prominent oncocytes in glandular tissue. Rare other associations have included ovarian or renal cysts, and renal calcinosis.

The etiology of this disorder is uncertain. The ultrastructural observation of numerous mitochondria has raised the possibility that this is a mitochondrial cardiomyopathy, associated with abnormalities of the oxidative phosphorylation system. However, there are reported instances of successful surgical excision of histiocytoid foci, with survival to at least 6 years after surgery, and such a cure would not be expected in genetic mitochondrial disorders, which are usually characterized by steady degenerative changes. Another leading hypothesis is myocardial or Purkinje cell hamartoma, which is supported by the observation that the histiocytoid cells occur in locations in the heart where myocytes are normally found, and by the fact that the cells morphologically resemble muscle. These findings may also suggest that this entity is caused by a developmental anomaly of the conduction system of the heart. Some pathologists favor the consideration of postviral injury, either limited to the heart or systemic, which could explain the rare associated extracardiac abnormalities. Finally, it has been proposed that this disorder may have a genetic basis. The higher incidence in females suggests that it may be an X-linked dominant trait. This is an important consideration as genetic counseling may be indicated for affected families.

This condition should be considered in the differential diagnosis of SIDS, necessitating a careful cardiovascular examination in every case.

Conclusion: Histiocytoid cardiomyopathy is a rare cause of cardiac arrhythmia of uncertain etiology, affecting infants and young children, and it may lead to sudden death. The recognition at autopsy of the characteristic histologic appearance of the histiocytoid cells and the selective use of special stains and immunostains permit correct diagnosis.

Sudden Death, Arrhythmia, Cardiomyopathy

G4 The Changing Faces of the Medico-Legal Autopsies at the Office of the Chief Medical Examiner of the State of Maryland—A Decade of Experience

Aurelian Nicolaescu, MD*, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD; Joseph A. Kufera, MA, National Study Center for Trauma and EMS, 701 West Pratt Street, Baltimore, MD; Jack M. Titus, MD, and David R. Fowler, MB, ChB, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD

The goal of this research project is to review the autopsies performed at the Office of the Chief Medical Examiner of the State of Maryland in the last 11 years.

A review of the autopsies performed at the Office of the Chief Medical Examiner of the State of Maryland, in the last 11 years, is presented to the forensic community to share our experience.

This poster will present the work of a team from the Office of the Chief Medical Examiner (OCME), State of Maryland and the National Study Center for Trauma and EMS.

Over the last eleven years the number of the medico-legal autopsies increased significantly, especially after 1997, from 2,997 autopsies performed in the year 1997 to 3,757 autopsies performed in the year 2000, a 25% increase. The increase is in comparison with the other types of cases performed by this Office, such as field inspections, OCME inspections, and approvals, which all showed a decline.

None of the protocols governing which bodies are autopsied vs. inspected have been altered during this time frame.

A look at the manner of death in our cases shows a dramatic increase (49%) in the autopsies classified as natural (from 959 in the year 1997 to 1,431 in the year 2000) and a significant increase (31%) in those classified as undetermined (from 531 in the year 1997 to 698 in the year 2000). The cases classified as accidents showed an increase of 22% and the suicides showed an increase of 5%. The homicides showed a 30% decrease after the peak from the early 1990s (641 cases in 1993 comparing with 473 cases in 2000). Because the most significant increase was in the cases classified as natural and undetermined, we further examined these categories.

In the cases in which the manner of death was classified as natural, the most significant increase was from 1997 to 2000, especially for atherosclerotic cardiovascular disease (from 313 in 1997 to 396 in 2000), hypertensive cardiovascular disease (from 6 in 1997 to 186 in 2000) and cardiac arrhythmia (from 53 in 1997 to 94 in 2000). There were no significant age, race or sex related differences. When we compared the data for all the counties that form Maryland, we noted that the greatest increase was in the cases from the most populous counties, Baltimore County, Prince George County and Montgomery County and the independent City of Baltimore.

We continued our study with a detailed view of the cases classified undetermined as manner of death. There were no significant age, sex or race related differences. Looking at the causes of death in this category we saw an increase in the cases related to drug use, drowning, and sudden death of an infant. Comparing the counties, the largest increases were in the City of Baltimore and in Baltimore County.

In conclusion, we consider that the significant increase in the number of the medico-legal autopsies in the State of Maryland is due to an increase in the number of the cases classified as natural and undetermined. The most important contribution to this increase is due to the death toll taken by the cardiovascular diseases, without respect to age, sex, or race.

Maryland, Autopsies, Increase

G5 Malaria Deaths in the United States: Case Report and Review of Deaths, 1979-1998

Robert Stoppacher, MD*, Milwaukee County Medical Examiner's Office, 5258 North, Bay Ridge Avenue, White Fish Bay, WI; and Stephen P. Adams, MD, Vermont Office of the Chief Medical Examiner, 111 Colchester Avenue, Burlington, VT

The goal of this research project is to review the deaths in the United States caused by malaria and, through a case report, raise awareness to the potential of malaria-related deaths in the forensic setting.

This poster will review all the deaths due to malaria in the United States between 1979 and 1998 paying particular attention to epidemiological factors provided by the Centers for Disease Control (CDC). Through a combination of both gross and microscopic images, it will then present a unique case of malaria diagnosed only at the time of medico-legal autopsy.

Malaria is the world's most important parasitic disease, accounting for an estimated 300-500 million new cases and between 1.5 and 2.7 million deaths annually. The majority of these deaths occur in sub-Saharan Africa where malaria is endemic and are the result of infection with *Plasmodium falciparum*. The number of deaths related to malaria in the United States is comparably much lower and involves so-called "imported" cases in which U.S. travelers acquire the infection upon travel

to endemic areas and subsequently return to the U.S., or in which infected foreign citizens travel to the U.S.

There were a total of 115 deaths due to malaria in the United States between 1979 and 1998 with an average of 5.8 deaths per year. Specific epidemiological data provided by the CDC regarding the 40 deaths that occurred between 1992 and 1998 revealed the following: Deaths occurred in patients ranging from 9 months to 85 years of age (median, 53 years). Thirty-eight (95%) of these were due to *P. falciparum* and two (5%) to *P. vivax*. Anti-malarial chemoprophylaxis was used in 40% of cases, not used in 45% of cases, and unknown in 15% of cases. Twenty-four (60%) of the cases involved U.S. travelers to endemic regions, of whom 59% traveled to Africa, 25% to South America, 8% to India, 4% to Haiti, and 4% to unspecified areas. The remaining cases included 11 foreign travelers to the U.S. (27.5%), 3 induced cases (7.5%), and 2 undetermined cases (5%). Thirty-nine (98%) of the cases were diagnosed ante-mortem and only one case was known to have come to the attention of the medical examiner/coroner.

An illustrative case report demonstrates many of the features associated with fatal malaria infections in the United States. The case involves a U.S. student who was studying in Ghana and who, by report, had not taken anti-malarial chemoprophylaxis. Despite being seen at the student health clinic upon returning to the U.S., the diagnosis of *P. falciparum* infection and cerebral malaria was not made until the time of medico-legal autopsy where the classic gross and microscopic features of cerebral malaria were identified.

This case represents one of the few cases of *P. falciparum* infection not diagnosed ante-mortem. Given the worldwide prevalence of the disease, increasing international travel, and rapidly developing drug-resistance, malaria will continue to be an important disease and should be considered in cases of sudden, unexplained deaths. By reviewing the major epidemiological features of malaria deaths in the United States and by presenting the major gross and microscopic findings of cerebral malaria, an attempt is made at raising the awareness of the forensic community to the potential of malaria related deaths.

Malaria, Plasmodium Falciparum, Deaths

G6 North Carolina's Death Investigation Database

D'Michelle P. DuPre, MD*, Duke University Medical Center, PO Box 3712, Durham, NC; and Kenneth S. Snell, MD, and Thomas B. Clark III, MD, Office of the Chief Medical Examiner, Chapel Hill, NC

The goal of this research project is to demonstrate the ease of use of a centralized statewide database to compare selected data fields with the US Census data to determine homicide victim profiles with shifts in population.

Searchable databases have long allowed for the comparison of data fields relating multiple groups. The North Carolina Office of the Chief Medical Examiner (OCME) maintains a database concerning its investigation of all deaths in North Carolina that fall under its jurisdiction. The database is maintained "in house" which allows quick and reliable information retrieval on cases in contrast to actual case files which may be archived in distant locations. The OCME database has case information dating back to 1973 and stores greater than thirty data fields on each case allowing for detailed comparisons within a group of interest. The data search can be restricted to specific fields thereby tailoring the search to data of interest and reducing the volume of data to be retrieved and compared. The ease of use and the ability to provide specific data of interest is demonstrated by the following search, which compares homicides in North Carolina in the years 1990 and 2000.

Six data fields are selected for comparison: Age, Race (including Hispanic), Sex, Date, Cause of Death (fifteen categories), and County of

death. This information is then compared to the US Census for North Carolina for the same years. The objective is to determine if shifts in population are reflected in the homicide victim profile.

The results demonstrate that the homicide victim profile tracks along with the shift in population. For example, the typical homicide victim in 1990 was a 27 year-old Black male who was shot, representing 55% of homicides while the population of Black males in 1990 was 22%. In 1990 the Hispanic population was 1.04% while the Hispanic homicide victim represented 1.34% of all homicides. In the year 2000 the typical homicide victim was a 27 year-old Black male who was shot, representing 51.4% of homicides while the population of Black males was 21.6%. The Hispanic population in 2000 was 4.7% while the Hispanic homicide victim represented 8.11% of all homicides. The actual number of homicides decreased by 141 cases while the percentage of homicides by gunshot rose from 63% in 1990 to 71% in 2000. Blunt force trauma cases remained about the same while sharp instrument cases decreased from 158 (19.3%) to 67 (10%).

The OCME database is a reliable source of information concerning death investigations in North Carolina, thereby allowing statewide comparisons within a group of interest to be compared to general census data.

Searchable Database, Homicide Victim, North Carolina

G7 “Homicide by Heart Attack” Revisited

Staci D. Turner, MD, Jeffrey J. Barnard, MD, and Sheila D. Spotswood, MD, Southwestern Institute of Forensic Sciences, 5230 Medical Center Drive., Dallas, TX; and Joseph A. Prahlow, MD, South Bend Medical Foundation and Indiana University School of Medicine, University of Notre Dame, South Bend, IN*

The goal of this research project is to review the criteria for ruling a death as “homicide by heart attack,” with illustrative examples from a metropolitan medical examiner’s office.

The term “homicide by heart attack” is used by some persons to describe sudden death due to underlying cardiac disease with an arrhythmia precipitated by the physical and/or emotional stress associated with the criminal activity of another person. Physical contact and/or injury may or may not occur in such scenarios. “Homicide” is an acceptable and appropriate manner-of-death ruling in such cases. Davis has published a set of criteria for pathologists to use when attempting to establish cause-of-death and manner-of-death rulings in cases where physical injury or contact does not occur. The criteria are as follows: 1) The criminal act should be of such severity and have sufficient elements of intent to kill or maim, either in fact or statute, so as to lead logically to a charge of homicide in the event that physical injury had ensued. 2) The victim should have realized that the threat to personal safety was implicit. A logical corollary would be a feared threatening act against a loved one or friend. 3) The circumstances should be of such a nature as to be commonly accepted as highly emotional. 4) The collapse and death must occur during the emotional response period, even if the criminal act had already ceased. 5) The demonstration of an organic cardiac disease process of a type commonly associated with a predisposition to lethal cardiac arrhythmia is desirable. Although Davis’ criteria specifically deal with cases in which there is no physical contact or injury, the authors apply similar criteria to all cases where sudden death due to heart disease is precipitated by the stress associated with another person’s criminal activity, whether or not physical contact or injury occurs. This is easily accomplished by leaving out the phrase “in the event that physical injury had ensued” for those cases where physical injury actually does occur. In this report, the authors present a series of five cases ruled as homicides using these criteria.

Case 1: A 40-year-old male was arguing with his girlfriend outside of his apartment when she started to strike him with a 2-3 foot long, light-weight, carved wooden statue. He was reportedly struck multiple

times in the head prior to his escape into the apartment, where he locked the door. Witnesses immediately called 911. Emergency Medical Services (EMS) personnel found him dead, in a chair in the living room. Autopsy revealed multiple superficial abrasions of the face and chest, along with a left periorbital contusion and two small lip lacerations. No skull, brain, neck or other internal organ injuries were identified. Other significant findings at autopsy included cardiomegaly (685 grams) with left ventricular hypertrophy, moderate coronary artery atherosclerosis, severe nephrosclerosis, and a remote pontine infarct. Toxicology tests revealed the presence of cocaine and its metabolites. Cause of Death (COD): Part 1: Cardiac arrest associated with stress and physical assault; Part 11: Cardiomyopathy; end stage renal disease; cocaine abuse; remote pontine infarct. Manner of Death (MOD): Homicide.

Case 2: The wife of a 74-year-old man arrived at his place of business just as an intruder was fleeing from the location after having robbed and assaulted the man. The man had sustained a punch to the jaw and was noticeably shaken, but refused transportation to the hospital via ambulance because he felt his injuries were limited to his jaw, which he presumed was broken. He went into the bathroom to clean-up and was then found unresponsive by his wife. She summoned EMS, who transported him to the emergency department, where he was pronounced dead. Autopsy revealed a fractured mandible, but no intracranial injury. The heart, which weighed 350 grams, had mild to severe coronary artery atherosclerosis, with near-complete occlusion of the right coronary artery. Toxicology was negative for drugs of abuse. COD: Blunt force head injuries associated with coronary artery disease. MOD: Homicide.

Case 3: A 66-year-old woman with a history of remote coronary artery bypass graft (CABG) surgery was suddenly awakened from sleep by an intruder who had broken into her home and was demanding money. After the woman became emotionally upset, the burglar fled. The victim was able to phone for help before she collapsed. She did not mention if the intruder had assaulted her. At autopsy, the decedent had multiple areas of senile purpura on her arms, as well as contusions of the right chest and left temple. No other injuries were identified. All resuscitative efforts failed. Autopsy also confirmed the presence of severe coronary artery atherosclerosis, with remote CABG surgery. Her heart weighed 510 grams. COD: Cardiac dysrhythmia due to atherosclerotic cardiovascular disease during an emotionally-stressful event (victim of robbery). MOD: Homicide.

Case 4: A 67-year-old woman was walking in a parking lot on her way from her car to the grocery store when she was stopped by a teenage male who demanded her purse. She refused, and the boy struggled with her for the purse, threatening to kill her if she did not comply. She was able to break away from him, run into the store, and relate what had happened to her prior to collapsing to the floor. All resuscitative efforts failed. At autopsy, there was no evidence of acute injury other than that which was considered related to resuscitative efforts. Other findings included hypertensive and atherosclerotic cardiovascular disease, with cardiomegaly (565 gm), severe coronary artery atherosclerosis, and a remote anterior left ventricular myocardial infarct. COD: Cardiac dysrhythmia due to hypertensive and atherosclerotic cardiovascular disease during an emotionally stressful event (victim of robbery attempt). MOD: Homicide. Adjudication: The teenager and an accomplice were charged with and tried for **, at which time they were found guilty of **.

Case 5: An obese, 52-year-old, diabetic man was involved in a physical altercation with a younger man. During the fight, the older man “acted as if he was having a heart attack.” He subsequently fled from the other man and attempted to drive himself to the hospital, but was so debilitated, that he stopped his car and had to ask for assistance. EMS responded and transferred him to the Emergency Department, where resuscitative efforts continued but eventually failed. Death occurred 30 minutes after EMS initiated treatment. Autopsy revealed rare superficial abrasions of the face, hemorrhage of the left sclera, and a small occipital contusion, but no other injuries. Hypertensive and atherosclerotic cardiovascular disease was present, with marked cardiomegaly (660 gm), severe

coronary artery atherosclerosis, and histologic evidence of remote, subacute, and acute myocardial infarcts. Well-developed coagulation necrosis with associated neutrophils was present focally. COD: Part I: Myocardial infarct due to hypertensive and atherosclerotic cardiovascular disease; Part II: Obesity, diabetes mellitus, and stress associated with a physical altercation. MOD: Homicide.

In each of the cases presented, the modified Davis criteria, as described above, were fulfilled. In most of the cases, physical contact definitely occurred, although in some, no injury was inflicted, and in none were the inflicted injuries considered life threatening in and of themselves. Case 3 is the best example in the series of a case where no definite physical contact occurred between the assailant and the victim. Although she had some minor injuries, none could be clearly associated with the criminal activity. In each case, the victims clearly feared for their safety, and the events were of a highly emotional nature. Also, in each case, the collapse and subsequent death occurred shortly after the initiating event, but it occurred during the emotionally volatile period of time immediately following the event. Finally, autopsy revealed significant underlying cardiac pathology in each victim, such that each was a prime candidate for experiencing a stress-induced cardiac dysrhythmia.

Cardiac deaths precipitated by physical and/or emotional stress occur frequently. When the stress is precipitated by criminal activity directed against the victim by another person, it is appropriate to consider these deaths as homicides. In order to appropriately certify such deaths, strict criteria as set forth by Davis should be satisfied. Complete autopsy, including histologic examination and toxicology, coupled with detailed reconstruction of the events with particular attention paid to their timing, is essential in order to appropriately certify such deaths. Appropriate certification may lead to successful prosecution of criminals. Failure to appropriately certify such deaths may result in failure to appropriately adjudicate such cases.

Homicide, Heart Attack, Manner of Death

G8 The Significance of Pulmonary Interstitial Emphysema in Fetal and Infant Autopsies

Wendy A. Lavezzi, MD, Department of Pathology and Laboratory Medicine, 56 South Westcott Road, Schenectady, NY; and Barbara C. Wolf, MD, Forensic Medicine, PC, Albany, NY*

The goals of this research project are to provide participant with the capability to distinguish "florid" from "equivocal" pulmonary interstitial emphysema on routine H&E-stained lung sections and to understand the value of the histologic finding of florid pulmonary interstitial emphysema in distinguishing live born infants from stillborns.

The most commonly documented cause of pulmonary interstitial emphysema (PIE) is the mechanical ventilation of infants with respiratory distress syndrome, but known causes also include vigorous resuscitation efforts by those not accustomed to small infant lung volumes, forceful respiratory efforts against inspissated mucus or a foreign object, and spontaneous PIE related to cystic lesions or infection.

We have previously commented on the importance of the histologic finding of PIE in the determination of live birth in two infants whose bodies were discarded shortly after birth. Because of the implications of the distinction of live birth from stillbirth in criminal proceedings, we undertook the current study to further elucidate the importance of the microscopic finding of PIE.

Sixty-five cases of infant deaths were retrieved. The infants ranged in age from birth to 11 months (mean 2.4 months). The causes of death in these cases included sudden infant death syndrome (28), sudden unexpected death, manner undetermined (8), homicidal or accidental asphyxia (3), congenital anomalies (13), infection (5), prematurity (1), head injury (2) and non-asphyxial trauma (5). Microscopic sections of the lungs were

compared with those of 21 third trimester stillborn infants ranging in gestational age from 28 to 40 weeks (mean 35 weeks). The number of lung sections ranged from 1 to 10 per case (mean 4). The slides were examined for evidence of PIE, defined as the presence of non-endothelial-lined spaces in the interstitium and subpleural zones. "Florid PIE" was defined as the presence of expanded and dilated interstitial spaces coalescing with subpleural cystically-dilated areas. This finding was distinguished from the more subtle finding of focal distinct but non-distended interstitial and subpleural spaces, which we termed "equivocal PIE." Immunohistochemical stains utilized to highlight endothelial cells (Factor VIII and CD 31) have been previously reported as being useful in the distinction of dilated lymphatic spaces from PIE. However, because of the cellular disruption frequently seen in postmortem bronchial and endothelial structures which can compromise the interpretation of these immunohistochemical studies, we relied upon conventional H&E-stained sections to evaluate the morphologic presence or absence of PIE.

Sixteen cases of florid PIE were identified. All were live born infants. An additional 46 cases of equivocal PIE were seen, including 35 live born infants and 11 stillborns. In 24 cases, no PIE was identified, including 14 live born infants and 10 stillborns. The causes of death in the cases of florid PIE included sudden infant death syndrome (9), homicidal asphyxia (1), hemorrhage and inattention at birth (1), congenital anomalies (2), and sudden unexpected death, manner undetermined (3). Twelve of these infants had received cardiopulmonary resuscitation and/or mechanical ventilation. In the cases of homicidal asphyxiation and hemorrhage and inattention at birth, no resuscitation attempts were made. In the remaining two cases, information concerning resuscitation was unavailable. Equivocal PIE was seen in 32 live born infants, all but 3 of whom had been resuscitated. Eleven resuscitated live born infants had no evidence of PIE. Of the 11 stillborns with equivocal PIE, resuscitation had been performed in two cases. Causes of death in both live born and stillborn cases with equivocal PIE were widely variable, as were the cases in which PIE was not identified. We attempted to correlate the presence of PIE in live born infants with sleeping position and with co-sleeping or non-co-sleeping. No consistent association was found.

In conclusion, the finding of florid PIE supports our previous observation of the association of PIE with live birth. However, no direct correlation between the presence of PIE and cause of death could be determined.

Interstitial Emphysema, Live Birth, Stillbirth

G9 Motor Vehicle Collision-Related Death Due to Delayed-Onset Subarachnoid Hemorrhage Associated With Anticoagulant Therapy

Ana E. Lopez, MD, Jeffrey J. Barnard, MD, and Charles L. White III, MD, Southwestern Institute of Forensic Sciences, 5230 Medical Center Drive, Dallas, TX; Jaime L. Oeberst, MD, Sedgwick County Regional Forensic Science Center, Wichita, KS; and Joseph A. Prahlow, MD, South Bend Medical Education, University of Notre Dame, South Bend, IN*

The goal of this research project is to describe a death related to delayed-onset subarachnoid hemorrhage following craniocerebral trauma in a person receiving anticoagulant therapy, and to alert the medical and forensic communities to this potentially lethal complication related to trauma and therapy.

Death due to craniocerebral trauma sustained in vehicular collisions remains a common cause of unnatural death in the United States. In many cases seen by forensic pathologists, death occurs at or shortly after the injuries are sustained. In some individuals, death occurs following hours, days, or weeks of medical intervention. Others die as a result of complications of their injuries months or even years following the initial

trauma. Various medical interventions may be considered contributing factors in these and other deaths. In this report, we present a case of a death due to delayed-onset subarachnoid hemorrhage associated with anticoagulant therapy which was administered to the victim of a motor vehicle collision because of an underlying prosthetic aortic valve.

On a sunny Texas afternoon, a restrained, 40-year-old woman was driving a late- 1980's model automobile on a dry, 2-lane asphalt, rural highway when an oncoming pick-up truck turned in front of her, resulting in a head-on collision. The woman was conscious, but required prolonged extrication, as she was pinned in her vehicle. She was transported to the nearest hospital, where she was found to have fractures of the right tibia, fibula, and calcaneus, as well as a laceration of the chin and multiple cutaneous contusions of her trunk. Past medical history was significant for a remote aortic valve replacement (at age 16 years for rheumatic heart disease), for which she was receiving chronic anticoagulant therapy. During her entire hospitalization, she remained on anticoagulant therapy for her underlying prosthetic heart valve. A cardiology consultation with echocardiography revealed no acute problems. She underwent surgical fixation of the tibia and fibula fractures at the local hospital prior to being transported to a metropolitan trauma referral center, where she was to undergo repair of the calcaneus fracture. Ten days after the accident, the victim developed altered mental status and agonal respirations, requiring emergency intubation. A computed tomography scan of the head and brain revealed acute basilar subarachnoid hemorrhage. The clinical impression was that the patient had suffered a possible ruptured cerebral artery aneurysm. Since brainstem function was absent, "do not resuscitate" status was established, and the victim died, 11 days after the automobile collision. Because of the nature of the incident, the case was referred to the medical examiner's office where an autopsy was performed.

Autopsy revealed the presence of surgically-fixed tibia and fibula fractures, cardiomegaly (450 gm), a prosthetic aortic valve, multiple cutaneous contusions, and a healing laceration of the chin. Head examination was significant for the presence of approximately 15 ml of patchy subdural hemorrhage over the cerebral convexities and in the posterior fossa, as well as moderate to extensive subarachnoid hemorrhage, most prominent over the cerebellum and inferior right temporal lobe. No cerebral artery aneurysms or vascular malformations, skull fractures or subscalpular hemorrhage were identified. Sections of the formalin-fixed brain revealed a hemorrhagic discoloration of the right medial temporal cortex which, on microscopic exam, proved to be a cerebral contusion. The subarachnoid hemorrhage was most voluminous immediately overlying the contusion. Histologic exam revealed no evidence of fat or bone marrow embolism. The cause of death was ruled "complications of blunt force injuries." Based on the autopsy findings and the clinical history, the final mechanism of death in this case was related to the subarachnoid hemorrhage. Since no grossly-evident vascular abnormality could be identified, the hemorrhage was most likely related to the underlying brain contusion with anticoagulant therapy contributing to the hemorrhage.

Deaths related to complications of traumatic injury are not rare. The causal relationship between the initial trauma and death may or may not be readily evident in such cases. In fact, clinicians and others may initially attribute the death to an unrelated natural disease process, as occurred in this case. The present case serves to remind clinicians and pathologists that any death following a traumatic injury must be considered a possible injury-related death. It also serves to remind physicians of the potentially deleterious effects of anticoagulant therapy, particularly in persons who have been injured.

Forensic, Complications of Therapy, Subarachnoid Hemorrhage

G10 A Comprehensive Analysis of Forensic Science Training in Forensic Pathology Fellowship Programs

J. Keith Pinckard, MD, PhD, Division of Laboratory Medicine, Washington University School of Medicine, Box 8118, 660 South Euclid Avenue, Saint Louis, MO; Donna M. Hunsaker, MD, Office of the Chief Medical Examiner, 810 Barrett Avenue, Louisville, KY; and Victor W. Weedn, MD, JD, Carnegie Mellon University, 4400 Fifth Avenue Mellon Institute, Room 292, Pittsburgh, PA*

The goal of this research project is to summarize current forensic science training in the nation's forensic pathology fellowship programs.

The forensic sciences are significantly impacting criminal investigations more and more each year. The advances in DNA identification technology alone have revolutionized the daily practice of forensic pathologists. For example, it is now commonplace for forensic pathologists to spot blood standard cards from all bodies for possible future DNA analysis. Other specialized fields in the forensic sciences, such as toxicology, arson analysis, firearm analysis, trace evidence and fingerprint examinations, also aide the forensic pathologist, as corroborative studies, to finalize the cause and manner of death in a wide variety of cases. Therefore, fundamental training in the forensic sciences is necessary to appreciate the complexities inherent in each field. To what extent are the trainees in forensic pathology fellowships around the country obtaining forensic science training?

This presentation will outline survey results regarding forensic science training from the 44 Accreditation Council for Graduate Medical Education (ACGME) accredited forensic pathology fellowship programs under the auspices of the College of American Pathologists (CAP) Forensic Identity Committee. The survey will assess the extent of training in the forensic sciences that fellows in forensic pathology are currently receiving. A formalized survey such as this has not yet been conducted and should provide a wealth of useful information about forensic-specific graduate medical education. The information gleaned from the study may aide members of the National Association of Medical Examiners (NAME) Ad Hoc Committee of Forensic Pathology Training in subsequent revisions to their recent training program guideline recommendations.

The first component of the survey pertains to the characteristics of the forensic pathology fellowship. How many fellows does the program train each year? Is the fellowship affiliated with a medical examiner or a coroner system? Is the medical examiner's or coroner's office accredited by the National Association of Medical Examiners? Is the office affiliated with an academic university or teaching hospital? This section is simply to obtain general information about each training program.

The second component of the survey is geographical. Is the medical examiner's office physically connected with the crime lab, or if not, how far from each other are they located? Specifically, with which components of the region's crime lab (i.e., DNA, toxicology, etc.) is the medical examiner's or coroner's office associated? The purpose of this section is to gain an understanding of the extent to which forensic pathology training programs are integrated with the crime lab.

The third component of the survey is qualitative. Questions in this section pertain to the nature of the involvement of the forensic pathology fellow in each of the areas of the crime lab. How much time is spent in each discipline? Is the exposure to the forensic laboratories simply a tour or does the fellow actually spend time training in each lab for a defined period of time? Are fellows encouraged to undertake independent research projects in the forensic sciences other than forensic pathology? These inquiries will further define the nature of education in the forensic sciences that today's forensic pathology fellows receive.

The presentation will summarize the results of all participating forensic pathology fellowship programs and discuss any trends that are

observed. The information gained from this study should prove valuable for assessing the current state of forensic pathology training with respect to the crime lab, and for formulating goals to strive for in the future as forensic pathology continues to become increasingly more integrated with other disciplines of forensic science.

Crime Lab, Forensic Pathology Fellowship, Training Program

G11 Postmortem Microbiology: Friend or Foe?

Kathryn H. Haden, MD, Lisette L. Lester, MD, JD, Sandra K. Elkins, MD, and Mark Cole, University of Tennessee Medical Center, 1924 Alloa Highway, Box U-108, Knoxville, TN*

The goal of this research project is to give participants a heightened sense of the various modern-day postmortem bacterial organisms, their relevance and their presence/absence based on sample site.

Introduction: Postmortem microbacteriological culture results are frequently difficult to interpret. Many organisms are cultured but the significance in the postmortem state is unknown. This can create dilemmas for forensic pathologists, particularly in those cases where a distinct anatomical cause of death is lacking. Many different culture techniques have been employed over the years and many different sites have been cultured, all with varying results. The emergence of new and resistant strains of bacteria prompted the investigators to establish what contaminants are present in the modern day and to compare the organisms cultured based on specimen site, relevance when compared to tissue sections and their presence based on time since death.

Methods: In this study, the authors obtained microbacteriological cultures from autopsies over a two-month period in the spring in a southeastern state. Bodies in a state of advanced decomposition were excluded from the study, resulting in a total of 34 cases. Five sites were sampled in the majority of the cases: subclavian blood, heart blood, spleen, right lung and left lung. Sterility was obtained either through searing of the tissues or the use of betadine, depending on the site being cultured. In addition, microscopic sections of the lungs were taken directly adjacent to the culture site to enable correlation of organisms cultured to the presence/absence of inflammation seen histologically. Pediatric blood culture bottles were utilized for both the subclavian and heart blood samples. Culturette swabs were utilized for the lung cultures and a small portion of spleen was removed in situ, and then ground with a tissue grinder. The latter three specimens were streaked onto three types of agar: 5% sheep blood, chocolate and MacConkey. Positive blood cultures (as determined in the BacT automated system) were also plated onto these three types of media. Gram stains were performed on every organism grown and then additional testing was instituted to further identify the organisms as needed.

Results: As one would expect, the majority of postmortem bacterial organisms cultured are contaminants. However, many common antemortem pathogens are also frequently cultured in the postmortem state, but are without histologic evidence of inflammation and are therefore felt to represent contaminants as well. Tissue sections are absolutely critical in determining the relevance of these particular organisms. In the cases where organisms were cultured that were felt to be a contributing factor in the person's death, there was histologic evidence of inflammation. All specimen sites sampled within a single case produced similar findings. Therefore, postmortem microbacteriological cultures can be useful tools in the process of death investigation, when used appropriately and in the full context of the case.

Microbiology, Bacterial Organism, Postmortem

G12 Sufentanil Toxicity in Healthcare Professionals

Jessie Adame, MD, Autopsy and Pathology Services, PO Box 920903, Houston, TX; Douglas H. Posey, MD, Joye Carter, MD, and Ashraf Mozayani, PharmD, PhD, Harris County Medical Examiner Office, 1885 Old Spanish Trail, Houston, TX*

The goal of this research project is to provide to the forensic community an awareness of two recent cases of sufentanil toxicity involving healthcare professionals.

We have observed two deaths involving sufentanil toxicity in healthcare professionals in a period of less than two months. This presentation demonstrates two autopsy cases from the Harris County Medical Examiner's Office involving sufentanil toxicity among healthcare professionals. Sufentanil citrate is available under its generic name of sufentanil and is often used in the surgical suite by anesthesiologists as an adjunct to general anesthesia. Sufentanil is available in Dosette ampules of 50-mcg/1 ml, 100-mcg/2 ml, and 250-mcg/5 ml. It is a Class II controlled synthetic narcotic, which is about 5 to 7 times as potent as fentanyl and 500 to 800 times as potent as morphine. The usual adult dose is 1 to 2 mcg/kg. Supplemental doses of 10 to 25 mcg may be given as needed. Profound analgesia is achieved with doses of 2 to 8 mcg/kg. Deep general anesthesia is achieved with doses of 8 to 30 mcg/kg. Sufentanil easily crosses the blood-brain barrier and is quickly routed to body tissues. After 24 hours, approximately eighty percent of the drug dose is excreted in the urine. Sufentanil is metabolized into N-desmethylsufentanil and O-desmethylsufentanil. Approximately thirty percent of a dose metabolizes as conjugates in both urine and feces. Sufentanil has a number of toxic effects including respiratory depression, acute respiratory arrest, seizures, hypotension (also sudden hypotension), euphoria, dizziness, muscle rigidity, drowsiness, nausea, vomiting, bradycardia, and irregular heartbeat. The literature reports of two deaths in adults after self intravenous administration of sufentanil indicating blood levels of 1.1 and 7.0 mcg/L and liver levels of 1.8 and 3.4 mcg/L. It is not clear if these adults were healthcare professionals.

The following are details of two cases involving sufentanil toxicity which have occurred in less than a two-month period. Case One is a 41 year-old Caucasian male anesthesiologist who was found in the bathroom, sitting on the toilet with his pants on and unresponsive. An empty syringe was found inside a dry beer can. A small vial of sufentanil 50 mcg, three-fourths empty, was found in the bathroom. The autopsy findings included a recent injection site in the left antecubital fossa with a 3/8 inch hematoma, cardiomegaly (450 grams) with moderate atherosclerotic cardiovascular disease, bilateral pulmonary edema and congestion, hepatomegaly (2550 grams), and erosions of the gastric mucosa.

Case Two is a 34 year-old Caucasian male registered nurse who was found at work in the ladies' bathroom face down on the floor with his pants and underwear down around his ankles. Fifteen (15) different ampules, vials, and bottles of medications were found in the bathroom which included one opened ampule of sufentanil. In addition, one previously used syringe with needle and cap was found at the scene. The autopsy findings included bilateral injection sites on the medial thigh, cardiomegaly (550 grams) with right ventricular dilatation and concentric left ventricular hypertrophy, and hepatomegaly (2400 grams).

Sufentanil can be assessed in the laboratory by multiple methods including gas chromatography with nitrogen specific detection, radioimmunoassay, and gas chromatography-mass spectrometry (GC-MS). The blood analysis for sufentanil was identified and quantitated by GC-MS method. Biological specimens were made alkaline (pH 13) using 2N, NaOH. Sufentanil was extracted using a mixture of hexane:ethanol (19:1). D5-fentanyl was used as an internal standard. The dried extracts samples were injected onto the GC-MS and the ions 250, target ions, 194, 195, 151 for D5-fentanyl and 250 (target ion), 290, 291, 140 for sufentanil were monitored. Postmortem blood in Case One was positive for ethanol

0.12 g/dL and sufentanil 2.95 mcg/L. The syringe wash was also positive for sufentanil. No other drugs were identified. In Case Two, sufentanil was the only compound in concentration of 2.63 mcg/L. The cause of death was sufentanil toxicity for both cases. The manner of death was ruled as accidental for both cases.

In conclusion, these two deaths resulting from sufentanil toxicity in Harris County Medical Examiner's Office in less than two months are warning signs of the popularity of this potent, narcotic substance among healthcare professionals with substance abuse problems.

Sufentanil, Healthcare Professionals, Harris County Medical Examiner Office

G13 Oxycodone (OxyContin) Related Deaths in Maryland 1998-2000

Ellen C. Riemer, MD, JD, Barry S. Levine, PhD, Jack M. Titus, MD, and David R. Fowler, MB, ChB, Office of the Chief Medical Examiner of the State of Maryland, 111 Penn Street, Baltimore, MD*

The goal of this research project is to examine the prevalence and features of oxycodone-positive deaths in the State of Maryland over a three year period from 1998 through 2000.

Oxycodone is an opioid agonist with a high oral:parenteral potency ratio relative to most other opioid analgesics. This is due to the presence of a methyl group on the aromatic hydroxyl group, which prevents its conjugation by glucuronic acid in the liver. Because oxycodone is less potent than morphine in its analgesic properties and has adverse effects that limit the maximum tolerated dose, oxycodone is frequently employed clinically in formulations containing aspirin or acetaminophen. In recent years, the number of deaths related to the abuse of oxycodone has appeared to be increasing.

We examined case records at the Office of the Chief Medical Examiner of the State of Maryland (OCME) over a three year period from 1998 through 2000, where toxicologic studies showed the presence of oxycodone in the samples submitted. The laboratory identifies oxycodone as part of its routine abused and therapeutic drug testing procedures.

The number of oxycodone-positive cases investigated by OCME has increased steadily from 1998 to 2000. In 1998, there were a total of 27 oxycodone-positive cases; in 1999 a total of 41 oxycodone-positive cases, and in 2000 there were 69 oxycodone-positive cases. Of these, the large majority of cases were in individuals between the ages of 32 and 49. In 1998, 67 percent; in 1999, 68 percent; and in 2000, 69.6 percent of oxycodone-positive deaths occurred within this age range. Most cases were in white individuals: In 1998, 85.2 percent; in 1999, 85.4 percent; and in 2000. Oxycodone-positive deaths in men outnumbered those in women. From 1998 through 2000, the percentage of oxycodone-positive deaths occurring in men were 70.4 percent, 70.1 percent, and 60.1 percent respectively. 41.6 percent of all oxycodone-positive cases were in the urban areas of Baltimore City or Baltimore County, while the remaining 58.4 percent occurred in Maryland's suburban and rural counties combined.

Of all oxycodone-positive cases from 1998 through 2000 (n=137), 41.6 percent of deaths (n=57) were attributed to oxycodone. Of the latter, 35.1 percent of deaths (n=20) were attributed to oxycodone alone, while the remaining 64.9 percent (n=37) were attributed to oxycodone in combination with alcohol and/or one or more other drugs.

This data suggests that oxycodone, especially when used in combination with alcohol and/or other drugs, contributed significantly to the number of deaths in Maryland from 1998 through 2000. Moreover, the use of oxycodone has increased significantly over this brief time period.

Oxycontin, Oxycodone, Death

G14 Deaths Related to Conduction System Pathology

Katarzyna Michaud, MD, Nathalie Romain, MD, and Patrice Mangin, MD, PhD, Institut Universitaire de Médecine Légale, Rue du Bugnon 21, Lausanne, Switzerland*

The goal of this research project is to inform the forensic community of fatal cases related to conduction system pathology.

It is not rare for pathologists to be confronted with the apparently natural deaths of young subjects without any prior medical history. Sometimes the exact cause of death remains unknown even after a complete autopsy and full toxicological analyses. In some of these cases examination of the cardiac conduction system can demonstrate pathological lesions which are described in the literature as a possible explanation of the fatal issue. On the other hand, rhythm disturbances are not always lethal. But, according to the circumstances in which they occur, they can lead to death. For example they can have dramatic consequences if the victim is driving or swimming. For these reasons the evaluation of the cardiac conduction system cannot be overlooked in forensic medicine.

Since 1998, the conduction system of the heart is systematically analyzed in our institute. A simplified and evaluated method is used. Samples of the conduction system are collected from the left approach to the ventricular septum. The initial block is cut into 5-7 blocks about 2-3 mm wide. From each block (always sectioned from the anterior face) at least 1-2 histological sections are prepared and stained with hematoxylin-eosin or with Masson trichrome. If suspicious lesions are noticed, more sections are made.

In this presentation, 25 cases are reported: 12 cases of sudden unexpected death and 13 cases of fatal accidents.

In the group of sudden unexpected death, the ages ranged from 11 to 52 years. For most of them the reports of the very last moments of life suggested a possible cardiac origin of death. Most of the time clinical data was unknown or insignificant. In the group of the lethal accidents which included cases of drowning, paragliding and road accidents, the police investigation strongly suggested a sudden sickness. The ages of the victims ranged from 15 to 70 years.

In the 25 cases, the macroscopic study of the heart (heart weight, examination of valves, coronary arteries, cardiac chambers and great vessels), as well as histological examination of working myocardium, were normal. The toxicological analyses were negative. However in all the cases, microscopic examination of the cardiac conduction system allowed to detect different pathological changes. Thus, lesions such as an abnormal small muscle entrapped into the bundle branches or in the interventricular septum, fatty infiltrations of the bundle of its branches, a replacement of the conduction tissue by empty spaces, the accessory pathways between conduction structures and myocardium, a stenosis of the arteries supplying the conduction system, and fibrosis of the septum with occasionally compression of the branches were detected. Such findings are described in the literature and reported as possible causes of rhythm disturbances and death.

Nevertheless, in cases of deaths which seem to be conduction system related, conclusions should be prudent, especially in forensic practice. Even if histological examination reveal pathological lesions, the death can be attributed to cardiac rhythm disturbances only if no other cause is found after a complete autopsy and toxicological analyses. Moreover, it is not possible to exclude that the pathological findings of the conduction system are not responsible for the sudden death, and that the cause of death is related to another unknown origin.

Microscopic examination of the cardiac conduction system, even with a simplified technique, is laborious. Moreover, the interpretation of the histological findings is difficult. However, the evaluation of the conduction system should be more systematically carried in routine forensic practice as it can explain not only the cause of sudden unexpected deaths, but also it can help to elucidate the circumstances of fatal cases initially supposed to be accidental.

Cardiac Conduction Systems, Sudden Death, Accident

G15 *Commissio Cordis Intermedius: Digital Interposition Between Projectile and Thorax*

William Q. Sturmer, MD, Office of the Medical Examiner, Arkansas State Crime Laboratory, PO Box 8500, Little Rock, AR*

The goal of this research project is to present the forensic community with a description of novel variation of a recognized mechanism of sudden cardiac death.

A 21-month-old male child along with his father and uncle were attending a stock car racing event on a somewhat muddy track. The vehicles repeatedly splattered hardened chunks of the dirt into a short protective wall at the curved edge of the roadway and, on occasion, into the spectators sitting in the adjacent bleachers.

As the uncle, who was sitting in the top row, was passing the child to the father who was in the seat below, a "whoosh" sound followed by a "pop" was described by the two adults. The uncle was struck in the dorsum of the third left finger at the proximal joint, having his hand placed over the chest of the child while transferring him to his father. The finger showed a "black, grainy" area as well as a "red mark", both gone when he reached the hospital. X-rays revealed no fracture. Upon later scene investigation, several irregular, hardened mud clods were found in and under the nearby seats, some approximating the dimension of a golf ball. The uncle had commented that the object that struck him felt about this size.

Following the "pop", the child immediately let out a cry, jerked his head back, appeared to have lost consciousness, and became limp. Breathing was said to be irregular with a rapid pulse noted. EKG initial rhythm showed approximately 270 beats per minute. The respiratory rate varied between 3 and 10 breaths per minute and the pupils were dilated. Soon the pulse weakened and efforts to resuscitate him at the field and continuing in a nearby hospital were unsuccessful. Agonal vomiting had occurred and some was present on the clothing. A small "red mark" was seen on the left side of the baby's lower ribs when his shirt was removed by the paramedics, and was also noted at the hospital. EKG now revealed asystole and he was pronounced dead one hour following the incident. There was a previous history of asthma with medications prescribed. He had been hospitalized two months earlier for otitis media and pneumonia, which cleared after antibiotic treatment.

Postmortem examination two days later revealed no bruising of the chest skin, underlying musculature, ribs, sternum, pericardium, or heart. The "red mark" on the chest observed at the track was not now evident. Microscopic examination of multiple heart sections and other tissues were essentially normal. There were no pulmonary changes indicative of asthma. Evidence of gastric aspiration was not observed. The only other injury was a small, patterned bruise on the lateral left forehead, noted on the day following the autopsy. The underlying skull and brain were grossly and histologically unremarkable.

The interposition ("intermediate object") in this instance may have accounted for the lack of a discrete injury on the chest or in the musculature of the child, although "hyperemia" of this area as well as on the uncle's finger were initially documented. A relatively high velocity impact to the thorax, however, remained as the lethal mechanism to a presumably vulnerable heart. Additional studies attempting to clarify the cardiac status will be described. The possible distribution of forces due to the interposed digit will also receive comment.

Sudden Death, Commissio Cordis, Intermediate Object

G16 Genetics of Sudden Cardiac Death: Prothrombotic Mutations of Blood Platelet Glycoprotein Receptors are Common Among Men Who Die of Prehospital Myocardial Infarction at Early Middle Age

Pekka J. Karhunen, MD, PhD, University of Tampere, POB 602, Tampere, Finland; J. Mikkilsson, Schools of Medicine and Public Health, University and University Hospital of Tampere, Tampere, Finland; M. Perola, Department Human Molecular Genetic, National Public Health, Institute Tampere, Helsinki; P. Laippala, Schools of Medicine and Public Health University and University Hospital of Tampere Department Clinic Pathology and Forensic Medicine, Tampere, Finland; and A. Penttila, Department. Forensic Medicine, University of Helsinki, Tampere, Helsinki*

The goal of this research project is to present new insights into the pathology of sudden cardiac death and to draw attention to the importance of genetic prothrombotic factors as predictors of sudden prehospital coronary death.

The knowledge on predicting and predisposing factors of sudden cardiac death (SCD) at early middle age has remained limited: only smoking and family history are known to be associated with SCD. Following the decline in the rate of myocardial infarction worldwide, sudden cardiac death has remained the most important unresolved factor in the mortality of coronary heart disease (CHD). As much as 90% of CHD mortality in individuals under 55 years occurs out-of-hospital. A key event in the development of acute myocardial infarction and sudden cardiac death is the rupture or erosion of a thin-walled atheromatous plaque distant from the site of the culprit stenosis leading to the development of fibrin-rich occluding thrombosis. When an atheromatous plaque is fissured or its fibrous cap is ruptured, platelet glycoprotein Gplb-DC-V (HPA-2) receptors are activated and start the binding of platelets to subendothelial collagen. At the same time, GPHb/Ma (HPA-1) fibrinogen receptors are also activated and begin binding fibrinogen, connecting platelets to each other, leading ultimately to the formation of coronary thrombosis. A mutation (CM) in the leucine-rich region in the Gplb receptor gene binding site leads to an alteration in the amino acid sequence (Thr/Met) and alteration in the binding activity. Another mutation (pIAI/A2) in the exon of Gp Hla gene with replacement of one amino acid (leucine with proline), resulting in a change in the protein conformation and in the spatial orientation of the fibrinogen-binding region of the receptor, affects the efficacy of platelet aggregation. There have been no detailed autopsy studies on the occurrence of these mutations among victims of sudden cardiac death.

The aims of the present project were to study the associations of the Thr/Met mutation of the Gp Ib-DC-V collagen receptor and the pIAIIA2 mutation of the Gp IIb/IIIa fibrinogen receptor with coronary thrombosis and MI in a carefully characterized autopsy series and to examine the possible age-dependency of this association.

The study series comprised 700 men (mean age 53.1 yrs, range 33 to 70) of the Helsinki Sudden Death Study (HSDS) subjected to a detailed medicolegal autopsy in 1981- 1982 (n=400), and in 1991 - 1992 (N=300). This series comprises all sudden unexpected cardiac deaths of men below 55 years living in the Helsinki city area (500 000 inhabitants) and also all violent deaths within this area during 2.5 years. Life style and various risk factors were ascertained by interviewing the spouse, a relative, or a close friend of the deceased. The interview succeeded in 500 (71.4%) cases. The presence or absence of acute MI and/or coronary thrombosis was confirmed by macroscopic and histological examination of the myocardium. The Thr/Met and pIAIIA2 polymorphisms were detected by PCR and restriction digestion.

The genotype frequencies of the Thr/Met polymorphism were 77.1% for ThrThr, 21.3% for ThrMet and 1.6% for MetMet genotype.

Respectively, the genotype frequencies of the plAIIA2 polymorphism were 73. 1% for plAIIA1, p,Al/A2 24.2% for and 2.7% for PIA'JA2.

Men with an acute MI (n=75) and coronary thrombosis (n=6 1) were more likely to be carriers of the Met allele of the Thr/Met polymorphism of the Gp Ib-IX-V collagen receptor (OR 2.5 and 4.0, respectively, p<0.005 for both) compared to controls who died of non-cardiac causes (n=340). In men under 55, Met allele carriers were over represented (OR 1.9) among victims of SCD (n=97) compared to controls (n=249). In men under 55, 14/28 (50%) of men with acute MI and 16/23 (69.6%) of men with coronary thrombosis were carriers of the Met allele compared to those 50/249 (20. 1%) who had died of non-cardiac causes (ORs 4.9 and 9.0, respectively). Similar associations were observed in the separate analysis of both individual autopsy series.

Our results suggest that prothrombotic mutations in blood platelet collagen and fibrinogen receptor genes occurring normally in 20-25% of the population are found in 60-70% of victims of acute fatal myocardial infarction below 55-60 years. This suggests that they are major risk factors predicting coronary thrombosis and early prehospital coronary death.

Sudden Cardiac Death, Coronary Thrombosis, Myocardial Infarction

G17 Under Reporting of Fatal Child Abuse by State Vital Statistics ICD-9 Codes

Mary H. Dudley, MD, and Shari L. Beck, BA, Chief Medical Investigator, Sedgwick County Regional Forensic Science Center, Wichita, KS; Larry Czarnecki, DO, Office of the Medical Investigator, and University of New Mexico School of Medicine, Albuquerque, NM*

The goals of this research project are to learn how to identify the difference in the incidence of fatal child abuse cases as reported by ICD-9 codes versus state child death review boards, to establish awareness of underreporting of fatal child abuse cases, and to discuss recommendations for improvement.

The purpose of this study is to document the difference in the incidence of fatal child abuse cases as reported by the International Classification of Diseases, Ninth Revision, codes versus that reported by state child fatality review boards. The ICD, designed to promote international comparability in the collection, processing, classification, and presentation of mortality statistics, includes translating reported conditions into medical codes. The coding rules consolidate conditions, and systematically select a single cause of death from a reported sequence of conditions. State child death review teams are comprised of multi-agency, multi-disciplinary members, who meet periodically to examine circumstances surrounding the deaths of children. State child review teams are comprised of members such as law enforcement, coroners, social services, physicians, educators, legal community and members of the Department of Health and Environment, who bring a variety of experience and perspectives on children's health and maltreatment issues. Under the ICD-9, category E967 is Child Battering and Other Maltreatment. For a homicide to be coded E967, the decedent must be younger than eighteen, and the death certificate must list evidence of prior abuse or the certifier must specify abuse, beating or other maltreatment. The general definition of child abuse by medical examiners and child fatality review boards is death of a child under the age of eighteen by the willful act of a person responsible for the child's welfare.

We retrospectively studied child abuse fatality data from New Mexico, Arizona, Kansas, and North Carolina for the year 1997. The incidences of death resulting from child abuse published in the 1997 annual report for state child death review boards and the deaths attributed to state vital statistics code E967 were compared. Preliminary review reveals a high percentage of under reporting by ICD-9 codes. This can be attributed to failure of the coding system to recognize fatalities due to abuse, inexperience of the coder, interpretation of the code (more than one code for similar conditions), and incomplete or inaccurate reporting on

death certificates. For example, a homicide due to an injury sustained from a single isolated incident of a child under the age of eighteen would not be coded as E967 (Child Battering and Other Maltreatment) due to the fact that there was no history of previous child abuse, beating or maltreatment. Problems occur with varying definitions of what constitutes abuse or neglect, and the failure to categorize neglect deaths as homicides.

We will present suggestions to improve upon the current system of recognizing and reporting fatal child abuse. Improvements in the recording of incidences of child abuse fatalities are crucial in the development of prevention strategies. Recommendations to improve data may include revising the format of death certificates, training coders or restructuring the coding system to include new codes specifically for medical examiner cases. An improved approach to reporting child abuse may require training of coroners, medical examiners and physicians to properly and universally complete death certificates. Items that may help to obtain a higher overall level of recognition of child abuse cases would include education and certification of those individuals responsible for investigating deaths. Standardization of scene investigation and autopsy protocols may be helpful, as well as stringent statutes requiring that autopsies be performed on all children under the age of two. Improvement to the current underestimated mortality figures will require cooperation and collaborative efforts between multi-disciplinary agencies including state vital statistics, child fatality review teams, medical examiners, law enforcement, and the legal system.

Mortality figures determined by ICD-9 coding alone was found to significantly underestimate the incidence of fatal child abuse in four states for the year 1997 when compared to medical examiner/coroner statistics and data from state child death review boards. Accurate recording of fatal child abuse is crucial to determine the true incidence of child homicide, to establish trends, and to allocate resources for prevention strategies.

Child Abuse, ICD-9, State Child Death Review Boards

G18 Venous Air Embolism— A Difficult Postmortem Diagnosis

Mitra B. Kalelkar, MD, Kendall Crowns, MD, and Edmund R. Donoghue, MD, Chief Medical Examiner, Cook County Medical Examiner's Office, 2121 West Harrison Street, Chicago, IL*

The goals of this research project are (1) to report a series of cases where circumstantial evidence and autopsy findings helped determine the cause and manner of death; (2) to illustrate through cases that, though an uncommon complication of a common procedure, venous air embolism can cause sudden and unexpected death; and (3) to bring home the point that awareness of this phenomenon is paramount in making the right postmortem diagnosis.

Case 1. A 59-year-old male on Methadone program for chronic drug abuse was found unresponsive in his hospital room. His central line catheter appeared to have been cut or melted. Suspicion of foul play was entertained initially until the County Sheriff's police ruled it out.

Case 2. While sitting on a chair in preparation for discharge, a 71-year-old female with a history of hypertension and scleroderma developed mental status changes soon after removal of central venous catheter. A family member witnessed this incident.

Case 3. While being detained by police for shoplifting, a 29-year-old female with a history of chronic renal failure on dialysis pulls out her central line catheter and collapses to the floor. The store security cameras recorded this incident.

Case 4. A 40-year-old male with chronic renal failure was found unresponsive in his motel room in a pool of blood with a dislodged dialysis catheter. He had a history of depression and suicidal tendencies in the past.

Central Venous Catheterization is performed frequently in the management of a variety of medical and surgical illnesses. The commonly

recognized complications of insertion and removal of a Central Venous Catheter (CVC) include thrombosis, infection both systemic and local, pneumothorax and hemorrhage. Venous Air Embolism (VAE) is another complication that is preventable, and carries with it a high incidence of morbidity and mortality. The risk of VAE associated with removal of CVC is not widely known, as is demonstrated by Case Two. Several factors known to predispose to the formation of VAE such as failure of spontaneous collapse of the catheter tract due to duration of catheter insertion, diameter of the indwelling catheter, upright position of the patients, deep inspiration or coughing while catheter removal or disconnection, played a significant role in these persons' demise.

The cases being described illustrate that postmortem diagnosis of VAE is difficult at best, but not impossible if one takes into account the medical history and circumstances surrounding death, and has a high degree of suspicion and awareness of this phenomenon.

Venous Air Embolism, Central Venous Catheter Removal, Sudden Death

G19 Virtopsy—New Horizons in Forensic Radiology: Documentation and Analysis of Gunshot Victims With Postmortem Multi-Slice Computer Tomography and Magnetic Resonance

Michael J. Thali, MD, Office of the Armed Forces Medical Examiner, AFIP - Annex, 1413 Research Boulevard, Building 102, Rockville, MD; K. Yen, Wolf Schweitzer, and E. Scheurer, Institute of Forensic Medicine, University of Berne, Buchlstrasse 20, Berne, Switzerland; P. Vock, Institute of Diagnostic Radiology, University of Berne, Berne, Switzerland; C. Ozdoba, and G. Schroth, Department of Neuroradiology, University of Berne, Berne, Switzerland; M. Sonnenschein, Institute of Diagnostic Radiology, University of Berne, Berne, Switzerland; Ch. Boesch, Department. Clinical Research, Magnetic Resonance Spectroscopy, University of Berne, Berne, Switzerland; M. Ith, Department of Neuroradiology, University of Berne, Berne, Switzerland; K. Brugger, Department. Clinical Research, Magnetic Resonance Spectroscopy, University of Berne, Berne, Switzerland; E. Spielvogel, Institute of Diagnostic Radiology, University of Berne, Berne, Switzerland; U. Koenigsdorfer, and R. Dorn, Institute of Forensic Medicine, University of Berne, Buchlstrasse 20, Berne, Switzerland; and R. Dirnhofer, Institute of Diagnostic Radiology, University of Berne, Berne, Switzerland*

The goal of this research project is to study the full-body documentation of seven gunshot wound victims, with multi-slice spiral computed tomography (MSCT) and magnetic resonance (MR), and subsequent comparison with the findings of the standard forensic autopsy.

Virtopsy - New Horizons in Forensic Radiology: Documentation and Analysis of Gunshot Victims with Postmortem Multi-Slice Computer tomography and Magnetic Resonance

Goal: The use of the new radiologic modalities in forensic science promises to be a great help for forensic pathologists. This paper will present the full-body documentation of seven gunshot wound victims, with multi-slice spiral computed tomography (MSCT) and magnetic resonance (MR), and subsequent comparison with the findings of the standard forensic autopsy.

Materials and methods: MSCT was performed on a General Electric Light Speed QX/i. The scan time for 350 axial slices of the head (high-quality data and overlapping data acquisition) was 40 seconds, and for the rest of the body we required only 20 seconds (high-speed data acquisition; 70 axial slices). The MR examination was performed on a 1,5 Tesla General Electric machine. Post processing (2-D and 3-D reconstructions of CT data sets) was performed with the GE Advantage Windows workstation. Then a classical forensic autopsy was made.

Results: With the spiral CT and MR examination and the subsequent 2-D multi-planar reformation / (MPR) and 3-D shaded surface display reconstruction (SSD), all the gunshot-created complex skull fractures and brain injuries (such as the wound channels and the deeply-driven bone splinters) could be impressively documented in complete and graphic detail. With the CT / MR examination it was also possible to document and demonstrate some signs of vital reaction to the gunshot: air emboli in the upper thoracic veins and the heart and the classic pattern of blood aspiration in the lungs.

Discussion: We agree with B.G. Brodgon, who says in his book, *Forensic Radiology*: "The sad truth is, that a century after the first x-ray was introduced as evidence in a court law, there is no general appreciation of the extent of the radiology potential in the forensic sciences." To the best of our knowledge this paper is the first study that compares prospectively the results of postmortem MSCT and MRI with the findings of forensic autopsies. Utilizing the modern methods of MSCT and MR it was possible to document the relevant forensics injuries. An advantage in comparison to the classic autopsy is that the data collection of the radiological examination is produced non-destructively. In addition, this radiological data, including the 2-D and 3-D reconstructions, can be archived, in contrast to the real injuries of the corpses. In summary, the radiological documentation has some significant advantages in comparison to the classic forensic autopsy and documentation. In the future this documentation and analysis process with MSCT and MR and magnetic resonance opens the door for a "Digital Autopsy" or a "Virtual Autopsy" in selected forensic cases.

Forensic Radiology, Computed Tomography, Magnetic Resonance

G20 Evaluation of 122 Forensic Autopsies of Unprotected Victims Killed in Traffic Accidents

Georges Krompecher, MD, Thomas Krompecher, MD, PhD, and Patrice Mangin, MD, PhD, Institut Universitaire de Médecine Légale, Rue du Bugnon 21, Lausanne, Switzerland*

The goals of this research project are to present the results of 122 autopsies of unprotected victims killed in traffic accidents. Proposals are made to improve the efficiency of the forensic procedure which is very complex.

Unprotected road users, such as pedestrians, bicyclists and motorcyclists, are not shielded by the body of a vehicle and are therefore at a high risk of being killed in a traffic accident. If it is impossible to undo the tragedy in a fatal accident, one must address the severe consequences it has on the family of the victim and on the drivers and their families as well. It is thus extremely important to establish the precise sequence of events in an accident and to assign clear responsibilities. If the police and the technical experts are primarily responsible for elucidating the circumstances surrounding an accident, a careful post-mortem forensic examination can provide significant and important evidence.

Because a forensic autopsy of a victim of a fatal traffic accident is a complex, laborious and time-intensive task, we wished to analyze the results from such work with the following objectives in mind:

- to evaluate the contribution of forensic investigations to the elucidation of the circumstances of an accident and of the responsibilities of the involved parties;
- to evaluate the efficiency of forensic investigations taking into account the significant time expenditure and efforts necessary to complete this work;
- to identify and propose preventive measures to reduce the frequency and gravity of traffic accidents; and
- to identify and propose improvements in the forensic investigations carried out in fatal traffic accidents.

Our study was conducted on 122 traffic accidents that occurred in Switzerland between 1979 and 1996 and which required the expertise of the University Institute of Forensic Medicine of Lausanne. To evaluate the autopsy findings, standard questionnaires were employed that addressed the following variables:

- age and gender of the victims,
- classification of victims as a function of their mode of transportation, survival,
- vehicles involved in the accident,
- speed of vehicles involved in the accident,
- location and circumstances surrounding the accident,
- visibility: lighting, weather conditions, color of clothing of the victims,
- cause of death,
- observed lesions,
- primary lesions,
- medical history, and
- toxicological analyses.

Our results are in agreement with those reported in the literature with respect to the following findings:

- the largest proportion of accidents involve elderly persons;
- elderly victims are most likely to survive the accident and succumb later from accident-related complications that would not be lethal for younger, healthier individuals;
- private automobiles constitute the largest category of vehicles involved in accidents;
- a high proportion of accidents occur within towns or villages;
- a high proportion of accidents occur in darkness;
- the prevalence of crano-cerebral lesions, polytraumatism, thoracic lesions and spinal chord lesions as the cause of death;
- the nature of the primary lesions;
- the role of alcohol consumption.

Based on the data published in the literature and on our own results, the forensic examination can provide very important information in establishing the degrees of responsibility of both the drivers and the victims of traffic accidents. The forensic examination is clearly an efficient approach; the information can often be obtained only by this means and its value is very significant. Such examinations must be conducted irrespective of constraints linked to time, cost, and efforts deployed by forensic scientists.

We make a series of proposals to increase the safety of unprotected road users and to improve the efficiency of forensic examinations in fatal traffic accidents.

Traffic Accidents, Unprotected Victims, Usefulness and Efficiency

G21 Undefeated by Surgery: The Utility of Post-Surgical Foot and Ankle Radiographs as a Basis for Identification

Jeremy Rich, DPM, Harvard Medical School, Beth Israel Deaconess Medical Center, 330 Brookline Avenue, Boston, MA; Nancy E. Tatarek, PhD, Ohio University, 293 Lindley Hall, Athens, OH; Robert H. Powers, PhD, Hamilton County Coroner's Office, 3159 Eden Avenue, Cincinnati, OH; Bradley J. Lewis, MD, and Dorothy E. Dean, MD, Franklin County Coroner's Office, 520 King Avenue, Columbus, OH*

The goals of this research project are to demonstrate to participants how 1) radiographic comparisons for positive identification can reliably be made in some cases, even if there has been an alteration in the anatomy; and 2) what may be done to quantitatively evaluate the "matchability" of a postmortem radiograph to a premortem film.

Foot and ankle radiographs can be utilized as the basis of identification in forensic investigations involving decomposed, mutilated, or

fragmented remains (1-6). The lower extremity may be better preserved in both aquatic and terrestrial environments than other anatomical regions (7). The structural complexity of the foot and ankle facilitates identification by providing potentially unique skeletal features and/or configurations.

The process of radiographic comparisons for identification is intuitively understood, but not easily represented in an algorithmic fashion. While the result of the comparative evaluation may be easily verbalized ("match" or "no match"), the process by which that determination is made may not be as easily described. Qualitative factors addressing the reliability of that match may also be difficult to convey. The authors evaluated the possibility of developing a numerical representation of the reliability of a match evaluation.

Experimentally, 30 sets of pre-surgical (premortem) and post-surgical (simulating postmortem) radiographs of the foot and ankle were obtained from a tertiary care medical center simulating a postmortem identification. Up to three different views were used, including, anteroposterior (AP), medial oblique (MO), and lateral projections. All sets were prepared by one author (JR), and included both real matches and actual mismatches to provide a potential false positive result. Premortem and simulated postmortem radiographs were separated by a surgical event to simulate the effects of an alteration in anatomy. The time lapse between the premortem and simulated postmortem radiographs ranged from 2 to 36 months.

The reliability of the match results was evaluated and graded by a numeric system. As a first approximation and as evaluated in the experiment described herein, we considered 10 characteristic skeletal features in the simulated postmortem radiographs. We then looked for the same radiographic features in the premortem films and scored the results as follows:

- +1: If the feature was present and matched.
- 0: If the feature was either not present or its presence could not be determined.
- 1: If the feature was present, but did not match, or if the trait was present in either the pre- or postmortem radiographs but not in both.

For each set, we added the score. The radiographic sets were independently evaluated according to the medicolegal standard, "with a reasonable degree of medical certainty, these radiographs came from or did not come from the same individual." Additionally, we noted if we could not determine with a reasonable degree of medical certainty whether or not the films came from the same person.

Examiners included a forensic pathologist, forensic anthropologist, physician-coroner, and musculoskeletal radiologist who graded the radiographs according to the 10-feature scheme noted above. As a second exercise, we evaluated the set for a match. A correlation between the score and whether or not there was a match was determined. Simulated postmortem radiographs were evaluated for mean and standard deviation of the "matchability" score. Similarly, the match reliability score was evaluated and finally the correlation coefficient between the two was calculated.

Preliminary results indicate that at least two matching characteristics are necessary for determining that two radiographs have come from the same person. At least two characteristics must be present in the films that do not match each other to determine that two radiographs are from different individuals. The three most useful traits of the ten skeletal features examined were a) the overall shape of the calcaneus and the cortical bone of the metatarsals, b) the trabecular pattern of the calcaneus and the metatarsals, and c) osteophytes.

It is anticipated that the approach described in this study may evolve into a radiograph scoring system allowing a quantitative variable to be considered in addition to a "yes or no" match result with regard to forensic investigations.

Human Identification, Radiographs, Surgical Modifications

G22 Paraphyly in *Lucilia Cuprina* (Diptera: Calliphoridae) Mitochondrial DNA: Implication for Forensic Entomology and Evidence for an Ancient Hybridization Event

Jamie R. Stevens, PhD, University Exeter, Biological Science, Prince of Wales Road, Exeter, United Kingdom; Richard Wall, PhD, University Bristol, Biological Sciences, Woodland Road, Bristol, United Kingdom; and Jeffrey D. Wells, PhD*, University of Alabama Birmingham, Justice Science, 901 15th Street South, Birmingham, AL

The goal of this research project is to learn about the large number of recent published papers and important conceptual issues concerning DNA and insect evidence.

The closely related species *Lucilia* (=*Phaenicia*) *cuprina* (Meigen) and *L. sericata* (Meigen) are widespread, common, and extensively sympatric blow flies. Both may be collected as evidence during an investigation of human death. Taxonomic identification of insect evidence is usually an essential first step in a forensic entomological analysis, because different species can have different habits, growth rates, etc. Recently several authors have proposed the use of DNA sequence data for identifying forensically important insects. This is because fly larvae (also called maggots) and eggs are often difficult or impossible to identify using anatomical features. Furthermore such specimens are often dead or dying by the time the entomologist receives them, and they cannot be reared to the more easily identified adult stage. An implied assumption of most authors who advocate this DNA-based approach is that the genetic locus used has an evolutionary history identical to that of the organism as inferred from traditional taxonomic characters. In the language of systematic biology, the morphological and DNA evolutionary trees are assumed to be concordant.

This assumption was tested using a global molecular systematic survey of *L. sericata* and *L. cuprina*. Specimens from Europe, Africa, North America, Australasia and the Hawaiian island of Oahu were each classified as one of these two species based on bristle patterns and male genitalia. For each specimen we obtained DNA sequence data from a nuclear locus, a 2.2 kb region of the large subunit of the 28S ribosomal RNA gene (28S), and a mitochondrial locus, a 2.3 kb region of the first and second subunits of cytochrome c oxidase (CO). The DNA extraction, PCR, and sequencing methods used were described in previous publications (Stevens & Wall. *Forensic Sci Int.* 2001. 120:116-23; Wells & Sperling. *Forensic Sci Int.* 2001. 120:110-5).

Polymorphic base positions within the 28S gene were largely confined to three distinct portions within the D domains, while those within CO were evenly spread across the region.

Phylogenetic analyses of the data using the calliphorids *Lucilia caesar* (L.) and *Calliphora vicina* Robineau-Desvoidy as outgroup species found a significant lack of concordance between the most parsimonious tree (also called a cladogram) based on the nuclear 28S sequence and that based on the mitochondrial CO sequence (Kishino-Hasegawa test, $P < 0.0001$). The 28S tree included monophyletic lineages corresponding to each of the species as defined by morphological criteria. In contrast, the CO tree strongly supported a paraphyletic *L. cuprina*, with specimens from Hawaii as the sister group (i.e., the most closely related lineage) of *L. sericata*. Prior to this study CO sequence analysis of an *L. cuprina* larva or egg from Hawaii may have misidentified the specimen as *L. sericata*. While that particular mistake is no longer possible, our results suggest that widespread geographic sampling and/or a multi-gene approach may be needed before DNA-based identification of carrion insects can be considered a reliable technique in all situations. It is most important to survey genetically isolated populations such as on remote islands.

A possible explanation for this evolutionary pattern is that the Hawaiian *L. cuprina* are descended from a hybridization event between a female *L. sericata* and a male *L. cuprina* with the subsequent loss of *L. sericata* nuclear alleles. Both flies were probably introduced to Hawaii by

human activity, and small initial populations would make the above scenario more likely. However, the observed genetic distances were about 0.9% sequence divergence between the Hawaiian *L. cuprina* lineage and the *L. sericata* lineage compared to about 0.2% sequence divergence within each of these lineages. This suggests that the *L. sericata* and Hawaiian *L. cuprina* CO diverged long before humans first reached the islands. Given the Pacific island route by which humans colonized Hawaii, as well as the fact that samples from other Pacific islands were not included in this study, we suggest that islands occupied earlier in the geographic expansion of Polynesian humans be surveyed for the possible origin of the Hawaiian *L. cuprina* clade.

Forensic Entomology, Non-Human DNA, Molecular Systematics

G23 Investigation of Italy's Deadliest Building Collapsed: Forensic Aspects of a Mass Disaster

Carlo Pietro Campobasso, MD, PhD*, Rosa Falamingo, MD, and Francesco Vinci, MD, Section of Legal Medicine (DIMIMP), University of Bari, Policlinico, Plaza Giulio Cesare, Bari, Italy

The goal of this research project is to respond to mass fatalities: Investigation and morgue operations.

In the early morning hours (approximately 3:00 a.m.) of November 11, 1999 a six-story apartment building, approximately 30 years old, collapsed before dawn in Foggia (viale Giotto, 120), Italy, killing many of the residents while sleeping and others trying to escape. Minutes before the structure crumbled some tenants were awakened by a loud cracking sound. Consequently, they knocked on doors, trying to wake other tenants and escaped just moments before the building collapsed. It took literally seconds for the building, which was in a working class suburb, to fall on itself floor atop floor. The collapse reduced the apartment building to a pile of rubble no more than one story high and a blaze soon broke out in part of the ruins. Search and recovery operations were immediately set up with the help of the local fire departments and military rescue divisions. Using trained dogs, emergency crews rescued approximately 17 people injured and trapped inside the structure. Most of the people who survived the crash were residents of the top floor.

Immediately after the crash the state attorney engaged two different groups of experts. He assigned to a group of engineers the task of establishing the cause of the event and to a group of forensic pathologists the task of identifying all the victims and determining cause and manner of death. For this purpose a Medical Examiner Team, composed of five forensic pathologists familiar with anthropological procedures for personal identification, was set up. Between 70 and 75 people were in the building when it collapsed but the number of the victims was unknown. The mass fatality morgue was established at the Pathology Division of the local hospital, just a few miles from the incident site. In the morgue, autopsy tables, coolers for body storage and medical facilities with X-ray and dental stations were available. The environment was divided in three sections: the first section was established at the catholic chapel next to the morgue for receiving the human remains and exhibiting them to the families; the second area was for inspection and removal of personal effects, photographing the remains and medico-legal autopsy; the third area was the final holding area for aftercare of the bodies before their release.

From 11 to 14 November, 1999 61 cadavers (31 males and 30 females), ages ranging between 3 to 86 years old, were recovered beneath the ruins of the building. All the victims were well preserved except for two cadavers largely burned by the explosion of gas pipes with missing body parts. Most of the victims wore night-dress clothes or were partly dressed, suggesting that they were overcome in the process of sleeping or getting clothes; only seven cadavers were fully dressed and several of them were found in the stairways as they were unable to get out in time as the building came down around them. Most of the victims (thirty people)

died almost immediately due to the severity of the multiple regional injuries observed during the examination; only four people died a slow death, trapped in the mass of pillars with air oxygen running out (asphyxia by confined space). Fourteen people died due to an asphyxia by mechanical fixation of the chest. For the rest of the victims (eleven people) the cause of death was an association of regional injuries and mechanical asphyxia by fixation or compression of the chest. Most of the victims were identified by visual recognition and/or clothing, personal belongings and body features (i.e., scars); for two bodies the positive identification was achieved respectively by dental comparisons with ante-mortem data and by DNA analysis.

The Engineers Team finally determined that the cause of the mass fatality was a structural collapse as the building's foundation was built with cheap materials. The above disaster was Italy's deadliest building collapse since 1959, when a falling building crushed at least 58 people a few miles from Foggia.

Mass Disaster, Building Collapsed, Personal Identification

G24 Differential Decomposition I: Partial Ground Contact

Kathryn H. Haden, MD, Department of Anthropology; and Murray K. Marks, PhD*, Department of Pathology, The University of Tennessee Medical Center, 250 South Stadium Hall, Knoxville, TN

The goal of this research project is to give participants the opportunity to achieve a greater understanding of time-since-death variables in this unique crime scene setting.

Purpose: Homicide victims bound to trees are not an atypical crime scene occurrence. In fact, 7% of rural wooded crime scenes involve ligature binding of the victim to a tree, post or other structure. Within the past 18 months, the junior author was requested to provide time-since-death estimations on three such cases long after the remains were autopsied/processed and buried. To date, our shared personal "case-based" events provide the only collective knowledge base about the decomposition rates of these specific victims. Later, i.e., post two weeks, time-since-death estimations come from our generalities of gross morphological change from the more common surface and buried bodies. Not surprisingly, the decomposition rate of above ground victims proceeds differently than surface finds and grave victims. Questions posed by law enforcement agencies regarding time-since-death estimation on bodies found above ground require special consideration when compared to our "collective" knowledge of surface decomposition events.

Materials and Methods: At the outdoor Human Decomposition Facility at The University of Tennessee Forensic Anthropology Center two nude and two partially clothed bodies were harnessed to trees with a variety of bindings to mimic the above mentioned scenario/scene. Of particular value was our ability to mimic the exact season of placement and record decomposition on a longitudinal scale. Five control bodies were placed on the ground surface several hundred yards away so that climatological data would precisely match. The five easily identified visual variables to assess time-since-death include: epidermal slippage, bloating, marbling, discoloration and entomology. No biochemical analyses were performed on any tissues or soil. Accumulated degree days for assessing time-since-death allow us to pinpoint precise time to morphological change.

Finally, the presence of blood from wounds of interpersonal violence was of particular concern as most homicide victims receive some perimortem perforative trauma from sharp-force, blunt-force, ballistic or sexual assault. This factor obviously hastens entomological activity and decomposition in wounds and necessitated our use of human blood during experimentation. Data were collected at 6-hour intervals for five weeks on each body for each variable (defined by Marks et. al., 2000) and correlated/converted to accumulated degree days (after Vass et. al., 1993).

Results: We found the rate of decomposition in above ground bodies to be significantly decreased when compared to our controls placed on the ground. All variables and levels of decomposition were reached at a later time than in those remains placed on the surface. Therefore, the assessment of time-since-death for these special cases cannot be estimated using time-since-death estimations for surface victims.

Time-Since-Death, Rate of Decomposition, Homicide

G25 Are Autopsies Necessary in Centenarians?

Andrea M. Berzlanovich, MD*, Ernst Sim, MD, Peter Fasching, MD, and Manfred A. Muham, MD, Department of Forensic Medicine, University of Vienna, Sensengasse 2, Vienna, Austria

The goals of this research project are to provide the forensic community with the understanding that the elderly are living longer and causes of death are shifting. At the same time, the rate of autopsies is very low, and the interest in geriatric autopsies is even lower. Thus, the prevalent cause of death in this age group remains poorly studied.

Only few necropsies have been performed in patients dying after age 100 years and little attention has been made on the clinical and morphologic features observed in these oldest of the old. For that reason we reviewed 28,312 consecutive autopsies done during a 12-year period (1989 to 2000) at the Institute of Forensic Medicine, Vienna, Austria.

We focused on cases who met our working definition of sudden natural death in very old people: "Unexpected or unexplained deaths of non-hospitalized persons over the age of 100 years, which apparently are due to natural causes that are not explicable with a reasonable degree of medical certainty." In particular, all persons who had not consulted a physician within 10 days before death were included and autopsied. Of the 20 study corpses, 8 were men and 12 were women; all were Caucasian. The age of these out-of-hospital patients ranged from 100 to 108 years.

Without periodical care from relatives or welfare centers, four persons lived alone in their homes. Another six persons also lived alone, but were regularly cared for by neighbors, relatives or welfare workers. 10 lived with at least one family member.

Sudden natural death occurred in all cases in private homes and in 35% of these cases while sleeping. Resuscitation was attempted in 10% of the cases. Sixty percent of the deceased were described as having been previously healthy. 30% had cardiac antecedents such as stable angina pectoris. Only one person had a history of myocardial infarction. Other pre-existing conditions were hypertension (20%), diabetes mellitus (15%), respiratory (10%) and gastrointestinal disorders (5%).

25% of the men and 40% of the women had a body mass index exceeding normal range.

The most common cause of death was cardiovascular disease (75%). 20% of the elderly died of respiratory illnesses, and 5% of gastrointestinal disorders.

Myocardial scars or focal myocardial fibrosis were detectable in 2/8 men and in 3/12 women, who died due to cardiac disorders. Three men and five women had acute myocardial infarcts. Calcification of the mitral annulus and of the aortic valves were present in 80%; 15% of the calcified valves were anatomically stenotic.

All deceased had extensive aortic sclerosis, mainly focused in the abdominal part. In all 20 corpses the aorta was dilated in its transverse and longitudinal planes, with aneurysm formation in four cases, two resulted in fatal rupture (1 man, 1 woman). Two cases of sudden death were caused by pulmonary embolism (1 man, 1 woman) emerging from the left femoral veins. Two patients died of bacterial pneumonia. A gastric ulcer caused perforation with acute diffuse peritonitis in one 106-year old man.

Although the quality of life cannot be assessed from the study of pathologic lesions alone, the reduced prevalence of chronic debilitating diseases may indicate that longevity is a desirable goal when medical

resources are available for diagnosis and treatment for acute medical problems. Our study underlines the need for more baseline data of the elderly which can be obtained only by more and well-performed autopsies.

Sudden Natural Death, Oldest Old, Autopsy Study

G26 In-Hospital Deaths for Forensic Autopsy

Istvan F. Szentmariay, MD*, and Gyorgy Dunay, MD, Institute of Forensic Medicine, Semmelweis University, Ullói Ut 93, Budapest, Hungary

The goals of research project are to present reasons, findings, gender differences and in-hospital survival time on in-hospital deaths where forensic autopsies were performed.

We have retrospectively analysed nearly 7000 in-hospital deaths in our forensic pathology department, using the chart review method. In-hospital death cases represent 35% of our total caseload, but there is a wide range in different groups (i.e., it is 70% of our all autopsies on 2-5 year-old age group, and only-quarter of those between the age of 21-30 years of age).

Out of all our in-hospital cases, the group of aging people (60 years and over) represents more than half of the cases. We have performed proportionally more autopsies with natural cause of death in every disease category on in-hospital cases, except for cardiovascular diseases (53% of all in-hospital natural cause of death cases and 82 % of all non-hospital natural cause of death cases were cardiovascular origin).

We have also compared the major natural and unnatural causes of death categories between our in-hospital and non-hospital cases. Interestingly, there were more unnatural cause of death cases on in-hospital cases and more natural causes of death cases from our non-hospital cases. We had more than twice as many male than female with natural cause of death in our non-hospital group and only 20% more males with similar natural cause of deaths in our in-hospital series. Suicide victims showed 2:1 m:f ratio in our non-hospital group, but the same ratio was less than 1 in our in-hospital group. We had more female accident victims from our non-hospital database, but our in-hospital group showed more than twice as many male accident victims coming for forensic autopsy after an accident.

We have also analysed survival time in each cause of death categories, showing age group and gender differences. An ample number of charts will be displayed to explain our findings.

In-Hospital Deaths, Forensic Autopsy, Survival Time

G27 Characteristics of Different Types of Fatal Head Trauma and the Factors That Influence Survival Time and Activity Prior to Death

Erin H. Kimmerle, MA*, University of Tennessee, 121 West Jackson Avenue North, Knoxville, TN; Matthias Okoye, MD, JD, Pathology Medical Services, PC Lincoln General Hospital, 2300 South 16th Street, Lincoln, NE; and Sue Gabriel, RN, BSN, Nebraska Wesleyan University, Lincoln, NE

The goals of this research project are to teach participants how to recognize and differentiate between different types of head trauma, including those caused by gunfire injuries and sharp and blunt force trauma. Further, participants will appreciate the relationships between the nature of these injuries, amount of blood loss, and role of drugs and alcohol to the amount of activity and time prior to death.

There is a wide spectrum of fatal head injuries, each with unique characteristics. Fatal injuries produced by gunfire, sharp, and blunt force trauma are discussed. The nature of these injuries and the presence of

different types of traumatic cranio-cerebral hemorrhages result in differing survival time (i.e., the amount of time between injury and the time of death) and activity. Importantly, the particular location of each injury, damage to blood vessels, the amount of blood loss, and presence of drugs and alcohol are discussed.

Statistical and descriptive analyses are used. Further, the frequency and type of hemorrhage, the association with the presence of cerebral edema and the demographic profiles of victims within each injury category are described. Variables analyzed include the type of weapon, location of injuries, number, size, and track of the wound(s), amount of blood loss, presence of alcohol or drugs, and amount of activity from time of injury to death. Additional variables specific to gunfire injuries include the distance of the shot and the caliber of the weapon. Finally, the position of the deceased in fatal motor vehicle accidents with resulting blunt force craniocerebral trauma and the use of safety belts are assessed.

Medico-legal cases from 1980-2000 were reviewed from the Lancaster County Coroner's Office in Lincoln, Nebraska, the Cook County Medical Examiner's Office in Chicago, Illinois, and the Knox County Medical Examiner's Office in Knoxville, TN. Information for this study was collected from a variety of documents including autopsy and police reports, medical records, death scene investigator's notes, and death certificates. Further, data is presented on gunfire injuries and blunt and sharp force trauma for over 200 homicide, suicide, and accident cases.

Our test results show that the presence of alcohol and drugs (56.8%) does not directly influence survival time or activity per se, however, they do affect blood loss, which in turn influences survival time and therefore activity. In gunfire and sharp force injuries, internal blood loss measured less than 500 ml, in 60% (6/10) of cases. Further, 55.3% (21/38) of gunfire injuries are single deeply penetrating gunshot injuries to the head, which means that in a small majority of cases, the bullet does not exit the cranium. The most commonly used firearms were .22 and .45 caliber weapons, each occurring in 23.8% (5/21) of cases. The majority of gunfire and sharp force trauma victims are male, at 85% (35/41); whereas, 70% (29/41) of all victims are under the age of thirty years old.

Gunfire Injuries, Blunt Force Trauma, Sharp Force Trauma

G28 Seizure Associated Fatalities: An Analysis of Cases in Milwaukee County

Michael A. Stier, MD*, University of Wisconsin-Madison, Department of Pathology, 1300 University Avenue, Madison, WI; and John R. Teggatz, MD, Milwaukee County Medical Examiner's Office, 933 West Highland Avenue, Milwaukee, WI

The goal of this research project is to present the information derived from a review of deaths associated with seizure over a five-year period. Relevant observations are emphasized.

Deaths associated with seizure disorders comprise a relevant proportion of routinely investigated cases by medical examiners and coroners. To better understand the nature and demographics of these cases, we chose to examine these deaths in a major medical examiner system. This work describes the findings of a systematic review of deaths associated with seizures occurring in a five-year period.

The database consists of deaths within Milwaukee County, Wisconsin, certified by the Milwaukee County Medical Examiner's Office (MCMEO) in the years 1995 through 2000. The computerized MCMEO case files were searched for the key word "seizure." All cases in which the investigator's report, the death certificate or the autopsy report contained the term are included in the review. The total number of cases is 164 deaths. Details regarding age, race, sex and other pertinent aspects were recorded.

The majority of cases consist of middle-aged (30-50 yrs.) African-American males. The manner ascribed to most deaths is natural, with accidental being second in frequency. In most cases, the decedents had a

history of a seizure disorder and deaths were attributed to seizure. Cause of the seizure disorders spanned the spectrum of possibilities. Etiological categories included developmental disease, traumatic, vascular lesions, drug-related, infectious, idiopathic, and neoplastic processes.

Several important aspects of seizure related fatalities were identified. Drugs of abuse played a role in a high percentage of deaths. Drugs were isolated in postmortem toxicological specimens and were implicated as causal to the seizure disorder in many cases. Alcohol was the principle drug within both categories. Cocaine was second in prevalence. In patients for whom anti-epileptic medicines were prescribed, a disproportionately high number revealed sub-therapeutic levels in postmortem toxicological analysis. Medical history in many such patients documented prior noncompliant issues. Additional reasons for this observation are a focus of discussion.

Certain determination of seizure as a cause of death is difficult. There are currently no morphological or laboratory tests, which confirm legitimate antemortem seizure activity. The "gold standard" is witnessed convulsion in the setting of a clinically defined seizure disorder. We reviewed the autopsy findings in witnessed cases of seizure related fatalities. Convulsive activity was observed in slightly more than 17% of cases. Several morphologic autopsy findings are noted in these cases. These include tongue bites, minor superficial contusions and abrasions to the face and head, and minor hemorrhage in deep cervical neck musculature. The most consistent finding was tongue bites, noted in over half of the cases. In those without documented tongue bites, many were edentulous or the tongue exam was omitted in the autopsy report. This observation indicates tongue bites are a useful postmortem marker suggesting perimortem convulsive activity.

These findings and additional statistics are presented. Significance of the data will be discussed.

Seizure, Epilepsy, Sudden Death

G29 Homicide by Second Impact Syndrome... or Unfortunate Coincidence?

Dwayne A. Wolfe, MD, PhD, Office of Medical Examiner of Harris County; Joseph A. Jachimczyk Forensic Center, 1885 Old Spanish Trail, Houston, TX*

The goals of this research project are to understand that the second impact syndrome is a rare and possibly underreported mechanism of death. The present case involves an adult individual who died following two contemporaneous head injuries — one accidental and the other inflicted. The learning objective of this presentation is to understand the various features of the second impact syndrome, and to evaluate the plausibility of the mechanism in fatal successive head injury cases. The importance of this mechanism, as it relates to manner of death, is a focus of this presentation.

The second impact syndrome is a clinicopathologic entity in which an individual sustains a concussive head trauma (with or without loss of consciousness) then, before symptoms of the initial injury have cleared, sustains a second, often relatively mild, head trauma. Closely related temporally with the second trauma, the individual develops uncontrollable cerebral edema, with or without subdural hematoma, and ultimately often succumbs. This form of head trauma has been most often reported in young athletes in collision sports such as football and boxing. The case reported here is a 48-year-old male who was the lone occupant in a single-vehicle car crash, and subsequently, less than 1 hour later, was assaulted and lost consciousness. On admission to the hospital, he had brain edema and bilateral subdural hematomas, which were partially evacuated. He remained comatose for nine days. Neuropathologic examination revealed severe brain edema with cerebellar tonsillar and bilateral transtentorial herniation, and residual bilateral convexity subdural hematoma. The brain had evidence of global hypoxic-ischemic injury, with symmetric necrosis

of deep cerebral nuclei. Microscopically, axonal spheroids were widespread; however, in the setting of global hypoxic-ischemic damage with no gross or microscopic intraparenchymal hemorrhages to indicate significant shear type injuries, the diagnosis of diffuse axonal injury was not warranted. Other autopsy findings were infectious complications of the comatose state, specifically bilateral bronchopneumonia with pulmonary abscesses and empyema. The historic and anatomic findings in this case raise a number of questions. First, "Can the injuries be ascribed to one or the other of the traumatic incidents?" Of themselves, the head injuries have no features to allow specific assignment to one or the other (manner undetermined). Second, "Can the injuries be ascribed to BOTH traumatic incidents?" Second impact syndrome, if established, provides a plausible mechanism by which the answer to the latter question is positive. If the death can be ascribed to both of the injuries (car crash and assault), then the manner of death is homicide. The existence of second impact syndrome has been questioned in the literature. One of the questions that has been raised relates to degree of documentation of both head injuries. In this case, some details of the first head injury are not well established. The vehicle, a pickup truck, had front-end damage, on the driver's side, and had been crashed into a stationary bridge support. An uninvolved party did witness and converse with the subject in the interim between the crash and the assault; the witness stated that the subject had a laceration of the bridge of the nose, indicating a blunt force impact to the face/head. However, the severity of the first "impact," whether the subject was restrained or not, and whether transient loss of consciousness occurred, are not known. Of note, details of the assault, in which the subject received a rapid succession of multiple blows to the head/neck and face, are well documented in congruous witness statements. A review of the literature does not reveal any previous reports of homicide by second impact syndrome.

Adult Head Injury, Second Impact Syndrome, Homicide

G30 A New Technique to Estimate a Postmortem Submersion Interval (PMSI) Using Algal Growth Rates

James Haefner, and John B. Wallace, PhD, Department of Biology, Millersville University, Millersville, PA; and Richard W. Merritt, PhD, Department of Entomology, Michigan State University, East Lansing, MI*

The goals of this research project are to present to the forensic community a new technique to establish a post-mortem submersion interval in aquatic habitats using algae on corpses. Attendees will learn that algal growth on corpses changes over time and how this change can be used to estimate a PMSI for a corpse in an aquatic habitat.

This presentation will include a portion of graduate thesis work which focuses on the role of aquatic organisms in pig decomposition in streams. The purpose of this presentation is to evaluate a new technique utilizing algal or periphyton growth on corpses as a method to estimate the postmortem submersion interval. The objectives of this study include 1) the identification and determination of the duration of each stage of decomposition, 2) the comparison of algal growth on pigs to a natural substrate such as ceramic tiles and, 3) the determination if algal growth differs between riffle and pool habitats.

This study was conducted on two 2nd order streams in Lancaster County, Pennsylvania. Stillborn pigs (six pigs per stream) and ceramic tiles were used as substrates for periphyton growth. The duration of each stage of decomposition was estimated in degree days. To examine spatial differences in periphyton growth, pigs and tiles were placed in riffle (high velocity) and pool (low velocity) habitats. Periphyton samples were collected from pigs and tiles every four days for approximately 40 days. Samples were transported to the lab for filtration and preservation. Chlorophyll-a concentrations in periphyton samples were determined through fluorometric analysis. Chlorophyll a comparisons between pigs

vs. tiles and riffle vs. pool habitats were analyzed with a 1-Way ANOVA and Fisher's pairwise comparison test. Regression analysis was used to compare chlorophyll *a* concentration as a function of time.

The literature identifies several stages of decomposition in aquatic habitats: Submerged Fresh, Early Floating, Early Floating Decay, Advanced Floating Decay, and Sunken. As we describe them in this study, they included: Submerged Fresh, Early Floating, Early Floating Decay, Advanced Floating Decay, and; Decay. Total degree days for pigs submerged in riffle habitats were 363.8, while pigs in pool habitats accumulated 773.8 degree days during the decomposition process. The duration of the Submerged Fresh and Floating Decay stages was significantly longer in the pool habitat compared to the riffle habitat. Chlorophyll *a* concentration increased as a function of time regardless of habitat. Chlorophyll *a* concentration was significantly greater on pig carcasses vs. ceramic tiles; whereas, it did not differ between riffle and pool habitats. Although periphyton growth on pigs in riffle and pool habitats was significantly impacted by a spate or rain event during this study, we found that chlorophyll *a* concentrations were still significantly correlated over time.

To date, an accurate measurement of a PMSI has been difficult in aquatic habitats. In terrestrial systems, insects have evolved to feed on carrion, this is not the case with aquatic insects. Aquatic insects essentially utilized the corpse as an extension of their natural substrate. Some species may feed on the corpse or on attached algae. Recent more qualitative evidence suggests that aquatic flora in the form of algae may provide a more reliable approach to estimate the PMSI in aquatic systems such as rivers or lakes. These studies have examined algae and other aquatic flora from a taxonomic perspective in an attempt to correlate species diversity with each stage of decomposition. Our study provides a more quantitative method to estimate a PMSI based on algal or periphyton growth over time. Since pig carcasses were found to have significantly more periphyton growth than ceramic tiles, we suggest that the nutrients leaching from a corpse may provide a more optimum habitat upon which algae may grow. An inherent problem with the use of algae from a qualitative or quantitative perspective is that rain events can change the composition and amount of algae on a corpse. Our study illustrates how a rain event impacts chlorophyll *a* concentration on pigs in riffles and pools in streams.

Postmortem Submersion Interval, Degree Days, Periphyton

G31 Assisting the Living

Butch M. Huston, MD, and Janis C. Amatuzio, MD, Midwest Forensic Pathology, 3960 Coon Rapids Boulevard, Suite LL21, Coon Rapids, MN*

The goal of this research project is to present to the forensic community a model of positive communication with grieving family members.

The death of a loved one may be the most difficult and traumatizing situation that a family has to endure. The coroner or medical examiner is thrust into the lives of the decedent's family and is therefore in a very unique position. The medical examiner/coroner need only invest a small amount of time to produce an immense and everlasting effect on the family's ability to accept their loved one's death and promote the healing process.

The relationship between the medical examiner/coroner and the decedent's family begins with the death scene investigation and the notification. But this should only be the beginning. The role of the coroner can extend well beyond determination of the cause and manner of death. There are many opportunities in which the coroner can interact with the family to instill compassion and assist with the grieving process.

A good opportunity for the medical examiner/coroner to interact with the family arises following the autopsy. In our office, the next-of-kin is called immediately after all postmortem examinations, except in cases of homicide investigations where communication is usually through law enforcement. An explanation of the preliminary findings is given and the family is informed if additional studies are pending. Calling the next-of-

kin after the autopsy gives them an opportunity to ask questions, to discuss property disposition and medical history, or just to tell you about their loved one.

Following the completion of the autopsy report, a condolence letter is generated expressing sympathy for the loss of their family member. This letter also gives the medical examiner/coroner the opportunity to review the autopsy findings and include any additional studies or tests that were completed after the initial phone conversation immediately following the autopsy. A short explanation of the cause of death is often helpful to the family. Any types of diseases that may have a genetic component should also be mentioned with directions to consult their family physician. Having this information on paper is also helpful to the family physician, particularly if a genetic or environmental cause of death was diagnosed. The family physician is then able to conduct genetic testing on remaining family members or suggest lifestyle changes. These explanations often reduce future phone calls by anticipating what questions may be asked. In cases of homicides, the letter can be brief and reiterate the information stated on the death certificate, especially if a criminal trial is pending.

Following the initial death investigation and postmortem examination of a possible sudden infant death (SIDs), our office generates a letter to the parents. The letter should include some general information about SIDs and inform the family that additional studies such as microbiologic cultures, metabolic screen, histology, toxicology and other tests may be pending. A final letter will then be sent to the family following completion of the autopsy report.

In difficult and emotional cases such as an infant overlay, possible medical malpractice or an unsuspected suicide, a meeting in the medical examiner/coroner's office may be suggested to the family prior to signing the death certificate. This will give the pathologist an opportunity to explain the final investigative and autopsy findings in a controlled environment. Open communication assures that there are no surprises when the family receives the death certificate.

These actions lend support during a very difficult period and may result in a positive attitude toward the medical examiner/coroner's office from the general public.

Condolence, Communication, Grieving

G32 Some Empirical Data on the Past and Future of the Autopsy

Jody E. Hooper, MD, United States Navy, General Medical Officer, 5240 Fiore Terrace, San Diego, CA*

The goals of this research project are to help participants: 1) become familiar with the history and purposes of the autopsy; 2) examine the causes and significance of declining autopsy rates and uses; and 3) consider suggestions to revitalize the autopsy based on a survey of physicians at a major university hospital.

Background: The autopsy has been an important method of exploration, education, and discovery for hundreds (perhaps thousands) of years. Medicine as a scientific field has progressed in tandem with the acceptance of the autopsy, the precision of its performance, and the accuracy of its results. Recently, however, autopsy frequency has declined from approximately 50% of patients dying in hospitals in the 1950s to a range of 5 to 13% of similar patients today. Reasons given in the literature for this decline include physician belief that modern diagnosis is so accurate that autopsy is not needed, cost (and lack of profit) of the procedure, fear of litigation prompted by autopsy findings, and the difficulty of communicating with families regarding autopsy. Given that individual physician opinions about autopsy are important determining factors in autopsy requests and use of results, it is helpful to understand the nature of these opinions and what influences them.

Methods: This study makes use of a survey on autopsy practices and opinions which was distributed to all attending physicians in a large,

urban, university affiliated medical center. The 10 question survey was distributed to 215 full time attending faculty based at the hospital or the adjacent Ambulatory Care Center. The survey was an anonymous, one page, multiple choice format questionnaire that could be completed in under five minutes. Clinicians first identified their department, years of practice, and approximate departmental autopsy rate. The inquiries then examined, among other topics, physician beliefs about the value of the autopsy for confirming diagnostic results, its possible use in clinical practice, the desirability of medical quality assurance using autopsy data, and the effects of litigation concerns on autopsy requests. Surveys were distributed to 24 individual clinical departments, including Pathology, based in the Medical School.

Results: A total of 53 physicians responded to the survey (24.7%). Departmental response rates varied from a high of 60% to a low of 0. Faculty varied in years of practice from 5 to over 20 years with the largest proportion having practiced for 5 to 10 years. Most (26/48 or 54.2%) respondents reported an estimated departmental autopsy rate of under 10% with the next largest group (17/48 or 35.4%) selecting "don't know." Overall, respondents were split almost equally on the question of whether their departmental autopsy rates were sufficient. Respondents were strongly in favor of the autopsy on questions that pertained to its potential usefulness. Most (36/50 or 72%) disagreed with the statement that current diagnostic procedures were sufficiently accurate to make autopsies unnecessary. Though respondents were more cautious on the question of whether the autopsy should be used for quality assurance, 28/50 (56%) strongly agreed or agreed that they would like to see this application in their departments. Interestingly, responding physicians disagreed (79.1% total) that concerns over litigation affected their decision to request autopsies, rejecting one of the primary causes for the autopsy decline cited in current literature. Responses did not differ significantly among physicians of various levels of experience, but did tend to separate along departmental lines.

Conclusions: The survey data suggest that the responding physicians continue to value the autopsy as a tool for diagnosis and education, even in the face of radically declining autopsy rates. Suggestions for improving the frequency and efficacy of the autopsy range from better standardization of requests and communication of results and reporting to centralization of hospital and forensic autopsies into regional centers. Clearly, a revitalized autopsy can help identify new diseases and environmental problems and improve the contribution of the procedure to the forensic sciences.

Autopsy, Diagnosis, Autopsy Rates

G33 The Postmortem Diagnosis of Skull and Brain Injuries by Imaging Methods (MRI, Multi-Slice CT)

Kathrin Yen, MD*, Wolf Schweitzer, MD, Eva Scheurer, MD, and Michael J. Thali, MD, Institute of Forensic Medicine, University of Berne, Buehlstrasse 20, 3012 Berne, Switzerland; Christoph Ozdoba, MD, Gerhard Schroth, MD, and Martin Sonnenschein, MD, Departement of Neuroradiology, University of Berne, Freiburgstrasse, 3010 Berne, Switzerland; Chris Boesch, MD, PhD, Michael Ith, PhD, and Karin Brugger, MR-Spectroscopy Center, University of Berne, 3010 Berne, Freiburgstrasse, Switzerland; Elke Spielvogel, Department of Neuroradiology, University of Berne, 3010 Berne, Freiburgstrasse, Switzerland; and Richard Dirnhofer, MD, Institute of Forensic Medicine, University of Berne, Buehlstrasse 20, 3012 Berne, Switzerland

The goal of this research project is to present to the forensic community a new application of a clinically well-established method in forensic medicine, i.e., the postmortem collection of data by utilizing imaging processes such as MRI and multi-slice CT.

Content: In 20 cases in which the deceased succumbed to skull/brain injuries, a forensic investigation had been ordered and whole body MS-CT and MR examinations were performed. In seven cases the cause of head trauma was secondary to a road accident; and three persons sustained blunt force trauma; in three cases, there had been a fall from a height; and seven persons died following shotgun injuries. MRI studies were performed on a 1.5 T GE Signa system; CT data were acquired with a GE LightSpeed multi-slice scanner. Post processing (2-D and 3-D reconstructions of CT data sets) was performed with the GE Advantage Windows workstation. Subsequently, a standard forensic autopsy was carried out. The radiological data were used to answer the forensically important questions such as the cause of death, the traumatological findings, the differentiation of antemortem inflicted injuries from post-mortem trauma, and the reconstruction of the traumatic sequence. Finally, the radiographically obtained results were compared to those obtained from autopsy findings.

Conclusions: In all examined cases, a forensic reconstruction (impact axis reconstruction, the priority of skull fractures, the direction of impact in traffic accidents, etc.) was possible based upon the radiological data obtained. Forensically important findings, such as scalp hematomas, fracture systems, direct and indirect brain injuries and various forms of intracranial hemorrhaging could be clearly detected and diagnosed. Secondary trauma consequences, such as brain edema, increased brain pressure, and secondary brain stem hemorrhaging, were correctly recognized.

A complete collection and documentation of forensic relevant data can be obtained by utilizing imaging processes. MRI and MS-CT are suitable methods for the post-mortem diagnosis and reconstruction of skull and brain injuries. The data obtained objectively in a non-destructive way showed to complement standard autopsy methods in many respects.

Forensic Radiology, Multi-Slice CT, MRI

G34 Use of Magnetic Resonance Microscopy for Evaluation of Retinal Hemorrhage

William R. Oliver, MD*, and Kimberlee Potter, PhD, Armed Forces Institute of Pathology, Washington, DC; J.C. Upshaw Downs, MD, Director, Alabama Department of Forensic Sciences and Chief Medical Examiner, PO Box 3510, Auburn, AL; and David R. Fowler, MB, ChB, Office of the Chief Medical Examiner, State of Maryland, 111 Penn Street, Baltimore, MD

The goal of this research project is to present to the forensic community a novel technology which allows nondestructive three-dimensional assessment of retinal vasculature.

In recent years, magnetic resonance technology has advanced to provide the ability to achieve extremely high-resolution spatial information associated with magnetic resonance spectra. The ability to achieve spatial resolution in the tens of microns through MRI allows the capture of truly 3D anatomic information at near histologic resolution with minimal deformation or registration error. The ability to capture nuclear magnetic spectra at high spatial resolution provides the opportunity to chemically and physiologically characterize those tissues. This has been used to great effect, for instance, in the elucidation of the 3D anatomy in embryos as well as characterization of 3D morphology and relationships in such things as new bone formation and cartilage growth.

The importance of retinal hemorrhage has been of some debate in the evaluation and diagnosis of child abuse. The ability to map perfusion in three dimensions as well as the ability to localize hemorrhage in three-space at high resolution provides the opportunity to map and volumetrically characterize these lesions in known child abuse and non-child abuse cases.

We have created three-dimensional visualizations of whole eyes at between 70 and 100-micron resolution, and are currently bringing on line a coil which will provide approximately 10-micron resolution using

Bruker magnetic resonance microscopes. Non-invasive three-dimensional maps of blood distribution can be achieved on formalin-fixed eyes without serial sectioning. While our current visualizations are striking, there remain nontrivial technical challenges ahead. These include appropriate mounting media. It is extremely important that no water remain on the surface of the globe; we have achieved good results both with embedding the entire eye in paraffin and by placing the eye in fluorocarbon. In both cases, the eye can later be evaluated by conventional means. Another limiting factor is the time necessary to achieve a sufficient signal to noise ratio at high resolution. Current scans require approximately 30 hours per eye. We are currently exploring methods of data reduction using combinations of thicker sections to provide super-resolution at higher speeds. We are beginning work on spectral analysis at high resolution and expect to provide a more certain extraction of hemoglobin distribution.

Visualization challenges include appropriate segmentation and voxel-counting to provide volumetric measurements of hemorrhage. Our current methods are watershed-based, but we expect to transition to the Imagine Toolkit (ITK), a freely-available software toolkit for segmentation and registration currently being developed by the National Institutes of Medicine and the National Library of Medicine Visible Human Project for segmentation of Visible Human tissues. This toolkit is in alpha distribution, but should be in general distribution within a year. We are also exploring the question of validation of volumetric measurements. Standard histologic sectioning can provide a standard whereby localization can be tested, but the choice of a "gold standard" for volumetric measurement of hemorrhage is not obvious.

While we are in the early stage of exploring this technology for this application, the three-dimensional retinal vascular imagery we have gathered provides a measurable visualization not achievable elsewhere. We are currently exploring validation issues, since any volumetric statements about hemorrhage must be matched with more conventional visualization of hemorrhage. This paper will provide a short review of the technology, visualization issues, validation issues, and early results in the three-dimensional characterization of these retinal lesions.

Magnetic Resonance Microscopy, Shaken Baby Syndrome, Retinal Hemorrhage

G35 Phenylpropanolamine and Acute Intracerebral Hemorrhage

Yvonne I. Milewski, MD, Office of Chief Medical Examiner, 520 First Avenue, New York, NY*

The goal of this research project is to assess the status of current scientific research and literature regarding Phenylpropanolamine and the risk of acute intracerebral hemorrhage.

This presentation reviews the case of a young woman who died from complications of two near-simultaneous, acute, bilateral basal ganglia hemorrhages. Complete autopsy examination, including the examination of the brain by a neuropathologist, and full toxicological examination, failed to uncover an etiologically specific risk factor for the intracerebral hemorrhage. The decedent ingested an over-the-counter cold preparation containing Phenylpropanolamine (PPA) minutes prior to the first intracerebral hemorrhage.

The literature on the toxic and fatal effects of PPA is extensive, spanning many decades. It is mostly represented by single case reports, or presentations of a small number of cases. Scientific study on the effects of PPA consists of a small number of animal studies and a few human studies, which have produced provocative but also highly controversial and contradictory results. There is significant variability in the clinical presentation of these patients. The proposed mechanisms by which PPA is said to produce these clinical results cannot consistently be applied to all of the reported cases. Despite this controversy, this presentation proposes that PPA as the cause of unexplained acute intracerebral hemorrhage in the proposed "at risk" population is a valid consideration.

A publication in the *New England Journal of Medicine* in December of last year and a recent FDA voluntary recall of over-the-counter preparations containing PPA have resulted in much media attention via the lay press and the Internet. As a result, the legal community has responded with media-based efforts to assimilate groups of cases of PPA toxicity, including fatalities, for the purposes of civil litigation. As public awareness increases, and because of the near total omnipresence of these over-the-counter preparations in American households, the forensic pathologist will be asked to consider PPA either as a possible cause of death in cases of otherwise unexplained acute intracerebral hemorrhage in the defined "at risk" population, or as a possible contributing factor in persons who are at risk of acute intracerebral hemorrhage from other diseases or conditions.

A familiarity with the current literature and an understanding of the proposed pharmacological actions of Phenylpropanolamine will better prepare the forensic pathologist in the evaluation of individual cases, and also in the preparation of responsible testimony in relevant litigation.

Phenylpropanolamine, Acute Intracerebral Hemorrhage, Spontaneous Intracerebral Hemorrhage

G36 The Use of Lidocaine to Commit Homicide

Brian C. Hunter, BA, MD, Department of Pathology, Sparrow Health System, 1215 East Michigan Avenue, Lansing, MI; John Trestail III, BS, RPh, Regional Poison Center, Grand Rapids, MI; and Stephen D. Cohle, MD, Spectrum Health East Campus, Pathology Department, Grand Rapids, MI*

The goals of this research project are to report the first case of Lidocaine being used to commit homicide outside a hospital setting; to pull known cases of iatrogenic homicidal Lidocaine poisoning into the forensic sciences literature; to review and compare the two groups highlighting similarities and differences; and, to distinguish those situations where an elevated Lidocaine level should trigger a more extensive investigation.

Lidocaine is a drug that is commonly used during the course of resuscitating critically ill patients. It is most effective at treating ventricular tachycardia associated with a myocardial infarct. It is therefore a drug commonly found on the toxicology reports of medical examiner cases. It is so common that one could even say that it has become part of the "normal flora" of drugs found in people who die suddenly and unexpectedly along with Cotinine and Caffeine. It is not uncommon for Lidocaine levels to be elevated, even above the "potentially toxic" level because of the grave situations in which the drug is administered. As a result, medical examiners/forensic pathologists can become desensitized to the dangers of this drug. Above therapeutic levels, it can cause severe cardiovascular and neurologic effects, including immediate asystole, apnea, and convulsions. It lowers seizure thresholds and may increase the risk of bradycardia and asystole. Yet the common assumption about Lidocaine is that if it is found in a patient's blood, it was administered by the careful hand of a physician or paramedic with the goal of saving the patient's life. The cases presented here illustrate that this is not always so. One case illustrates how Lidocaine was used as a tool to commit homicide by a non-professional, while the other three show that when used in the medical setting, it is not always with a therapeutic intent. The former case is the first reported of its kind, while the latter cases have been chronicled in the popular press.

In this paper, the cases of iatrogenic homicide are reviewed, characterizing the perpetrators, the victims, the motives, and the keys to recognizing the deaths as homicides. The majority of the focus however, is on the case involving the homicidal Lidocaine poisoning outside the hospital. Similarities and differences between that case and the hospital-based homicides are highlighted with the goal of raising awareness as to when an elevated Lidocaine level should trigger a more extensive investigation.

The majority of known Lidocaine homicides have been committed by so called “Medical Murderers.” These are health care professionals of one form or another who made Lidocaine their weapon of choice. Robert Diaz was a 46 year old nurse who killed 12 patients (and possibly 50 more) by Lidocaine injection while he worked as a nurse at two California Hospitals. His motive stemmed from his desire to appear to have a “doctor’s” knowledge of how sick patients were and to “predict” when they would die. Joseph Dewey Akin was convicted of killing a quadriplegic patient by injecting him with Lidocaine for the “fun of watching him die.” He committed this crime in Birmingham, Alabama but was suspected to have killed 17 others while working at a hospital in Atlanta, Georgia. And finally, Randy Powers was a 26-year-old respiratory therapist who was never convicted of murder but was convicted of “assault with a deadly weapon” and “practicing medicine without a license.” He gave an eleven-month-old child an intramuscular injection of Lidocaine inducing a high fever and seizure activity. He participated in the resuscitation and was originally thought to be a hero. Physicians, however, identified a needle puncture wound on the child’s thigh and toxicology revealed elevated Lidocaine levels. Powers was suspected to have been involved in many other unexplained deaths. The bodies that were exhumed, however, failed to show needle puncture wounds or elevated Lidocaine levels.

The case of homicidal Lidocaine poisoning outside a hospital was perpetrated by the husband of a 69 year old female with a past medical history most significant for Alzheimer’s Disease, schizophrenia, and macular degeneration. He was her sole caretaker but was also an active volunteer at the Red Cross and at a local Michigan hospital. On the day of her death, he found her lying on her bed around 8:00 a.m. She was unresponsive and this prompted him to notify emergency medical personnel. On arrival, paramedics determined that she had been dead for some time and pronounced her dead at the scene. Police and the medical examiner investigator found the scene secured with no evidence of a struggle. The decedent was found lying supine on her bed and on top of her bedding. Her husband reported that she was in her usual state of health and had no complaints when he put her to bed the prior evening (around 11:00 p.m.). The autopsy confirmed the diagnosis of Alzheimer’s Disease and revealed moderate atherosclerotic cardiovascular disease. There was no evidence of injury or needle marks. EKG leads were the only evidence of therapy. Postmortem urine toxicology revealed Lidocaine, Tocainide, Meperidine, Salicylate, and Caffeine. A postmortem blood drug screen (subclavian blood) revealed Lidocaine 12.4 mcg/ml (potentially toxic >8 mcg/ml) and Salicylate (non-toxic levels). Paramedics confirmed that EKG monitoring was the only resuscitative procedure performed on the decedent. The medical examiner investigator confirmed that there was no evidence at the scene of accidental ingestion of topical anesthetics. Subsequent police investigation revealed that her husband had the opportunity, motive, and ability to administer the IV Lidocaine and may have been involved in previous attempts to kill her. Follow up testing (including DNA analysis) confirmed the presence of Lidocaine and ruled out the possibility of specimen mix-up at the laboratory. Based on this information the cause of death was determined to be Lidocaine poisoning and the manner of death was homicide.

This paper is valuable for multiple reasons. It first pulls cases of homicidal Lidocaine poisoning into the forensic literature. Secondly, it highlights how the deaths of elderly people and the severely ill are often treated casually despite the fact that they are precisely the people most likely to be the victims of homicidal poisoning. It highlights how elevated Lidocaine levels are treated with similar benign neglect. This is clearly illustrated in the comment by one forensic pathologist who was asked to evaluate the toxicology report knowing only that it was a case of an elderly person who died at home. He quickly stated “there is nothing here,” automatically attributing the elevated lidocaine level to “an artifact of resuscitation.” This paper illustrates how the hobby or profession of the assailant/caregiver can give important clues as to the cause of death and to the poison used. And finally, it illustrates how doing a thorough scene

investigation including a detailed medical and social history of the decedent and the family can alert investigators to a situation perfect for homicidal poisoning.

Lidocaine, Homicide, Poisoning

G37 Where Do People Die Suddenly and Unexpectedly?

Istvan F. Szentmariay, MD, Gyorgy Dunay, MD, and Marta Hubay, MD, Institute of Forensic Medicine, Semmelweis University, Ullo Ut 93, Budapest, Hungary*

The goal of this research project is to discuss statistical data and major trends on different places of death of unnatural and unexpected natural death categories along with gender differences.

There is no place like home even when it comes to dying. Home would be an ideal setting, but never possible for all of us. The vast majority of unnatural and unexpected natural deaths occur outside of the deceased’s residence. None can predict the place of death in a sudden lethal event. In the last seven years we have performed nearly 20,000 forensic autopsies in our institution. Using retrospective chart review of this group we analyzed the place of death from many aspects.

We used eight categories to further sub classify the place of death: a person’s own home, someone else’s home, public place, roads, buildings, workplace, ambulance and hospitals. We investigated for age related trends (i.e., only 3.4% of the 16-20 year-old category died in their own home, but almost one third of those over the age of 70 years died at home). We also reviewed our data by investigating manner of death, including natural, homicide, suicide, and accident victims. Our statistical analysis gives data on place of death in major natural and unnatural cause of death categories. We also depict the monthly and the weekday distribution of deaths occurring in different places. Higher work place deaths occur on Monday; higher sudden deaths in buildings on Thursday; high numbers of cases from ambulances on Friday; and, high workplace related deaths in January and October, etc. Further discussion regarding types of cases accepted for forensic autopsy from hospital versus ambulance/home environments will also be highlighted. Very important features of the presentation will be the analysis of gender differences in each of the categories discussed. The high number of cases (nearly 20,000) allowed us to make interesting conclusions on where our forensic cases are coming from.

Place of Death, Home Deaths, Ambulance

G38 The “Holy Crown United” Southern Italian Mafia Organization Homicides

Francesco Introna, MD, Francesco Faggiano, MD, Alberto Tortorella, MD, and Antonio De Donno, MD, University of Bari, Italy, Istituto di Medicina Legale, Policlinico, Bari, Italy*

The goal of this research project is to present to the forensic community the aspects of the homicides perpetrated by “Holy Crown United” (Mafia Organization) in the South of Italy.

The Authors reported all cases of homicides committed from 1986 to the present by the “Holy Crown United” The “Holy Crown United” was a complex and territory infiltrated Mafia Organization operating in the southern part of the Apulia (southern Italian region), well connected with the Albanian Mafia, quite completely routed in 1995-1995. The “Holy Crown United” specialized in burglary, extortions, bank robberies, illicit traffic of drugs and arms, and illegal immigration of boat people. The deep religious significance of the chosen name “Holy Crown United,” the historical origin, the internal organization in eight levels, and the meaning behind the crime rituality are briefly described.

Seventy-five homicides are reported to be victims involved in the illegal activities of the organization, members of the gang who needed to be punished, their family or relatives, and other innocent people.

Cause and manner of death are described. In all cases large calibre firearms were used. Post-mortem treatment of the bodies described the homicides as terrifying. The bodies were usually charred to demonstrate the Organization's strong power and to frighten the remaining population.

All the members of the Organization to be punished were executed; if this proved to be impossible, homicides on their relatives, close friends, family members were performed. Bodies were then hidden by burial on free land, somewhere in Apulia, so no one could cry or have mercy on their graves. All this violence was directed at close relatives or friends of the deviated members to further threaten them so that they would not retaliate on the Organization. All the criminal acts perpetrated by the "Holy Crown United" were performed using a high volume of fire, sometimes including bombs. Those who were killed or who vanished were called "victims of white lupara" (lupara is a shotgun with cut barrels typically used for Mafia crime) The cadaver research modality, the approach and the rescue of these bodies, the personal identification techniques, and autopsy and ballistic results are reported.

In these cases, a body was usually found through information obtained by "pentiti," a "Holy Crown United" member that decided to collaborate with the State Attorney, in order to obtain protection even for his/her relatives and/or a lighter sentence of guilt. In these particular cases, personal identification of the body was extremely important to have proof that all the information given by the informer was correct.

The methods used by the "Holy Crown United" allowing no possibility of finding any cadaver remains are reported. Peculiar cases are described, such as the personal identification obtained by an isolated patella, or the hierarchical position of a victim in the organization resolved by the analysis of a tattoo.

Holy Crown United, Southern Italian Mafia Organization Homicides, Case Report

G39 Homicide Attempt With a Japanese Samurai Sword

Jean-Sebastien Raul, MD, Laurent Berthelon, MD, Annie Geraut, MD, Antoine Tracqui, MD, PhD, and Bertrand Ludes, MD, PhD, Institut de Médecine Légale, 11 Rue Humann, Strasbourg Cedex, France*

The goal of this research project is to explain to participants the importance of examining all the material evidence to show the mechanism of injuries caused by a Japanese sword.

A 30-year-old man was admitted in the emergency unit of the Hospital of Strasbourg with a right 2.5-cm long low thoracic wound caused by a sharp object. After an emergency thoracic and abdominal CT-Scan, consequent bleeding led to rapid laparoscopic surgery showing a penetrating wound located at the right side of the liver. The wound had crossed the right inferior pleural cavity and the diaphragm. A right hemothorax was treated with a drainage tube, whereas the wound of the liver was clotted and thus needed no complementary treatment.

The victim explained that he had been attacked while sitting in his car in the parking area of a shopping center by another man armed with a Japanese sword with whom he had a quarrel a few months earlier. According to this statement, the perpetrator gave a first blow on the windscreen of the car, a second blow on the front right passenger's car window, and finally a third direct blow which hit him on his right side. The assailant was quickly identified and arrested by the police. He gave another version arguing that he had only given two circular blows and that the second blow had unfortunately hit the victim.

The public prosecutor gave us the opportunity to examine the sword and the victim's clothes. The sword was a sharp, 76-cm long, 2 to 3-cm wide Japanese sword as used by samurais, bought by the assailant during a journey in the French Caribbean and sharpened by himself. A sample of

blood was taken for DNA typing. The clothes worn by the victim were an anorak, a sweater and a polo shirt. On each of these pieces of clothing, a 2 to 3-cm long slit could be seen. This gave evidence of penetration by of the sword.

The CT-Scan showed a deep 4-cm long wound of the liver giving another argument for a penetrating wound. Close examination of the sword, the clothes of the victim, the size of the skin injury, and the aspect of the thoracic and abdominal CT-Scan provided sufficient evidence to confirm the victim's statement.

The use of Japanese swords in homicides is rare. A Japanese samurai sword is a sharp, cutting object which may inflict two different kinds of injuries: penetrating or cutting. This paper focuses on the importance of the examination of all the evidence, showing to the Court only one possible mechanism of injury: a penetrating sharp force wound.

Japanese Sword, Homicide, Evidence

G40 Sharp Force Injury Fatalities in New York City

James R. Gill, MD, and Charles Catanese, MD, New York City Office of Chief Medical Examiner and Department of Forensic Medicine, 520 First Avenue, New York, NY*

The goal of this research project is to present participants with an overview of sharp force injury deaths in one year in New York City.

Several studies in the United Kingdom and Sweden have examined large numbers of sharp force injury deaths. Most of these studies involved long time periods for data collection that ranged from 9-45 years in order to examine from 28 to 279 sharp force injury deaths. There have been a few large cohort studies of sharp force injury fatalities in the United States. We reviewed the case records of 120 people who died from sharp force injuries in New York City in a single year, 1999. The epidemiological profile, circumstances, toxicology findings, location, and injuries were examined.

There were 120 deaths: 101 homicides, 17 suicides, and 2 accidents. The causes of death included: 112 due to stab(s) with or without incised wounds and 8 pure incised wound fatalities of which 5 were suicides. No sharp force injury fatality had an undetermined manner of death. In sharp force fatalities, the patterns of injuries and the circumstances often demonstrate the intent of suicide or the hand of another in a homicide, thus allowing the investigator to discern the manner of death.

The locations of injuries may help determine the manner of death. It is extremely rare for a person committing suicide to cut his/her face. Hesitation and defense injuries also are useful in determining manner, as may the clustering of wounds which were seen in twice as many suicides (41%) as homicides (17%). Tight groups of wounds may assist in the investigation and reconstruction of homicides and suicides. In a homicide, grouping of sharp force injuries usually indicates that the decedent was repeatedly stabbed following incapacitation. In a suicide, injuries may be concentrated over accessible vital region(s) and typically are superficial (i.e., hesitation marks). In addition, suicidal incised wounds tend to be parallel or colinear. In a homicide, with continued infliction of injury after incapacitation of the victim, the grouped wounds, typically deep, may not be in an accessible area to the decedent (e.g., the posterior thorax) and are typically deep.

"Defense wounds" were reported in 49% of the homicides and "hesitation" wounds were found in 65% of the suicides. There were no self-inflicted sharp force injuries of the face and no sharp force injury suicides by Hispanics, Asians, or anyone under the age of 18 years. Over half of the suicides at home occurred in the bathroom and 78% of these occurred in the bathtub. A study of suicide by stabbing in the United Kingdom of suicide by stabbing found that the majority of decedents were discovered in the bedroom or kitchen. Suicide notes were found in 24% of the cases, and an additional 24% verbally expressed a plan to commit suicide.

Deaths due to a single stab wound occurred in 34% (34/101) of the homicides and 24% (4/17) of the suicides. Of these 38 deaths, 58% were of the anterior thorax (chest) and 71% injured the heart and/or great vessels. The remaining deaths with single stab wounds involved the femoral artery, abdominal organs, or head. A common question with fatalities from a single stab wound to the anterior trunk is, "Was the decedent intentionally stabbed or did he/she run into the knife?" When considering this issue, it is helpful to consider the overall directions of the stab wound track. It is extremely unlikely for a person to be stabbed by "running into" a knife that is positioned other than perpendicular to the decedent's body.

The age range was 5 to 84 years for homicides (mean of 34) and 18 to 76 for suicides (mean of 49). There were more men than women for both homicides (3.2 to 1) and suicides (2.4 to 1). Hispanic (40%) and Black (44%) decedents made up 84% of the homicides. Among the suicides, 65% were White and 35% were Black. Alcohol and/or illicit drugs were found in both homicides and suicides as in other studies on sharp force injury fatalities. Detection of ethanol and/or illicit drugs constituted 61% in the homicide and 12% in the suicide groups. Among male and female homicide victims, ethanol and/or illicit drugs were detected in 72% and 38%, respectively. More homicides occurred in the warmer months from April to September. The percent of sharp force-related homicides that occurred indoors was similar in the colder (51%) to the warmer months (49%). The percent of homicides that occurred outdoors (typically on the street) was greater in the warmer months (78%) than the colder months (22%).

Forensic Pathology, Sharp, Forensic Science

G41 No Homicide on Christmas Eve !? — Case Report of an Unusual Stab Wound of the Brain

Martin Bauer, MD*, and Dieter Patzelt, MD, Institute of Legal Medicine, University of Wuerzburg, Versbacher Str. 3, Wuerzburg, Germany

The goals of this research project are to learn about the clinical and autopsy findings of stab wounds of the brain with particular emphasis on an unusual case, which was initially misdiagnosed as cerebral contusion and led to false conclusions concerning the manner of death.

A Russian immigrant was celebrating Christmas in his apartment with his wife and a friend. One or two bottles of vodka were also present. After a while the men began to argue and the tenant wanted his mate to leave. The argument turned into a fight on the stairs. Eventually the mate was laying unconscious on the stairs, a knife in his hand and bleeding from several chest and skull wounds. The wife of the tenant who had only some minor cuts called the emergency doctor. The victim was admitted to nearby Wuerzburg University Hospital by helicopter and immediately underwent diagnostic CT and surgery. At this point he was first seen by the 24-hour forensic service provided by the Wuerzburg Institute of Legal Medicine. According to the clinical findings, diagnoses were stab wounds of the chest and abdomen, with penetration of several ribs, and cerebral contusion, with beginning cerebral swelling.

The victim was said to be eccentric and alcohol-dependent in contrast to the presumed assailant who was a well-integrated employee with intact family and personally known by one of the police investigators. Obviously, nobody wanted to have a "case" on Christmas Eve. This may explain why the police initially believed that the victim's injuries were self-inflicted. During examination of the knife found in the victim's hand by the forensic pathologist, however, it became clear that the blade was not thick and pointed enough to penetrate bone or cartilage which meant that the weapon involved was unknown.

After the emergency treatment of the victim, his condition deteriorated due to further elevation of intracranial pressure and his death came

within the next days. Since the brain injury had to be considered as future cause of death, the police insisted on the possibility that a fall on the sharp-edged stair could have caused the brain injury. The case then would have been qualified as bodily harm or as accident and not as homicide, and there would have been no need to intensify the search for a murder weapon during Christmas. The forensic pathologist in charge agreed eventually to this interpretation although the wound margins seemed to be rather sharp and regular. But, due to the therapeutic intervention no closer examination of the wound could be performed. The assailant remained under arrest, the intensive care unit personnel worked at their best and everybody had a nice Christmas.

As expected the victim died two days after Christmas. The autopsy revealed that the brain injury was clearly caused by a stab wound of the left temporal region. In the following days, the police presented every knife they found in and around the apartment of the assailant, where his wife and children still lived. Due to the lapse of time since the day of the fight there would have been enough occasions for the tenant before his arrest, or for his wife, who must have witnessed the fight but who refused any statement, to walk off with the knife. However, about ten days later one knife found in the apartment met all the requirements to be considered as the murder weapon. Moreover, despite several dishwasher cleanings, DNA from the deceased could be found on the blade by STR analysis. The retrospective examination of the CT scans revealed findings consistent with an intracranial stab wound and not typical for contusions due to blunt injury or fall.

This case is presented for several reasons:

1. Cranial stab wounds are rare events and present problems in clinical and forensic differential diagnosis as long as the patient is alive. They allow for exact requirements for the presumed weapon involved. This will be illustrated by our case and by a short literature review.

2. Forensic investigation under the influence of external factors like holidays or personal relationships may exert subtle pressure on the forensic pathologist which may be difficult to resist. Although this case could be worked up completely despite the delay in considering the case as homicide, the forensic scientist never should rely on clinical information and should never agree to any statement he is not totally convinced of. All clinically available information including CT scans should be personally reviewed by a forensic specialist who is familiar with radiography of brain injuries or by a radiologist who has forensic casework experience.

Stab Wounds of the Brain, Homicide, Clinical Diagnosis

G42 Accidental Hanging Death of a 10-Year-Old Boy From a Lanyard Key Chain

J. Scott Denton, MD, Cook County Medical Examiner's Office, 2121 West Harrison Street, Chicago, IL

The goal of this research project is to recognize the dangers of lanyard key chains around the neck and the importance of a thorough death scene investigation, especially when hanging deaths of children are at issue.

Any item around the neck can be dangerous, especially if the item hangs loosely and can become entangled in moving machinery or caught on a fixed object. The popularity of lanyard key chains has exploded in recent years. They are used to hold keys or identification badges at home, school, and work. The lanyards are made of strong woven cloth or nylon material, made to hang around the neck to the mid-chest with a plastic or metal clasp at one end to hold keys or badges securely. The lanyard chains are also commonly imprinted with advertising or promotional slogans or logos. The danger is that these lanyard chains are extremely strong and do not break or separate if they become entangled.

Case Report: A 10-year-old Black male child was found in his mother's bedroom hanging and suspended by a lanyard key chain around his neck from an elevated metal bedpost of a four-poster bed. He was

found by his mother when she returned home from work early in the evening. He had been home alone during the day while she worked, and was not at school due to a one-day suspension for a note-writing incident. His mother lowered him from the bed post, laid him on the bed, and called police. Resuscitation was unsuccessful and his body was brought to the Medical Examiner's Office as a presumed self-inflicted event.

Examination showed a well-developed and well-nourished 10-year-old child with a sharply backwards- and upwards-slanting abraded ligature impression mark consistent with the lanyard found around his neck and accompanying the body. His neck additionally showed marked hypermobility, and internally showed dislocation of the first and second cervical vertebral bodies with posterior neck muscle hemorrhage, consistent with an abrupt drop-type hanging.

Scene investigation, reconstruction and interviews were conducted to determine the nature and circumstances of the hanging. The boy commonly wore the lanyard chain outside his clothing to hold his house key so that he could let himself into the home after school. His mother stated that he was often reprimanded for jumping up and down on her bed and swinging from the crossbars that connected the four raised bedposts. This swinging had caused the crossbars to bend downward, which was noted by investigators. The metal bedposts were of sufficient strength and configuration to support his weight and to catch the lanyard while he was jumping up and down. The lanyard itself, which had no safety release clasp, could easily support his weight without breaking. It was concluded that there was no evidence of an intentional hanging. With the autopsy and scene investigation findings, the death was ruled an accidental hanging. Medline review reveals no similar incidents involving lanyard key chains.

Methods are available to prevent accidental hangings by lanyards. A simple do-it-yourself method involves cutting the lanyard chain in the back to form two ends, and affixing commercially available adhesive Velcro to refasten the ends. This prevents the lanyard from supporting body weight or withstanding enough force to cause injury, but still allows it to hold keys and badges securely. Another method requires that the manufacturer use a "break-away" fastener where the two lanyard cloth ends meet at the clip in the front. The use of lanyard key chains has markedly increased, and as with any item around the neck, there is a danger in its use. Fortunately, means are available to prevent this type of injury from recurring while still preserving the lanyard's useful function, especially for children.

Lanyard Key Chain, Hanging, Children

G43 Sudden Death in Baseball: A Case Report and Review of Literature

Abraham T. Philip, MD, Alexander M. Chirkov, MD, and Richard J. Evans, MD, Office of the Chief Medical Examiner, 720 Albany Street, Boston, MA*

The goals of this research project are: (1) to document a cause of sudden death on the baseball arena; and (2) to review the currently available literature about the causes, patterns, and consequences of baseball fatalities.

Sports, as they say, is big business. Death in such a setting, in and around the sporting arena, attracts much public attention and media coverage. We have, after all, come a long way from the era of the gladiators and the days of blood, gore and death as spectacular spectator sports. Thus, it is not surprising that deaths occurring due to stampedes secondary to stadium collapses or mayhem perpetuated by soccer hooligans make banner headlines around the world. Deaths of participants in sporting events also generate widespread media coverage, public outcry, and political pontification. Such deaths are no surprise when they occur as a consequence of illicit or prescription drug abuse. Moreover, we are psychologically prone to think of sudden deaths due to fatal impact injuries as more likely to occur in contact sports like boxing, football or

hockey than in non-contact sports like baseball. Most catastrophes leading to sudden and unexpected death of young athletes in non-contact sports are often the consequence of unsuspected congenital or acquired cardiovascular disease. A less well-recognized cause of sports related sudden death on the baseball, cricket, hockey or lacrosse fields is "Commotio Cordis." We present here a case report of a sudden death due to fatal impact occurring on a baseball field.

The case report is that of an 18-year-old male who was playing baseball. He was chasing a ball hit to the outfield, when he collided with a fellow player. As no video or photographic records of the fatal event was available, it could not be verified whether the shoulder, arm, elbow or the knee of the fellow player made contact with the neck of the victim. The victim was observed to collapse and become cyanotic soon afterwards. The emergency medical services responding to the scene were unable to intubate him and so transported him to the nearest available hospital. An emergency tracheotomy was performed which revealed significant hemorrhage within the trachea. An emergency thoracotomy was subsequently performed. Despite the several therapeutic maneuvers, the victim succumbed to his injuries. At autopsy, fractures of the cricoid and thyroid cartilages were present. Aspirated blood was present within all major bronchi and extending into the bronchioles.

It is estimated that more than 19 million children are involved in youth baseball in the United States. A Consumer Product Safety Commission Report stated that in the 5 to 14 year-old age group, more fatalities and injuries necessitating emergency room visits occurred in baseball and softball compared to any other sport. There were 88 deaths related to baseball in the 5-14 year age group between 1973 and 1995, of these deaths, 68 were caused by impacts with the ball, 13 were caused by impacts with the bat, and 7 were from another cause or were of unknown cause. These data translate into one death in youth baseball for every 4.75 million participants. The case report that we present is thus a documentation of a very unusual and really freakish accident. In our search of the literature, we failed to find a similar case of sudden death during a baseball game.

Blunt Neck Trauma, Sudden Death, Baseball

G44 Post Collision Vehicular Fires—Determination of Probability of Occupant Survival Post Impact

Joseph L. Burton, MD and Paul R. Lewis, Jr., MS, BME, Burton & Associates, 13784 Highway 9, Alpharetta, GA*

The goals of this research project are to present the forensic community with an explanation of the analysis necessary to determine the survivability of a post collision vehicular fire. This analysis can also be used in the determination of death in other cases in which fire may mask the injuries and death.

This paper will discuss the problems of determining the survival of an occupant involved in an automotive crash that subsequently involves a post collision fire. This will provide some insight into the primary questions involved in this type of incident. Did the occupant survive the collision? Did the occupant sustain injuries that, even though the fire and/or its consequences may have played a role in the death, prove he/she would have died from the collision injuries regardless?

To make this determination, one of the first steps in the analysis is to consider the collision dynamics of the incident. The first parameter, and probably the most important, is the Delta V or crash severity of the incident. As important as the Delta V are the direction of the impact to the vehicle, and a rollover, if one has occurred, how many rolls and at what speed the rollover began. The next parameter is the pulse or duration of the crash and also whether or not there are airbags in the vehicle and if these devices deployed during the incident.

After the investigator has an understanding of the collision dynamics, he must analyze the next piece of the puzzle, the injury pattern. This includes determination of all the injuries sustained in both the collision and due to the post collision fire. Within this portion of the analysis, consideration has to be given to the method of removal of the bodies from the vehicle as well as the mode of transport to the forensic science laboratory. During this examination a determination of true traumatic injuries versus fire related injuries should be separated out. Of additional importance, an attempt to determine whether or not restraints were in use may be possible based on types of injuries present, absence of injuries, and information from vehicle inspection.

A toxicological analysis should be performed to determine the carboxyhemoglobin levels of the victims. Due care has to be taken in the use of the values in the overall determination of the cause of death. This requires further investigation into what types of materials were contained within the fire environment, what type of air exposure, and whether the decedent(s) were smokers.

To complete the piecing together of this complex puzzle, consideration of witness accounts to the incident have to be evaluated. These persons can provide testimony as to the intensity of the fire, movements of any of the bodies within the fire, sounds and other noises heard from the fire during its progression.

The determination of post collision survival and whether death has occurred as the consequence of a vehicle fire is a complex issue. In some cases post mortem examination and autopsy may stand alone in answering this question. In many cases, however, even with a post mortem and autopsy, the additional information accumulated in the investigation is extremely important and necessary in making such a determination.

There may be cases in which without an autopsy there is enough accumulated information from other sources to determine that there is a reasonable probability that the person survived the crash, and that fire, within a reasonable degree of forensic, medical and scientific probability caused the death of the individual.

Fire can mask many types of death including homicides, suicides and natural deaths. It is only the work of a skilled and trained investigator that the answers from the dead in such a case can be heard.

Fire Death, Carboxyhemoglobin, Vehicle Fire

G45 Decapitation by Motorized Shoulder Harness: A Case Report

Thomas W. Young, MD*, C. Chase Blanchard, MD, and Ronald E. Brasfield, Office of the Jackson County Medical Examiner, 660 East 24th Street, Kansas City, MO

The goal of this research project is to present an unusual traffic fatality associated with a motorized shoulder harness, and to inform the audience how a shoulder harness without a lap belt can cause serious and fatal injury.

Deaths associated with motorized shoulder harnesses have been the subject of recent litigation. Automobiles with motorized shoulder harnesses automatically draw the harness against the occupant when the ignition is turned on. This "passive" restraint may give the occupant of the vehicle a sense of security, allowing him or her to think he or she would be safe in a frontal collision. In truth, the occupant is at serious risk for injury unless the lap belt is fastened. Failure to use a lap belt results in injuries from "submarining" — the harness restrains the movement of the lower body forward during a frontal collision while the upper body. Serious and fatal thoracic and neck injuries can occur from submarining. Also, the shoulder harness without the lap belt does not prevent occupant ejection. The following case illustrates an unusual and fatal injury pattern resulting from the use of a motorized shoulder harness alone: decapitation.

While driving a two-door sedan and traveling at about 80 miles per hour on an interstate highway, a 58-year-old female collided with two

slower cars prior to leaving the road at a high rate of speed. As her vehicle rotated counter clockwise, it became airborne after leaving the shoulder of the road. The left rear of the car forcefully struck the ground, and the driver was ejected to the left and rearward through the opened driver side door. Her headless body and decapitated head were found 100 feet from each other.

Autopsy disclosed the level of decapitation to be at the base of her neck, level with her shoulders. About 2 inches of cervical spine and attached hemorrhagic soft tissue protruded from the margin of decapitation. Brush abrasions lay in the skin of the upper chest and over the right clavicle, and contusions involved the tissues inferior to the right clavicle and in the right upper anterior chest. The cervical spine disclosed a ragged fracture-transection between cervical vertebrae three and four. Additional injuries included a frontal deep scalp contusion, light subarachnoid hemorrhage throughout the cerebrum and cerebellum, and fractures of the anterolateral aspects of right ribs one, three, four, five, six and seven. Other head, trunk or extremity injuries were slight to absent. Toxicologic evaluation of blood from femoral vessels and urine disclosed no evidence of ethanol or drugs.

Examination of the vehicle disclosed damage mostly to the front and left rear portions of the vehicle. The driver side door was deformed in an open position. In spite of the frontal damage, there was minimal to no intrusion into the front occupant compartment. There was no evidence of damage to the steering wheel or dash and no evidence of body impact against the front windshield. The shoulder harness was in the fully engaged position, and the receptacle was bent to the left toward the opened driver-side door. Blood and tissue stained the shoulder harness from 4 to 9 inches from the receptacle. There was no evidence of lap belt use at the scene of the accident.

During her ejection through the driver-side door at a high rate of speed, the fabric of the shoulder harness decapitated the victim. Failure to use a lap belt with the shoulder harness allowed her neck to be severed by the harness as her body ejected from the vehicle.

Traffic Fatality, Motorized Shoulder Harness, Decapitation

G46 The Memorials at the Lockerbie and Ermenonville Forest Air Disaster Sites

Gordon K. Murphy, MD, 814 Hathaway Road, Dayton, OH*

The goals of this research project are to 1) earn that mass disasters involving aircraft evoke swells of both communal anger and grief. These evolve into the need to keep alive the memory of both the event and the victims by erecting memorials; and 2) recognize that the forensic scientist may benefit personally and professionally by seeking out and viewing these memorials.

Visiting and viewing memorials brings forcibly and poignantly to the forensic scientist both the reality and the finality of the disasters which they commemorate. This may be true in particular when the scientist has previously read extensively about the disasters and has seen images of them in the media.

A memorial, for instance, a monument or a holiday, serves to keep alive the memory of a person or an event. It serves as an historical record, and may recognize and give permanence to valiant lives or deeds. A memorial may also keep alive the memory of a tragedy, serving as a site for gathering, mourning, and remembering.

Thus, memorials have been erected to commemorate sites of forensic interest, primarily mass disasters, both natural and man-made. Of these, and particularly in the second half of the 20th century, a number commemorate aircraft crashes in which there was great loss of life; i.e., aircraft disasters.

A recent visit to Europe enabled the author to visit two such memorials: the first, that to the destruction by sabotage, and the subsequent crash of Pan Am Flight 103 in Lockerbie, Scotland on December 21, 1988; the

second was that to the crash of Turkish Airlines Flight 981, in the Ermenonville Forest northeast of Paris, France on March 3, 1974, following the loss of a rear cargo door which irretrievably damaged the plane's controls.

Motives for the visits included adding to knowledge of these disasters gained through reading and the media, coming to terms with emotions brought about by this research, and recording images to be used in teaching.

Lockerbie: The small town of Lockerbie is in southwest Scotland, just north of the border of the English county of Cumbria. Portions of the aircraft and the passengers fell both into the town and onto surrounding countryside.

The Garden of Remembrance is located at the edge of the town. Rolling fields and hills are all about. High-flying airliners, some flying transatlantic routes similar to that set out on by Pan Am 103, are seen and heard directly overhead. A large, central memorial of tablets bearing the names of all of the victims is flanked by individual tablets to passengers and crew. There are attractive flowers and plantings. Several miles in the opposite direction, in hills and fields above the town, is the small Tundergarth parish church. Nearby, the cockpit and anterior cabin of the 747 "Maid of the Seas" fell into a field; images of this wreckage have been published throughout the world. In the churchyard was erected a small cabin, the Tundergarth Memorial Room, which contains a large book in which there are text and images of the passengers and crew, and floral arrangements.

Ermelonville Forest: This dense virgin forest contains a number of structures of historic interest, and is a popular recreational site for both Parisians and other visitors. The crash occurred deep in the forest, and the memorial is accessible only by graveled footpaths through the forest. This is a soaring memorial of dark grey Cornish stone, adjacent to which is a tablet bearing a commemorative poem. Most unexpected, and most riveting, is the finding of numerous small, usually charred fragments of the crashed DC-10 previously retrieved from the surrounding forest and laid upon the edges of the monument. Other such artifacts still lie in surrounding vegetation. Opposite the memorial are low stone tablets bearing the names of passengers and crew. Aircraft taking off from Paris Charles de Gaulle Airport are seen and heard just south of the Forest.

Conclusions: Visiting and viewing public memorials to aircraft disasters give visible evidence of the strong communal feelings of both grief and the celebration of individuals' lives engendered in the survivors following such disasters. It also makes much more immediate and memorable to the forensic scientist, who has previously heard and read of a disaster, the locale and immediate surroundings of the same, the magnitude of loss of life, and the conflicting emotions which were, and always will be, so strong within the survivors. Even more poignant are the continual commercial air traffic above and near the memorial sites and the finding of artifacts at one.

Aircraft Accident, Forensic Sciences, Memorial

G47 Experiences Following the Crash of Singapore Airlines SQ006 Boeing 747-400 in Taipei

Kai-Ping Shaw, PhD*, John M. Fong, ME, John Wang, ME, Ching Hu, ME, Ming-Houng Chen, ME, Chiang-Shin Liu, ME, Tse-Hua Lo, ME, and Chia-Tung Shung, Ministry of Justice Investigation Bureau; and Chang-En Pu, MS, Institute of Forensic Medicine, Ministry of Justice, Taipei, Taiwan

The goals of this presentation are to address the events following the aviation disaster of Singapore Airlines SQ-006 and to detail the standard operation procedures used during this experience.

On October 31, 2000, at approximately 23:17 Taiwan time (15:17 UTC), Singapore Airline Flight SQ-006, with Singapore registration 9V-SPK, Boeing 747-400 aircraft, entered the runway under construction

at Chiang-Kai-Shek (CKS) Airport, Taiwan. Heavy thunderstorm and strong wind from typhoon "Xiang Sane" arrived at the time of this aviation accident. Before taking off, the airplane cracked when it collided with the runway construction equipment and the impact produced a fire. There were a total of 179 people on board: 159 passengers, 3 flight crew members, and 17 cabin attendants. Official reports show that 83 people died (including 4 cabin crewmembers) and 44 people were injured. The accident of Singapore Airline SQ-006 at CKS International Airport resulted in the instant deaths of 79 persons from 19 different countries. 77 bodies were rescued from the scene immediately after the fire was extinguished; two of 79 bodies were found under the cracked aircraft about 43 hours after incident.

Although many of the bodies were identifiable, the prosecutor's office of Tau-Yuan District Court (40 km to the south of metropolitan Taipei) decided to request the DNA typing method to confirm identity of each body; in addition, odontological and anthropological identification that included one X-ray mobile van was also requested. Immediately after this accident, the Criminal Investigation Bureau, Ministry of Interior and medical examiners of IFM were asked 1) to collect the samples, mostly consisting of muscle tissue from deceaseds' bodies; 2) to label carefully the evidence; and 3) to follow independently the chain-of-the-custody. STR profiling system was applied and MJIB and IFM were assigned to collect the family members' blood samples. STR profiling types were processed for further paternity matching. In order to increase the efficiency of DNA typing, the forensic scientists of molecular biology were organized into a blood collector group, a DNA extraction group, a STR typing group, and STR matching work stations as a DNA typing and identifying mass production chain. The CODIS 13 STRs were applied to fulfill the DNA data interchange. The first group of families arrived on the next day at 8:30 a.m., about 9 hours after the crash; their blood samples were drawn for DNA typing to establish genetic relationship to the decedents. 20 hours after the crash, the first group of 12 bodies was identified including anthropological and odontological examination and DNA confirmation.

After five days of mass production operation in the DNA laboratory, 80 bodies matching their relatives from 19 different countries were identified including one rescued survivor who died about 24 hours after incident. Another two decedents died in the hospital; these two were identified by next-of-kin. One of the 80 decedents was identified by STR direct matching (STR typing result and blood sample sent from Singapore) from a previous blood sample left in the blood bank of Singapore. An exceptional case involved one decedent who was identified after the CODIS 13 data of decedent's family member sent from India. 15 of 65 decedents were identified by sibship profiles with collateral consanguinity and paternity test with linear consanguinity, respectively.

Forensic DNA matching correlated with odontological and anthropological examination is a very accurate and efficient tool used to identify badly injured bodies. Established professional guidelines as standard operation procedures of DNA typing and body identification played a crucial role in coping effectively with mass disaster of Singapore Airlines SQ-006 Air crashed Accident.

G48 Mortality Estimate for the 1994 Northridge Earthquake

Christopher A. Rogers, MD*, and Lakshmanan Sathyavagiswaran, MD, Department of Coroner, 1104 North Mission Road, Los Angeles, CA

The goals of this research project are to present sources of error in the Medical Examiner's report of mortality from a widespread disaster.

On January 17, 1994, a large earthquake occurred in a suburb of Los Angeles, causing widespread damage. The Los Angeles County Department of Coroner received a large number of requests from the

media for the number of earthquake-related deaths. There were also several requests for identity of the victims, both from the media and for purposes of compensating the families.

The official death toll of 57 was based on the following case definition: "A death is considered earthquake-related if it occurred on the day of the earthquake, and it was a direct result of trauma (such as structural collapse) or if it resulted from a stress-related illness." The official death toll underestimates the actual death toll because it does not include the following:

1. Deaths from atherosclerotic disease that were not reported to the Coroner. Deaths from atherosclerotic cardiovascular disease increased on the day of the earthquake, but then decreased for several days afterwards.
2. Deaths occurring in other counties.
3. Delayed deaths, including deaths from aftershocks and suicide.
4. Deaths from an earthquake-related epidemic of Coccidioidomycosis.

Based on analysis of excess mortality on the date of the earthquake, the actual death toll was approximately twice the official death toll.

Mortality statistics from a widespread disaster have sources of variation not present in a confined disaster. These include the region surveyed, the time interval examined, and the causes of death considered. In this situation, it may be impossible to give an accurate death toll, or to determine the identity of many of the victims.

Earthquake, Mortality Statistics, Northridge

G49 Death in the Desert: Multiple Fatalities as a Consequence of Environmental Exposure

Bruce O. Parks, MD, Eric D. Peters, MD, Cynthia M. Porterfield, DO, Diane Karluk, MD, Walter H. Birkby, PhD, and Bruce E. Anderson, PhD, Office of the Medical Examiner, Forensic Science Center, 2825 East District Street, Tucson, AZ*

The goal of this research project is to further illustrate the multidisciplinary nature of death investigation, especially as this pertains to multiple deaths and resource management within a medical examiner's office.

In May of 2001, the Office of the Medical Examiner, Pima County, Arizona, was requested by the Yuma County Medical Examiner to provide assistance in the investigation of the deaths of fourteen people who had been found in a remote area of the Sonoran Desert near Yuma, Arizona. Explicit in this request was the need for the determination of cause of death for each of the fourteen individuals—all of whom were presumed to be Mexican Nationals—as multiple charges of homicide were to be filed against the person or persons responsible for leaving these unfortunate people in such a desolate landscape. Both the Yuma County Sheriff's Department and the Pima County Sheriff's Department, as well as the FBI, assumed a role in the investigation because at the time of the postmortem examinations it was uncertain whether these cases would be prosecuted by state or federal officials. Serving as a much-needed liaison between the medical examiner's office and relatives of the victims was the Mexican Consulate in Tucson. This assistance was invaluable because the majority of the decedents were not identified when they were received into our office. The receiving of fourteen individuals en masse—in addition to the regular daily caseload—into a medical examiner's office can create problems, as well as additional stress, but these problems and stresses can be managed by mobilizing the appropriate resources.

The immediate resources tapped were the employees of the office of the medical examiner. To the credit of these dedicated personnel, workdays were lengthened, days off were postponed, and vacations were delayed without complaint. Teams were organized so that the examinations of the usual daily caseload could be conducted while the examination of the fourteen related deaths could be performed with continuity. The

office was a beehive of activity for a few days, with all of the medical examiner employees working along side representatives of the sheriff's office, the FBI, and the Mexican Consulate. Because this multiple-death event offered the unique opportunity to gain experience in managing a future mass-disaster, our office implemented another resource: mobile refrigerated storage space. To this end, a local beverage distributor donated—and delivered to our door—a refrigerated trailer. Although it was not necessary to utilize this storage space in this instance, logistical experience was gained that will be beneficial if the need ever arises.

After the post mortem examinations were completed, it was revealed that each of the fourteen individuals died as a result of exposure to an arid, desert environment. To date, thirteen have been identified by a variety of techniques and repatriated (with the assistance of the Mexican Consulate) to Mexico. Efforts to identify the final individual continue. Through the utilization of the various resources available to the medical examiner, successful resolution of a multiple death event was accomplished.

Multiple Deaths, Multidisciplinary Investigation, Resource Management

G50 The Role of the Forensic Anthropologist in Determining the Manner of Death in Suicidal Shotgun Wound to the Back of the Head

Brian C. Hunter, MD, Department of Pathology Sparrow Health System, 1215 Michigan Avenue, Lansing, MI; Norman J. Sauer, PhD, and Todd W. Fenton, PhD, Department of Anthropology, Michigan State University, East Lansing, MI; Joyce L. de Jong, DO, Department of Pathology, Forensic Pathology Division, Sparrow Health System, 1215 Michigan Avenue, Lansing, MI; and Michael G. Koot, BA, Department of Anthropology, Michigan State University, East Lansing, MI*

The goals of this research project are: (1) to present a case of suicidal shotgun wound to the back of the head, (2) to outline the methods employed in the reconstruction of the fragmented skull to understand the bullet trajectory, and (3) to discuss how this reconstruction was crucial in supporting the alleged manner of death.

The value of the forensic anthropologist in assessing trauma to and identification of skeletonized remains is clearly understood and is widely accepted in both the forensic anthropology and forensic pathology communities. Assessing such trauma in completely fleshed remains, however, is not as clearly defined or as well recognized. What is clear is that there are cases of significant skeletal trauma in fleshed remains where cause and/or manner of death are in question. In these cases the services of forensic anthropologists can also be invaluable because of their ability to reconstruct fragmented bones, to recognize injury patterns, and to determine possible weapons used to inflict the trauma. This paper discusses a case of complex cranial trauma in a fully fleshed body and illustrates how forensic anthropology can assist in determining the cause and manner of death.

The case involved a 33-year-old male who reportedly shot himself with a 12-gauge shotgun loaded with deer slug ammunition in a successful suicide attempt. The decedent had a history of depression and multiple ongoing social stressors including an impending divorce, the recent loss of a job, and impending foreclosure on his house. He had been arguing off and on with his live-in girlfriend on the day of his death. During their final altercation he verbally threatened to commit suicide and retrieved a gun from another room in the house. His girlfriend reported that he placed it near his right ear at an upward angle and pulled the trigger. The gun did not fire and she turned to leave the room. As she walked away, she heard the gunfire and turned to find him on the floor, surrounded by blood. Paramedics were called and pronounced him dead at the scene. Police

responded and “determined” that it was a suicidal gunshot of the head but could not determine the entrance site. The county medical examiner did not order an autopsy and the body was released to the funeral home. During the embalming process, the funeral director noticed that the entrance wound was at the rear of the skull and questioned the likelihood of the presumed scenario (i.e., a self-inflicted shotgun wound to the rear of the head). Upon receiving this information, the medical examiner ordered an autopsy on the embalmed body. Autopsy revealed a massively distorted head with shattering of the cranial vault and virtually complete evacuation of the endocranial space. An entrance site was identified on the right side of the occipital squamous, approximately two inches posterior to the right ear and soot was identified on the inner and outer tables of the adjacent bone. Because numerous skull fragments were missing or dislodged, it was impossible to identify the exit site(s) or to determine the trajectory of the projectile. The question posed at autopsy was this: could this really be a suicidal shotgun wound to the back of the head or is this a homicide being disguised as a suicide? There was evidence to support the hypothesis that it is physically possible to commit suicide in this fashion if the slug took a tangential course through the skull. Therefore, the determination of the path of the bullet was considered critical.

The complexity of the cranial injuries and the gravity of the questions raised warranted the involvement of the forensic anthropologists from Michigan State University. At the time of the autopsy, it was the anthropologists’ opinion that a proper determination of the exit wound and therefore the bullet trajectory required the removal of the head and ultimately the examination of the relevant skeletal material devoid of flesh. The head was defleshed and reconstructed at the Michigan State University Forensic Anthropology Laboratory. This process resulted in the identification of a minimum of three exit sites (i.e., the slug had fragmented) in the right parietal area, posterior to and to the right of bregma, and allowed for the reconstruction of the most likely trajectory. From the reconstructed cranium, it was apparent that the bullet entered the skull from the right side of the occiput, fragmented and that the fragments took a steeply vertical path along the right side of the head. The determination of the wound path made it possible to conclude that the death was consistent with a self-inflicted gunshot wound to the back of the head and these findings were consistent with the girlfriend’s account.

Examination of Fleshed Human Remains, Suicide, Anthropology

G51 Sudden Death Due to Myocardial Infarct Associated With Systemic Lupus Erythematosus: Two Case Reports and a Review of the Literature

Joyce L. de Jong, DO, and Brian C. Hunter, MD, Sparrow Health System - Forensic Division, 1215 East Michigan Avenue, Lansing, MI*

The goal of this research project is to understand the etiology of myocardial infarcts associated with systemic lupus erythematosus.

The authors present two cases of sudden death due to myocardial infarcts (MIs) associated with systemic lupus erythematosus (SLE) and discuss the etiologies for MIs associated with SLE.

The two patients, one a 29-year-old white female and the other a 25-years-old white female, had known diagnoses of SLE. Both collapsed at home, one with no acute complaints and the other, who was 22-weeks pregnant, had complained of bilateral arm pain for two days prior to her death. At autopsy of the 29-year-old woman we found multiple aneurysms of the right coronary artery caused by arteritis. One of the coronary artery aneurysms was thrombosed and the inferior wall of the left ventricle had an AMI. The second case showed occlusion of the left anterior descending coronary artery by atherosclerosis and thrombus with an associated anterior and lateral wall AMI.

AMI is a recognized fatal complication of SLE. Reported mechanisms include atherosclerosis, arteritis, coronary artery aneurysms, intracoronary thrombi without significant coronary artery disease, coronary embolus from verrucous endocarditis, and coronary ectasia. In general, older age at diagnosis, longer time since diagnosis, longer duration of corticosteroid use, hypercholesterolemia, and postmenopausal status are more common in women with lupus who suffer cardiovascular events.

Patients with SLE often have accelerated atherosclerosis. An autopsy study of 21 women between the ages of 16 and 37 with SLE showed >75% narrowing by atherosclerosis of one or more coronary arteries in 10 of the women.

The accelerated atherosclerosis seen in lupus may be due to hypertension, chronic corticosteroid use, and hyperlipidemia.

Although uncommon, coronary arteritis associated with SLE and resulting in MI, is well documented. In addition to the case presented here, several other cases of coronary artery aneurysms and MI in patients with SLE have been reported. The uncommon vasculitis of major coronary arteries and the vasculitis of small coronary artery branches are not usually seen in drug-induced lupus-like syndromes.

Patients as young as 8-years old are reported to have suffered MIs due to intracoronary thrombi without significant coronary artery disease in SLE. The presence of antiphospholipid antibodies (such as the lupus anti-coagulant) has been associated with such thrombotic events in SLE. In one reported case, thromboses of small intramural arteries of the heart were associated with a thrombus in a coronary artery.

Conclusion: AMI is a well-described complication of SLE. Accelerated atherosclerosis is the most common risk factor for an AMI in patients with SLE, but a number of other mechanisms may result in the vascular stenosis responsible for the infarct.

Systemic Lupus Erythematosus, Myocardial Infarct, Sudden Death

G52 Unexpected Multicystic Encephalopathy After Accidental Intoxication by a Corrosive Agent: Case Report

Giancarlo Di Vella, MD, PhD, Maura Belviso, MD, Sazione di Medicina Legale, DIMIMP, University of Bari, Italy; Gabriella Serio, MD, PhD, Giuseppe Parisi, MD, Roberto De Blasi, MD, Unità Operativa di Neuroradiologia, University of Bari Italy, Policlinico, piazza G. Cesare, Bari, Italy*

The goal of this research project is to illustrate an unusual neuropathological autopsy finding and to discuss the probable etiology, using text and photographs.

Multicystic encephalomalacia is an extremely dramatic disease usually presenting in the immature fetus. The lesions typically occur in the white matter, because of this region’s putative higher metabolic activity and, therefore, high vulnerability to anoxia related to active myelinization. The cysts may vary greatly in size and be distributed throughout the cerebral cortex bilaterally. A few, rare studies have reported cerebral encephalomalacia in adult life in patients following toxic intoxication or after gastrointestinal surgery. We report an unusual case of multicystic encephalomalacia observed in a 55-year-old man with a history of alcohol intake, who had undergone partial gastrectomy after caustic ingestion. In March 1998, the patient accidentally ingested caustic liquid (Sumazon – containing sodium hydroxide, sodium hypochlorite and phosphates) used for dish washing. On his arrival in hospital, a stomach pump was administered and appropriate pharmacological treatment was started. Esophago-gastro-duodenoscopy (EGDS) performed two days later showed acute esophagitis and gastritis due to caustic ingestion, with multiple irregular ulcers especially in the antro-pyloric region. On discharge, the control EGDS demonstrated diffuse gastric scarring. In April, the patient was hospitalized for persistent post-prandial vomiting

associated with epigastric pain, and EGDS showed tight stenosis of the scarring in the pylorus. Partial gastroduodenal resection was performed according to Billroth II. In May, due to persistence of the vomiting and progressive deterioration of the patient's nutritional status, he was examined once more and the presence of a mechanical obstacle to the passage of food was excluded. Irritation of the residual gastric mucosa induced by bile and pancreatic secretion was postulated to be the cause, and a new operation was proposed (biliary and pancreatic derivation). On 24 May 1998, the patient was admitted to a surgical ward and refractory vomiting, malnutrition, anemia, electrolytic alterations (Na^+ , K^+ ; H^+) and calcemia were recorded, together with a state of mental confusion, visual disturbances, vertigo and paresis of the right arm. The patient was administered parenteral nutrition and a crano-encephalic CT scan was performed, which showed asymmetry of the lateral ventricles ($\text{sin} > \text{dx}$) and cerebral atrophy; no areas of pathological density were revealed in the parenchyma. On 4 June the patient died of irreversible cardiac arrest. As there was some suspicion of malpractice, the judge ordered an autopsy. External examination of the cadaver evinced greenish areas of putrefaction over the inferior abdominal quadrants, various tattoos of varying sizes, no teeth in the superior maxillary arch, and the scars due to the partial gastrectomy. On sectioning the body, acute polyvisceral congestion was observed (right lung gr. 650, left lung gr. 680; heart gr. 300; liver gr. 1400; spleen gr. 130; right kidney gr. 220, left kidney gr. 240); scars were due to partial gastrectomy, absence of pleural, pericardiac and peritoneal leakage. The brain, weighing 1,250 grams, was asymmetrical in the two hemispheres, and flattened grooves and wide circumvolutions were apparent. The circle of Willis showed scattered atheromatous plaques along the walls of the vessels. Examination and section of the encephalon were performed after fixation of the organ (30 days in 20% formalin); before cutting into the parenchyma, post-mortem brain magnetic resonance imaging (MRI) coronal proton density and T2 scans showed multiple cyst-like lesions involving the subcortical white matter and basal ganglia. The genu of the corpus callosum presented an area of gliosis on the left side. All these aspects were absent on the CT scan performed only a few day before exitus. Section of the encephalon confirmed the presence of cystic lesions in the white matter, containing cerebrospinal fluid and ranging in diameter from 3 mm to 1.3 cm, symmetrically distributed along the cerebral hemispheres, in the brain stem, the ganglia of the base and the cerebellum, especially the periventricular areas. The left ventricle was dilated and there was no tissue herniation. Sections 4-5 microns in size, stained with hematoxylin-eosin, Pas, Luxol Fast Blue, Azan-Mallory, Grocott and Zihel-Nielsen, were observed under the optical microscope and it was seen that the cystic cavities mainly involved the white matter and rarely the grey matter, and that they had no epithelial sheath and were delimited by zones of astrocytosis. Demyelinized foci were present, and there were areas of gliosis in the corpus callosum. Tests for bacteria (mycobacterium tuberculosis and atypical mycobacteria), fungi (candida and cryptococcus), viruses (cytomegalovirus, herpes) and protozoa (toxoplasmosis) were negative. Histology of the other organs confirmed the overall state of congestion but provided no other noteworthy findings apart from areas of fibro-adipose tissue in the ventricular myocardium (left and right) and hepatic steatosis. Death was thus attributed to the synergic effect of the cerebral lesions provoked by the metabolic acidosis together with the persistent electrolytic imbalance. The case we describe confirms the reports in literature indicating ungovernable vomiting as a rare, severe complication of gastroresection and suggests that a metabolic imbalance may be etiopathogenic for cerebral cyst formation in the adult. To ensure correct diagnosis at autopsy, therefore, examination and MRI of the brain, previously fixed in formalin, is advisable to investigate the features of tissue damage in cases of death induced by metabolic imbalance.

Corrosive Agent Intoxication, Electrolytic Imbalance, Multicystic Encephalopathy

G53 Notochord Regression Failure Initially Suspected as an Abusive Fracture in an Infant

Patricia A. Aronica-Pollak, MD, 2708 Neonlight Drive, York, PA,
Vincent H. Stefan, PhD, Department of Anthropology, Lehman College,
CUNY, Bronx, NY, Jerri McLemore, MD, Office of the Medical
Investigator, University of New Mexico School of Medicine,
Albuquerque, NM, and Madelyn Stazzone, MD, Radiology Department,
University of New Mexico School of Medicine, Albuquerque, NM*

The goal of this research project is to have participant become familiar with an atypical case of notochord regression failure initially suspected as an abusive fracture in an infant

Background: The evaluation of any infant death must include a full skeletal survey in order to detect any possible trauma. The finding of suspicious trauma would eliminate the diagnosis of sudden infant death syndrome as a cause of death and may suggest abusive treatment by the caregivers.

Case History: The decedent was a four-month-old male infant. According to reports, the decedent was found by his father in a crib under a blanket unresponsive in the early morning hours. He was brought to the emergency room with a poor respiratory effort. He was intubated but continued to decline and never regained consciousness. He was pronounced dead approximately four days after admission to the hospital. Evaluation in the hospital included an antemortem skeletal survey and ophthalmologic examination. These were both unremarkable except for a defect of the 3rd lumbar vertebra which was interpreted as a possible fracture. However, follow-up radiological studies of the lumbar vertebrae failed to reveal a definite fracture. There was no history of trauma or abuse.

Pathological/Anthropological Assessment: Initial examination of the antemortem radiographs taken of the infant revealed a clear defect of the vertebral body of L3, with a slight defect in L5. Autopsy examination failed to reveal any fractures or hemorrhages in the lumbar area. In order to accurately determine if the defects were due to developmental abnormalities or trauma, the lower lumbar vertebrae were removed, dissected and macerated for evaluation. The defects were also noted in the postmortem radiological examination.

Visual examination of the vertebrae revealed a complete coronal cleft of the centrum of L3, while the centrum of L5 possessed only slight indentations of the lateral aspects. No residual defects were noted on L4. Linearly transecting the two portions of the centrum of L3 were residual cartilaginous tissue and the remnants of the notochord. The coronal cleft and the cartilaginous tissues are consistent with the failure of the notochord to regress appropriately during the development of the vertebral body (Barnes, 1994). This would interfere with the normal unification of the anterior and posterior portions of the centrum, and give the false appearance of being fractured. Microscopic examination confirmed the diagnosis of notochord regression failure. This type of vertebral body cleft defect is more commonly seen in the lumbar region.

Conclusions: The pathologic correlation to the radiological findings of this defect in the spine was failure of the notochord to regress, a developmental defect and not the result of trauma. No other developmental or congenital anomalies were identified. No other significant trauma or anatomic cause of death was identified and the cause of death was classified as sudden infant death syndrome. Although a rare occurrence, failure of the notochord to regress is an important entity, primarily because it may be confused with an abusive traumatic fracture.

Notochord Regression Failure, Fracture, Child Abuse

G54 The Clinical and Pathological Features of Fatal Concussion

Stephany Fiore, MD*, and Vernon Armbrustmacher, MD, Office of Chief Medical Examiner, 520 First Avenue, New York, NY

The goals of this research project are to present the clinical and pathologic features of fatal concussion, with emphasis on potential contributing factors.

Diffuse brain injuries (DBIs) are the most common type of head injury and form a continuum of progressively severe brain dysfunction. The majority of cases fall under the clinical heading of Cerebral Concussion, in which minimal or no sequelae follow a brief period of unconsciousness, and rarely come to the attention of the forensic pathologist. More frequently encountered are the severe DBIs associated with motor vehicle or pedestrian accidents, assaults, or falls from a height. The hallmark of DBI is damage to the axon resulting from the shearing forces of rotational acceleration. The severity of the injury and length of survival determine the degree to which axonal injury can be appreciated microscopically. The characteristic finding of axonal bodies becomes apparent 18 to 24 hours after injury. With the use of immunohistochemical stains for beta-amyloid precursor protein (?APP), the window between injury and detection is reduced to three hours. Small hemorrhages in the parasagittal subcortical white matter, corpus callosum, and dorsal brainstem, as well as mild subarachnoid (SAH) and/or intraventricular hemorrhage can be macroscopic markers of axonal injury due to the susceptibility of small blood vessels to the same shearing forces.

Rare are the cases in a sudden death following blunt head trauma where autopsy fails to demonstrate any injury to the brain, either macroscopically or microscopically. This entity has been referred to as *commotio cerebri*, fatal concussion, and reflex death. While this subject is well known anecdotally, it is obscure in the literature. A couple of articles have been published in recent years that discuss possible pathophysiologic mechanisms for death in these instances. The general consensus is that a "concussion" of the reticular formation in the brainstem is paramount to the lethal outcome. Whether this event triggers death via a cardiac dysrhythmia or apnea remains a topic of debate. Ethanol intoxication has long been recognized as a cofactor in the mechanism of death in certain individuals; however, this finding is not absolute.

The purpose of this study is to determine the incidence of fatal concussion in New York City and to further delineate its clinical and pathological features, as well as possible contributing factors, in order to gain a better understanding of possible mechanisms for sudden death in these instances.

The electronic database for the Office of Chief Medical Examiner in the city of New York was retrospectively searched from January 1997 through July 2001 for potential cases that met criteria for fatal concussion, that is immediate death following blunt impact to the head; no skull fractures, epidural or subdural hemorrhages, or focal brain injuries; and no other explanation for death. Identified cases were reviewed to determine the circumstances surrounding death, resuscitative efforts, acute intoxications, and underlying natural disease. A complete autopsy including toxicologic studies and neuropathology consultation had been performed in each instance. Microscopic evaluation of the brain was not included due to the short survival period. Findings were recorded in a new database for analysis.

Seven cases were identified during this 4 ½ year period. All victims were male and the ages ranged from 14 to 56 years (mean 34.4 years). Two of the decedents fell from standing and struck their head on the ground, two fell down a flight of stairs, and two were struck by an object. The seventh individual was an unrestrained passenger in a motor vehicle accident. Toxicology was negative in one instance. Of the remaining six decedents, five were acutely intoxicated with ethanol (0.12-0.36 g%). In

one of these five, cocaine was additionally detected in the blood and ethylbenzoylecgonine in the urine. Furthermore, chronic alcoholism was a recognized factor in four of these five decedents. Cannabinoids were detected in the blood of the seventh individual. Six of the decedents had cardiac hypertrophy defined as a heart weight exceeding 0.5% of body weight in kilograms or a left ventricle wall thickness \geq 1.5 cm. The heart in the seventh individual fell well below the expected weight. Traumatic injuries were limited to scalp lacerations in two victims. Additional findings of thin SAH were present in three decedents. One instance involved a blow to the posterior neck with hemorrhage in the muscles overlying the second to the fourth cervical vertebrae, but no detectable injury to the spinal cord or vertebral artery. The remaining individual had no external manifestations of trauma to the brain, but a few small hemorrhages in the frontal white matter and pontine tectum were detected upon sectioning.

Fatal concussion is an infrequently encountered entity that has received little attention in the literature. It is generally accepted that the sudden nature of death in these instances results from a "concussion" to the vital centers in the brainstem. But what is a concussion? Recent studies have shown that patients who suffer a cerebral concussion and survive but die shortly afterwards from another cause have evidence of axonal damage demonstrable using immunohistochemical stains for ?APP. With this information, one can consider axonal injury the structural defect common to all DBIs and it is the distribution and extent of damaged axons that determine the severity of brain dysfunction. It is the belief of these authors that fatal concussion falls within the continuum of DBIs and the reason autopsy often fails to demonstrate any injuries is because of the extremely brief survival period between impact and death. The presence of subtle hemorrhagic markers supports the theory that axonal damage plays a mechanistic role in the death of these individuals. The reticular formation in the brainstem controls the autonomic functions of the body, most importantly breathing and heart rhythm. Therefore, axonal damage within this vital center could theoretically trigger episodes of apnea and/or cardiac dysrhythmias. Of the two, cardiac arrhythmia is by far a more common cause of sudden death.

The second question we must ask is why do some people die from a concussion while others survive with minimal residual effects? This study identifies two cofactors that can help explain why some people may be predisposed to sudden death following what otherwise appears to be minor head trauma: ethanol intoxication and cardiomyopathy. Conduction disturbances and arrhythmias are frequently seen in those with cardiomyopathy whether it is due to hypertension, ethanol or stimulant abuse, or of an idiopathic nature. Acute ethanol intoxication alters sympathetic activity resulting in tachycardia or bradycardia depending on the level of intoxication. Ethylbenzoylecgonine, a byproduct of the concomitant use of cocaine and ethanol, is another recognized cardiac toxin, which can induce ventricular arrhythmias. Even cannabinoids have been associated with electrical disturbances in the heart. Five of the six decedents in this study with an underlying cardiomyopathy were also under the influence of an arrhythmogenic substance. Each of the individuals had at least one cofactor present. It seems reasonable to conclude then that a blunt impact to the head or upper cervical spinal cord producing a concussion in the brainstem can easily trigger a fatal arrhythmia in an individual with an underlying predisposition to sudden cardiac death.

Fatal Concussion, Cardiomyopathy, Ethanol Intoxication

G55 "Doctors as Detectives" (1987 - 2001): Fifteen Years of Introducing Forensic Medical Science to High School Students in Northwest Ohio and Southeast Michigan

Frank P. Saul, PhD, Regional Commander, USPHS DMORT 5, OH;
Julie Mather Saul, BA, Director, Forensic Anthropology Laboratory,
James R. Patrick, MD, Lucas County Coroner, Diane Scala-Barnett, MD,
Deputy Lucas County Coroner, Robert B. Forney, Jr., PhD, Director of
Toxicology, and Robert A. Burns, DDS, MS, Consultant, Forensic
Odontology, Lucas County Coroner's Office and Medical College of
Ohio, 2529 Arlington Avenue, Toledo, OH; Jerome DeBruin, PhD,
Professor of Education, University of Toledo, 2801 West Bancroft,
Toledo, OH*

The goals of this research project are to describe a low cost and minimal effort approach for sharing forensic medical science with local high school students and their teachers.

In the May/June 2001 issue of *Academy News*, President Mary Fran Ernst indicates that "middle and high school teachers are now clamoring for information and pleading for resources and assistance to help them incorporate forensic sciences into their science and math curriculums." She also states "the Academy is now providing you an opportunity to help our children and the forensic sciences" and asks "Are you going to step up to the plate?" (President's Message). In actual fact, Toledo Ohio, members of the AAFS associated with the Lucas County Coroner's Office and the Medical College of Ohio "stepped up to the plate" in October 1987 and have since shared forensic science with at least 4,400 students and their teachers from at least 40 high schools in Northwest Ohio and Southeast Michigan.

In 1989, we presented a poster on this subject at the AAFS Annual Meeting. At that time we wrote in our abstract:

"A desire to replicate the AAFS' Student Academy locally led forensic scientists from the Medical College of Ohio and the Lucas County Coroner's Office to organize a day long series of lectures, posters and demonstrations for area high school students. Although lead time was short, the response to our announcement was overwhelming and we were forced to limit participation to about 200 students and teachers from 33 schools (requests indicated that at least twice as many wished to attend). Presentations by forensic pathologists (Patrick, Desley and Scala-Barnett) introduced the general field, followed by specialists from anthropology (Saul and Saul), odontology (Burns and Strickland) and toxicology (Forney and Darling). Questionnaires filled out by participants (analyzed by DeBruin) indicated that these potentially disconcerting presentations were well received and it was unanimously requested that the event be repeated annually."

We have now (as of 3 October, 2001) successfully conducted fifteen of these annual programs for about 300 students and teachers per year since we began the series on 20 October, 1987. The format remains essentially the same with morning presentations on the basic forensic medical sciences by members of the Lucas County Coroner's Office (forensic pathology, anthropology, odontology and toxicology). Separating each topic are 15 minute breaks during which time students can view exhibits and demonstrations and speak one-on-one with forensic scientists. A one-hour break for lunch (supplied on campus) is followed by a one-hour afternoon session on some special aspect of forensic science, usually given by guest faculty. These afternoon sessions vary from year to year.

The afternoon programs provided an opportunity to focus on DNA as early as 1990 ("Molecular Biology in the Courtroom") and have also included airplane crashes and other mass fatality incidents, forensic entomology, crime scene analysis, facial reconstruction, blood spatter analysis, burial customs (and grave robbing), the role of dogs in death investigation, etc. Guest speakers have come from a variety of agencies including the Armed Forces Institute of Pathology, the FBI Evidence Response Teams and other law enforcement agencies.

Teachers have often indicated that these programs provide an applied and meaningful context for some of their basic science teaching. Several schools have developed courses that relate to our program. In addition, a number of students have obtained access to internships at the Coroner's Office through this program.

Program expenses are minimal and include administrative costs (donated), lunch and room rental. The buffet lunch at the Hilton Hotel on the Medical College campus has risen from \$5 in 1987 to about \$13 and auditorium rental at the Dana Center, also on campus, has risen from \$125 in 1987 to about \$600. Occasional donations from the Ohio Embalmers Association (for providing them with a similar program) and a few other outside donations have helped us hold down the registration fee which has risen from \$5 in 1987 to \$15. Some schools pay the fee but most registrants pay their own way. Financial aid has always been offered but never accepted.

Forensic Medical Sciences, High School, Teachers and Students

G56 Exsanguination From a Dialysis Catheter: Trace Evidence Examination in Determining Manner of Death

Michael A. Trimpe, BS, Robert R. Pfalzgraf, MD, and Carl L. Parrott, Jr., MD, Hamilton County Coroner's Office, 3159 Eden Avenue, Cincinnati, OH*

The goal of this research project is to recognize an unusual cause of death in patients undergoing chronic renal dialysis, and the usefulness of trace evidence examination in resolving the issue of manner.

A blind, 70-year old man receiving thrice-weekly renal dialysis for chronic renal failure was found dead in his wheelchair in blood-covered clothing. He had exsanguinated and sustained venous air embolism from an exposed, indwelling central venous dialysis catheter coiled on his upper chest, inspection of which showed a number of transverse slits, most of them superficial, but at least one of which penetrated to the catheter lumen. Deliberate cutting of an indwelling venous catheter is occasionally encountered as a means of suicide, and the multiplicity of the defects, somewhat resembling hesitation marks, suggested that possibility. The alternate possibility of structural failure of the plastic catheter was also entertained.

The catheter was submitted to the trace evidence section of the Hamilton County Crime Laboratory for examination, specifically to determine if the defects in the tubing were cuts or breaks and, if cuts, what implement might have been used to cause them.

Microscopic examination of the catheter revealed a series of 18 slits within the space of approximately one inch. Two of the slits reached the lumen. They were sequentially shallower with increasing distance from the deepest slit. Though uniformly transverse, the slits were not perfectly parallel. Many, indeed, were not straight and could not have been made by a sharp-edged tool.

In cross sectional view, the inside edges of the slits appeared fractured and displayed no markings or striations indicative of being made by a tool. A known cut was made with a scalpel blade in the tubing away from the area of interest. Comparison photographs were made of the questioned splits and the known cut, revealing obvious differences between the known and questioned defects. Additionally, near the questioned defects, a series of fine cracks in the plastic was observed, analogous to fractured glass.

Several tools collected at the scene of death and submitted to the laboratory were also examined and eliminated; however, on the basis of examination of the tubing, it was concluded that the decedent's exsanguinating hemorrhage was due to structural failure of the plastic tubing rather than to its deliberate incision.

Exsanguination, Dialysis Catherer, Trace Evidence Examination

G57 Sudden Death Due to Idiopathic Giant Cell Myocarditis: Case Report and Literature Review

Maryanne Gaffney-Kraft, DO, Hong Yin, MD, and Patrick E. Lantz, MD, Department of Pathology, Wake Forest University Baptist Medical Center, Medical Center Boulevard, Winston-Salem, NC*

The goal of this research project is to increase forensic awareness of idiopathic giant cell myocarditis as a cause of sudden cardiac death and discuss the pathogenesis, histologic findings and differential diagnosis.

We present a case of a 15-year-old female with a one-week history of chest pain who had been diagnosed with costochondritis and treated with prednisone and hydrocodone + acetaminophen. She was found unresponsive in the bathroom. An EKG in the Emergency Department showed an elevated ST segment with a slightly widened QTc interval of 449 ms. Because of her continued instability she was transferred to a tertiary medical center. During transport, she had narrow complex tachycardia and was given two doses of adenosine without result. She had persistent pulselessness and CPR was discontinued and she was pronounced dead 3½ hours after being found unresponsive.

Major findings at autopsy included diffuse tan-gray areas of poorly delineated necrosis and infiltrates with focal areas of serpiginous hemorrhage mainly involving the left cardiac ventricle. These extended from the apex to the base, mainly involving the inferior left ventricle but also involving the posterior septum and free wall. About 40% of the ventricular myocardium appeared replaced by the tan-gray hyperemic infiltrate. The right ventricle was less involved. Microscopically, the myocardium exhibited extensive myocytic necrosis with a polymorphous, non-granulomatous mixed inflammatory infiltrate containing multinucleated giant cells. Special stains for acid-fast bacilli and fungi were negative. Other findings included epicardial fibrinous adhesions, a pericardial effusion, bilateral pleural effusions, pulmonary edema, cardiomegaly (420 gm) and Hashimoto thyroiditis.

Idiopathic giant cell myocarditis is a rare form of myocarditis of unknown cause characterized by the presence of multinucleated giant cells. It often causes rapid congestive heart failure and dysrhythmias in young- to middle-aged adults. At autopsy, the distinctive features often include cardiac enlargement, ventricular thrombi, grossly visible serpiginous areas of ventricular myocardial necrosis and microscopic evidence of multinucleated giant cells within an extensive inflammatory infiltrate. The cause of myocardial giant cell myocarditis remains obscure although it has occurred in association with autoimmune disorders.

The differential diagnosis of idiopathic giant cell myocarditis includes cardiac involvement by sarcoidosis, tuberculosis, syphilis, rheumatic fever, fungal infections, rheumatoid arteritis, inflammatory pseudotumor, metastatic osteosarcoma and lymphoma.

Idiopathic Giant Cell Myocarditis, Sudden Death, Cardiac Death

G58 Immunopathological Study of Methamphetamine (MAP)-Induced Fatalities

Fang-Chun Chung, MS; Chang-En Pu, MS, Section Chief; Way-Lin Lin, Associate Researcher, Institute of Forensic Medicine, 40-11, Lane 103 Hsing-An Street, Taipei, Taiwan (Roc); Way-Hwa Lee, Professor; John M. Fong; and, Kai-Ping Shaw, Chairman, Department Forensic Pathology, Institute of Forensic Medicine, 40-11, Lane 103 Hsing-An Street, Taipei, Taiwan (ROC)*

The goal of this research project is to understand the mechanism of MAP-induced neuro-toxicities and the correlation of the MAP-induced behavioral sensitization and its dopaminergic system of MAP abusers.

The abuse of illicit drug is a worldwide phenomenon that causes serious social problems. Hence, such abuse prompts much attention regarding the issue of illicit drug abuse and additionally related public hazard and criminal activities. It is essential to understand the pathogenesis of MAP-induced lesion in order to propose a prospective anti-drug program and to inform the public on the government's strategy. Long-term MAP abusers may become addicts and may generate psychotic, self-destructive behavior and emotional disturbances. A close relationship exists between MAP-induced fatalities and high homicide rate (25-30% in the manner of death) in comparison to opiate-related fatalities and low homicide rate (0-5%). MAP induces long-lasting deficits in the innervations involving the striatum from DA (dopamine) neurons of *substantia nigra*. This study is primarily based on MAP-induced fatalities collected from the IFM. We used Hematoxylin & Eosin stain (HE) and immunohistochemical treatments, including tyrosine hydroxylase (TH), vesicular monoamine transporter (VMAT), neuronal membrane DA transporter (DAT) and glial fibrillary acidic protein (GFAP), to understand the morphological characteristics. We evaluated alterations of catecholamine metabolites within *substantia nigra pars compacta* and *reticula* of the ventral midbrain of MAP-induced fatalities with the history of long-term MAP abuse. Furthermore, this study aims to identify the relationship of the nigrostriatal dopamine system with its deficits and the alterations of dopamine neuron in the *substantia nigra*. In this study, the assessed cases of MAP abuse were divided into control group and MAP group (four male and four female fatalities in each group). The sections of *substantia nigra* in midbrain were isolated, stained with HE stain, and then with Immunohistochemical stains (TH, VMAT, DAT and GFAP). It has been demonstrated that the morphology of dopamine neurons of MAP-related fatalities under HE stain exhibit a metaphase-like nucleus and nucleoli in the *substantia nigra* correlative with a metamorphosis of cytoplasma characterized by a granular aggregation that segregated into lucid and granular zones. It develops into four "circularities" in the marginal region of DA neuron under HE stain in MAP-induced fatalities. Decreasing numbers of the enzyme-positive neurons after immunological treatment of TH, VMAT, DAT were noted. However, increasing numbers of spines with enlarged round-shape vesicles of terminal synapses become aggregated after the treatment of GFAP, showing neo-growth of glial cells with innervations. This implied that MAP-related DA neuronal lesions were associated with regeneration of glial processes. Under the observation of Laser Scanning by using a confocal microscope after the fluorescent treatments of TH, VMAT and DAT, the fluorescent activity of the MAP group appeared attenuated compared with control. These data demonstrate that long-term dopaminergic deficits with retardation of dopaminergic-metabolite enzyme could reduce the neuronal fluorescent activity. Chronic abuse of MAP may cause morphologic alterations in *substantia nigra* and a decrease in the number of enzyme-positive neurons after immunological treatments of TH, VMAT, and DAT. On the other hand, increasing numbers of GFAP-positive glial cells aggregate after treatment with GFAP implying the healing process with gliosis. These studies demonstrate that long-term dopaminergic deficits may decrease neuronal activity by destruction of the DA neuronal terminal and cause degeneration as well as neo-growth of glial cells as part of the healing process. This study demonstrates well the relationship of dopaminergic deficits and the behavioral model of MAP abusers. In conclusion, these results will assist in the recognition of the mechanism of MAP-induced neurotoxicities, in explanations of MAP-induced behavioral sensitization, and will also provide strategic schema for the government's anti-drug program.

Forensic Science, Dopamine, Methamphetamine

G59 Experiences of Human Bodies Identified by DNA Typing in Singapore Airlines SQ006 Crash in Taipei

Chang-En Pu, MS, Ministry Justice Investigation Bureau, PO Box 3562, Taipei, Taiwan; Chi-Hsiang Chao, Division Chief, Ministry Justice Investigation Bureau, Taipei, Taiwan; Fang-Chin Wu, Wen-Hsiung Ho, Kuo-Chun Wu, Ling-Min Meng, Researcher, Ministry Justice Investigation Bureau, Taipei, Taiwan; and Kai-Ping Shaw, Director of Forensic Pathology, Institute of Forensic Medicine, Ministry of Justice, Taipei, Taiwan*

The goal of this research project is to establish the standard operation procedure to manage the mass disaster during the experience of Singapore Airline SQ-006 Air crashed Accident by using CODIS 13 STRs profilers to identify badly wounded bodies.

On October 31, 2000, approximately 2317 Taiwan time (1517 UTC), a Singapore Airlines Flight SQ-006, with Singapore registration 9V-SPK, Boeing 747-400 airplane entered the incorrect runway at Chiang-Kai-Shek (CKS) Airport, Taiwan. Heavy rain and strong wind from typhoon "Xiang Sane" prevailed at the time of the accident. The airplane was destroyed by its collision with the runway construction equipment and by post impact fire. There were a total of 179 people on board with 159 passengers, 3 flight crewmembers and 17 cabin attendants. Official report, 83 people died (including 4 cabin crews), and 44 people injured. After the airplane SQ-006 of Singapore Airline got an accident at CKS international airport before taking off, 79 persons from 19 different countries died instantly. Although some of the bodies were identifiable, the prosecutor's office of Tau-Yuan district court (40 km away located southern Taipei metropolitan) decide to request the DNA typing method to confirm each body identity in addition to odontological and anthropologic identification.

Immediately after this accident, the Criminal Investigation Bureau, Ministry of Interior and medical examiners' of IFM were asked to type the sample from deceased's bodies and STR typing were applied, and MJIB and IFM were assigned to collect the family members' STR for further paternity matching. For the purpose to increase the efficiency of DNA typing, the forensic scientists of molecular biologist were organized into blood collector group, DNA extraction group, STR typing group and STR matching work stations as a DNA typing and identifying mass production chain. The CODIS 13 STRs were applied to fulfill the DNA data interchanging.

The first group of families arrived on the next day 8:30am about 9 hours after the crash accident and their blood samples were drawn for DNA typing to establish genetic relationship to the deceased, with the access of the 24 hour running-basis working team, 20 hours after the crash, the first group of 12 bodies were identified. After five days' mass production operation in the DNA laboratory, 80 bodies matching their relatives from 19 different countries were identified including one once rescued decedent died about 24 hours after incidence. Another two decedents died in the hospital without identification problem. Due to lack of lineal or collateral consanguinity information of one decedent to claim the body until the odontological and anthropological characteristics were confirmed. One of the 80 decedents was identified by STR direct matching (STR typing sent from Singapore) with previous blood sample left in the blood bank of Singapore. An unique case of a decedent was identified after the CODIS 13 data of decedent's family member who were unable to be Taiwan in time. 15 of the decedents were identified by sibship profiles due to collateral consanguinity. 65 of the decedents were recognized by paternity test with linear consanguinity. Forensic DNA matching is an accurate and efficient tool for badly crashed bodies identifying in addition to the odontological and anthropological method. To establish the professional guideline as the standard operation procedure of DNA typing and body identification is a crucial role to cope the mass disaster effectively during the urgent operation period. The Singapore

Airlines SQ-006 Air crashed accident by using STR CODIS 13 profilers to identify badly wounded bodies during five days' experience is worth for strategic schema.

Forensic Science, CODIS 13, Air Crash

G60 A Case Report of Sudden Death in a Patient With Kartagener Syndrome

Cristin M. Rolf, MD, University of Kentucky Department of Pathology & Laboratory Medicine, Central Laboratory Facility, 100 Sower Boulevard, Suite 202, Frankfort, KY*

The goals of this research project are to (1) Review the pathophysiology of Kartagener Syndrome with emphasis on the cardiac manifestations, and (2) to demonstrate how cor pulmonale can complicate Kartagener Syndrom as a result of chronic lung disease (bronchiectasis) and obesity resulting from the side effects of the medication used to treat lung disease.

A 23-year-old obese white female was diagnosed to have immotile cilia syndrome and hypertension since eight years of age. She had been trying to lose weight and was a cigarette smoker. The night before her death she and her friends were dancing at a dance hall during which she drank six wine coolers. She went to bed without any complaints and awoke the next day to help a friend clean house. She sat down on a couch laughing and drank a soft drink (Mountain Dew). Suddenly, without complaint she fell forward and stopped breathing.

Upon their arrival, EMS found the decedent supine on the floor, apneic, cyanotic, and pulseless. Quick look monitors revealed pulseless ventricular tachycardia. Despite ACLS protocol, the cardiac rhythm deteriorated to an agonal rhythm. She was pronounced dead upon arrival to the hospital. Follow-up coroner interview with the decedent's mother revealed that the decedent and a sister had immotile cilia syndrome. Throughout childhood she underwent surgical procedures for duodenal obstruction and complications from situs inversus. Her sister, still living with immotile cilia syndrome, had a "hole in the heart" that healed without surgery. She and her sister were prescribed steroids to control both nasal congestion and chronic bronchiectasis of immotile syndrome. The decedent and her sister battled obesity throughout their lives and had tried many diets. The decedent was not on any diet medications at the time of death. The only other sudden death in the family was that of a grandmother at the age of 36.

On external examination, she was an atraumatic, extremely obese female with a body mass index of 44 kg/m². Internal examination revealed situs inversus with polysplenia and bilateral "left sidedness" (bilobed right lung). Bronchiectasis was prominent in both lungs with increased fibrovascular tissue around the affected airways on microscopic examination. The heart weighed 580 grams and exhibited biventricular hypertrophy. Other findings in the heart included a ventricular septal aneurysm with an associated tethered septal leaflet of the tricuspid valve. There was evidence of aortic insufficiency. No isomerism was seen between the atrial appendages. Other findings included a foreshortened thoracic cavity and early nephrosclerosis of the kidneys.

In view of the sudden collapse and anatomic findings on autopsy, the cause of death was ascribed to cardiac dysrhythmia due to biventricular hypertrophy resulting from Kartagener Syndrome. Cor pulmonale was characterized by right ventricular hypertrophy. Other conditions contributing to the development of pulmonary hypertension included obesity with a foreshortened thoracic cavity, sleep apnea, and chronic pulmonary disease. Kartagener Syndrome or Immotile Cilia Syndrome consists of the triad of sinusitis, bronchiectasis and situs inversus. Ciliary motility of cells of the body is abnormal due to defects of structures in the microtubular doublets within the cilia. The most common defect is absence or abnormal dynein arms. Impaired ciliary motility predisposes the body to infection resulting from poor bacterial clearance from the

sinuses and bronchi. Males affected with the condition are infertile due to the immobility of the sperm tails. Cell motility during embryogenesis is affected and results in situs inversus in about half of the patients. The mode of inheritance is autosomal recessive and the phenotype is variable. This is a case of sudden death in a patient with Kartagener Syndrome manifesting cor pulmonale as a complication.

Kartagener's Syndrome, Cor Pulmonale, Situs Inversus

G61 Micro-Computed Tomography: An Advantageous Tool for the Analysis of Patterned Tool Marks in Bones

Michael J. Thali, MD, Office of the Armed Forces Medical Examiner, Armed Forces Institute of Pathology - Annex, 1413 Research Boulevard, Building 102, Rockville, MD; Ulrike Taubenreuther, Institute of Medical Physics, University of Erlangen, Germany; Marcel Braun, Institute of Forensic Medicine, University of Berne, Berne, Switzerland; Nicolette Scholz, Institute of Medical Physics, University of Erlangen, Germany; Walter Brueschweiler, Institute of Forensic Medicine, University of Berne, Berne, Switzerland; Willi Kalender, Institute of Medical Physics, University of Erlangen, Germany; Richard Dirnhofer, MD, Institute of Forensic Medicine, University of Berne, Berne, Switzerland*

Micro-Computed Tomography (Micro-CT) may offer a worthwhile opportunity to analyze patterned injuries in bone. In the field of forensic science, it has not been possible until now to non-destructively document such damages to bone. However, based upon high resolution imaging of these patterned injuries, it is now possible to draw conclusions on the injury-causing instrument. In fact, those conclusions may lead to the identification of the perpetrator.

Materials and methods:

Based on a real murder case, porcine pelvic bones were experimentally stabbed with multiple knives. Afterwards these bone samples were examined with a micro-CT system developed at the IMP Erlangen. This cone beam scanner can achieve an isotropic resolution from 10 to 100 μm for sample diameters from 1 to 40 mm. We used a scan protocol of 720 projections for a 360° rotation with a 512 detector matrix. The 512³ data volume is reconstructed using a modified Feldkamp algorithm. Resolution in the specific bone samples is 30 to 75 μm depending on the sample size. Until the present, analysis has been performed by visual inspection of double oblique slices of the reconstructed volume to optimally display the plane cut by the knife using Impact View (VAMP GmbH, Erlangen, Germany). Additionally, stabbing wounds were quantitatively evaluated by measuring distances and angles. We also tried out different stabbing techniques in and out with and without additional rotation of the knife.

Results:

The micro-CT datasets of the injured bone samples were used to obtain those 2D slices that optimally showed the stabbing wounds inside. Based on the measured distances and angles, it was easily possible to uniquely identify the size and shape of the injury-causing knife in straight stabs. Additional rotating and twisting cause broader wounds, thus an expert visually selects the injuring instrument from a choice of known knives by fitting the shape to the stab in the micro-CT image. In this way, not only the knife can be identified, but also information about the action of injury is received.

Conclusions:

In the field of forensic pathology, Micro-CT provides a new and advantageous tool for the non-destructive examination and analysis of patterned tool marks in bones. By using the micro-CT technology, new horizons are open for matching a possible injury-causing instrument against the patterned lesion in the bone.

Forensic Radiology, Micro Computed Tomography, Patterned Injuries

G62 Immunohistochemical Study for Determining the Time of Injury to Rats Following Stab Wounds and Blunt Trauma to the Brain

Mona M.A. Hassan, MD and Ragaa T. Darwish, MD, Department of Forensic Medicine & Toxicology, Alexandria, Egypt; and Samar M. El-Sheikh, PhD, Department of Pathology, Faculty of Medicine, University of Alexandria, 33, Safeya Zaghloul St. #52, Alexandria, Egypt*

The aim of this research project is to investigate the possibility of utilizing changes in the proliferating astrocytes expressing glial fibrillary acidic protein (GFAP) and proliferating cell nuclear antigen (PCNA) in determining the time of brain stem injury following stab wounds and mechanically induced injury.

Astrogliosis is a predictable response of astrocytes to various types of injury caused by physical, chemical, mechanical, and pathological trauma. It is characterized by hyperplasia, hypertrophy, and an increase in glial fibrillary acidic protein (GFAP), which is an intermediate filament protein. GFAP is the principal marker for brain astrocytes; whereas, proliferating cell nuclear antigen (PCNA) is an intrinsic marker of DNA replication. In forensic pathology, there are few reports concerning the differentiation of early antemortem brainstem injuries from postmortem injuries following stab wounds and blunt trauma. In the present study, investigation was carried out to determine the possibility of utilizing changes in the astrocytes expressing glial fibrillary acidic protein (GFAP) and proliferating cell nuclear antigen (PCNA) following stab wounds and mechanically induced injury in determining the time of brainstem injury. Forty-eight rats (150-200 g) were divided into two groups (24 rats in each group) and received stab wounds and blunt trauma respectively. After the rats were anaesthetized, sagittal median incisions of the scalp were made right above the foramen magnum. For antemortem injury, a 3-mm deep stab wound was made with a sterilized stainless steel needle through the upper median point of the foramen magnum. For brain stem contusions, a 10g impact rod was allowed to drop from a height of 5 cm at the same site. The rats were killed 1, 5, 24, and 48 hours after trauma. For post-mortem injuries, the brainstem was either stabbed or mechanically traumatized 15 minutes after the rats were killed, and the brain was removed one hour after injury. For the normal control, no wounds were made and the brain was removed 15 minutes after death. The brain was then placed in 10% formalin solution, embedded in paraffin, and serial 5 μm sections were prepared. In each of the studied group, one section was stained with hematoxylin-eosin according to routine procedures and two sections were stained by immunohistochemical method for GFAP and PCNA. In the antemortem group, GFAP-positive astrocytes showed a gradual increase in number after injury and their immunoreactivity became intense especially at the vicinity of the wound. On the other hand, there was no significant difference between the postmortem injury group and the normal control group. Proliferating cells were identified by immunostaining for PCNA, which showed a high labeling index around the wound at 48 hours. The results indicate that early brainstem injury could be diagnosed by GFAP immunohistochemistry. Also, the chronological changes in the number of GFAP-positive cells could be utilized in determining the time of brainstem injury. PCNA could be used as a marker for survival after fatal head injuries.

Brain-Stem, Glial Fibrillary Acidic Protein, Proliferating Cell Nuclear Antigen

G63 Postmortem Interval Decomposition Chemistry of Human Remains: A New Methodology for Determining the Postmortem Interval

Arpad A. Vass, PhD, Stacy-Ann Barshick, PhD, Gary Segal, PhD, John Canton, PhD, James T. Skeen, Jennifer C. Love, PhD, and Jennifer A. Synstelien, BA, Oak Ridge National Laboratory, PO Box 2008, Oak Ridge, TN*

The goal of this research project is to present to the forensic community a novel and accurate methodology for determining the postmortem interval.

This study was conducted to characterize the chemistry associated with the decomposition of human remains with the objective of identifying time-dependent biomarkers of decomposition. The purpose of this work was to develop an accurate and precise method for measuring the postmortem interval (PMI) of human remains. Eighteen subjects were placed within a decay research facility throughout the year and allowed to decompose naturally. Field autopsies were performed and tissue samples were regularly collected until the tissues decomposed to the point where they were no longer recognizable (encompassing a cumulative degree hour (CDH) range of approximately 1,000 (3 weeks). Analysis of the biomarkers (amino acids, neurotransmitters and decompositional by-products) in various organs (liver, kidney, heart, brain, muscle) revealed distinct patterns useful for determining the PMI when based on CDHs. The initial results of this study demonstrated that one particular compound, oxalic acid, is an important determinant which affects PMI decisions. This compound was not initially targeted as important in PMI determinations, but was discovered incidentally. Oxalic acid derivatizes easily and is readily detectable in even the earliest tissue samples with a characteristic molecular ion of $m/z=261$. This compound, given time, then goes through a reduction reaction, apparently converting a $C=O$ group to a methylene group producing an oxalic acid derivative with a molecular ion at $m/z=247$ and is subsequently identified as hydroxyacetic acid (glycolic acid). This reduction reaction occurs at different times (CDHs) depending on the tissue type and is an informative PMI indicator by itself.

Other important compounds, which have been found to be reproducible between corpses, include a variety of amino acids and gamma amino butyric acid (GABA). In order for a compound to be relevant for PMI determinations in this study, its ratio compared to other biomarkers must be reproducible over time. Initial tissue surveys indicated that the common, odoriferous amine indicators of decomposition, cadaverine and putrescine, would be useful biomarkers. Unfortunately, this was not the case in this study. While the concentrations of these compounds were quite abundant ($>3,000$ ng/mg tissue) in some instances, the values (between corpses) were quite inconsistent as were the precursors of these compounds (lysine and ornithine). GHB was also a disappointment as a useful biomarker.

Since every death involves its own unique set of circumstances, the model was designed to take into account the many ways in which individuals perish. To accomplish this, the model was developed to encompass more than one indicator organ. For instance, if the individual's heart was damaged by trauma, there are four other organs from which to obtain useful data. The more organs used, the narrower the PMI becomes. Crossmatching PMIs from several organs can result in intervals as narrow as five CDHs, a time frame below the ability of the investigator to obtain reliable temperature data. This model also has the distinct advantage that additional information about the victim, such as weight, is not required since the model was developed based on ratios between the biomarkers and not absolute values. One of the interesting results to emerge from this study was the observation that every organ studied produced such a varied assortment of complex biomarker information. Intuitively all the organs should possess a relatively similar

composition. While the water content and assortment of cellular enzymes varies from organ to organ, the basic building blocks should be quite similar. During putrefaction, the abdominal organs (kidney, liver) are exposed to different bacterial populations than the thoracic organs (heart, lungs) and while this may produce varying results initially, it appears as if the tissue still exerts its "personality" long after decomposition has progressed to the point where the organs are no longer recognizable.

It has been demonstrated that proper use of these methods allows for PMIs so accurate that the estimate is limited by the ability to obtain correct temperature data at a crime scene rather than sample variability.

Postmortem Interval, Time-Since-Death Determination, Tissue Composition

G64 Effect of Ant Activity on Decompositional Rates and Estimation of Postmortem Interval: A Case Study

William C. Rodriguez, III, PhD, Office of the Armed Forces Medical Examiner, Armed Forces Institute of Pathology, 1413 Research Boulevard, Building 102, Rockville, MD*

The goal of this research project is to demonstrate the problems encountered when estimating the postmortem interval in cases involving blowfly and ant invasion of human remains. This presentation will provide insight into foraging behavior of ants on blowfly larvae which can significantly retard the decompositional process and lead to false assumptions of a short postmortem interval.

The use of forensically significant insects to estimate the postmortem interval is well established. Analysis of insects for the estimation of the postmortem interval is primarily based on the development of the fly. The fly families commonly utilized in these analyses are the Calliphoridae (Bottle Flies), Sarcophagidae (Flesh Flies), and Muscidae (House Flies). Postmortem estimates provided by these insects are most accurate within the first thirty days, and involve the determination of the larval developmental age under reported environmental conditions. Adult flies are attracted to a body within minutes to hours after death. Each female is capable of ovipositing hundreds of eggs on the deceased which hatch within approximately twelve to twenty-four hours. The newly emerged larvae migrate about the body feeding with a ravenous appetite.

Not only are flies attracted to a decomposing body, but a large array of insects, including beetles, wasp, and ants are, too. The successional pattern of these carrion frequenting insects is quite unique as some come to feed on the decomposing tissues, while others prey upon other insect species attracted to the body. Ants, for example, are commonly associated with a decomposing body, and are typically observed shortly after death or during the early postmortem phase. Many small punctate or scratch type lesions may be observed on a body which are the result of postmortem ant attack. Soft tissue injury resulting from postmortem ant attack is many times misinterpreted by inexperienced examiners as the result of antemortem trauma.

Ants are not only attracted to a decomposing body corpse as a food source, but also as an opportunistic event by which the adult ants feed on fly eggs and larvae. Entomological studies have demonstrated that scavenging ant colonies are capable of removing fly eggs and larvae which have been deposited on a corpse in such numbers as to actually slow the rate of decomposition. Early removal of fly eggs and larvae many times leads to the misconception of a short postmortem interval. In cases involving postmortem interval estimates based on entomological evidence, the presence or absence of ants should be taken into account.

One such case in which postmortem ant activity was initially overlooked involved the shooting death of a young male in Washington State. In early May 2000, the body of a twenty-two year old Caucasoid male

was discovered in a partially wooded area of the US Army post, Ft. Lewis, Washington. During the examination of the death scene, investigators noted the presence of a large number of red and black ants crawling over the corpse. The only other carrion frequenting insects noted in context with the remains were a few fly eggs which were located in the hair of the scalp.

Examination of the body found the decompositional state to be moderate, with exposed epidermal tissues exhibiting a leathery consistency with an orange-brown discoloration. A white-colored mold was also noted growing on exposed body surfaces. Rigor was pronounced, but easily broken with pressure, and livor was fixed. The internal organs were in a relatively good state of preservation. Cause of death was attributed to multiple gunshot wounds to the head, one to the right parietal area which exited the left parietal area, and a second which was located along the occiput, which exited at the nose.

Based on the minimal state of decomposition and the absence of blowfly larvae and unhatched fly eggs, the postmortem interval was thought to be relatively short, approximately twenty-four to forty-two hours. A secondary review of the decompositional findings and reported environmental conditions suggested a longer postmortem interval, approximately four to six days. The wooded terrain and loose soil conditions along with the considerably cool temperatures and precipitation were found to be conducive to retarding the decompositional changes. Cool temperatures and intermediate precipitation also acted to slow degradation of the body by limiting carrion insect activity, specifically that by blowflies. The limited number of blowfly eggs and absence of larvae were attributed not only to the inclement weather conditions, but in large part to the foraging activity of ants inhabiting the corpse in large numbers. As a result of the ant activity and environmental conditions, the degradation of the corpse was significantly retarded.

Investigation into the death revealed that the deceased had been murdered by another soldier approximately five and a half days prior to the discovery of the corpse. A suspect later confessed to authorities that the shooting was accidental; however, evidence revealed the shooting to be intentional and robbery to be the motive. The accused was found guilty and sentenced to life in prison. When faced with estimating the postmortem interval, investigators should take into account not only environmental conditions which are conducive for delaying decomposition, but the presence of foraging ants which can delay the degradation of the corpse by eradication of blowfly larvae.

Decomposition, Entomology, Postmortem Interval

G65 Forensic Entomology: Decomposition in Cars

Ian Dadour, PhD, Centre for Forensic Science, University of Western Australia, Nedlands, Australia*

The goals of this research project are to determine the entomological succession on a decomposing pig inside a vehicle following its sacrifice by CO poisoning (suicide pig), to calculate the time of decomposition of a suicide pig and determine temperature fluctuations inside vehicles.

Decomposing animal tissues provide an opportunity for flies to utilize the fauna and flora of microorganisms. Cadavers undergo a series of predictable changes during decomposition, and are “visited” by a succession of flies and other insects. This ordered process has handed us an invaluable tool for estimating the age of cadavers (post mortem interval), and the biology of this process has resulted in the science of Forensic Entomology. One current program at UWA is determining the post mortem intervals of pigs decomposing in vehicles (simulated suicides).

The significance of this research is: the requirement by police, coronial and justice systems for accurate information on cadavers, particularly in regard to homicide and suicide, and the accuracy of the

Post Mortem Interval (PMI) which depends on the available knowledge base, and which in most cases is dependent on a number of facts and assumptions concerning insect biology, behavior and ecology. It is the assumptions that require investigation especially in cases of suicide and suicide/homicide. The police service and the justice systems are constantly expressing concern about the accuracy of the PMI.

Most suicides conducted in vehicles happen in isolated areas where the vehicle is parked in wooded areas for the purposes of concealment. Generally, this is a shaded area or an area with minimal exposure to the sun. The methodology includes sacrificing 45kg pigs using CO gas. Following death, the pigs are quickly dressed and placed inside a vehicle. CO gas is pumped into the vehicle for another 5 hours. Decomposition is recorded using infrared video cameras as well as daily observations of insect activity. Decomposition rates are compared with two other pigs (one pig sacrificed by CO poisoning and the other by head bolt) decomposing under normal conditions. Each pig has a datalogger placed inside its throat, abdomen and colon. The temperature inside the car is also measured and compared with the recorded ambient temperature.

One particular aspect of this work is the modeling of temperatures inside vehicles. To determine how a body decomposes inside a vehicle, it is important to understand the temperature changes inside a vehicle. The temperatures inside the trunks and passenger compartments of 30 vehicles (sedans) have now been measured under a variety of conditions. These include full sun and shade and partial shade. Vehicles are placed in a north/south and east/west position and the temperature in each vehicle is monitored every 30 minutes over a three week period. This work has now been extended into community service especially in cases where young children or animals are confined to cars on hot days. This study demonstrates how vehicle temperatures increase in a parked situation in direct sunlight with windows completely closed and with windows slightly open.

Forensic Entomology, Postmortem Decomposition Inside Vehicles, Entomological Succession

G66 Deceased, Dismembered, and Disarranged: Central Nervous System Consequences of an Unusual Body Disposal Strategy

John M. Andrews, MD, Jeffrey P. Gutstadt, MD, Hideo H. Itabashi, MD, Steven J. Dowell, BS, Mark S. Schuchardt, Department of Coroner, County of Los Angeles, 1104 North Mission Road, Los Angeles, CA; and Elizabeth A. Miller, PhD, Department of Anthropology, California State University, Los Angeles, CA*

The goal of this research project is to present an unusual thermal artifact of intracranial contents in a dismemberment case, and suggest mechanisms by which it develops.

Postmortem criminal dismemberment of the human body may be performed in the context of one or more of several possible motives, including but not necessarily limited to, ease of disposal of a body to prevent discovery of the death; to confound body identification; aggressive body mutilation in homicides reflecting intense emotion on the part of the assailant; as a symbol intended to intimidate or otherwise convey some message to others; during the course of ritualistic behaviors associated with either a natural death or with a homicide; or in the context of behavior related to necrophilia or other forms of psychopathology. Based on information available at the time of this report, the victim presented herein was dismembered for the purpose of covert disposal.

The dismembered body of a 73-year-old male was found in refrigerator and freezer compartments of his private residence. He was last seen alive three weeks prior to discovery of the remains. Recovered body parts included torso, head, neck, hands, feet and several smaller tissue fragments but did not include the remainder of the extremities.

Body parts were found in a variety of containers and wrappings, and the methodology suggested an above-average level of dissection skill and anatomic knowledge. For example, the neck was disarticulated between C7 and T1, and the torso between L2 and L3 with minimal damage to adjacent bone.

Tool mark analysis was consistent with use of at least two instrument classes: a saw and a sharp instrument such as a knife. The partially dissected head and neck was found in the refrigerator, incompletely submerged in brownish liquid in a large metal pot with lid. The color, texture and histologic appearance of the head and neck tissues were consistent with having been subjected to prolonged boiling. No other body parts demonstrated evidence of thermal injury; most were frozen.

The general autopsy findings included generalized atherosclerosis, (with an estimated 75% obstruction of the right coronary artery and 50% obstruction of the left anterior descending coronary artery), myocardial interstitial fibrosis, pulmonary emphysema, and post mortem autolysis/putrefaction. The scalp had been removed. Gross, microscopic, and radiologic examination of body parts revealed no definite evidence of antemortem trauma. Since the evidence that dismemberment was postmortem and a negative toxicology examination did not exclude foul play leading to death (particularly given other information discovered during the investigation) the cause and manner of death was listed as undetermined.

The primary focus of this presentation is on the appearance of the intracranial contents. There was no skull fracture. Removal of the cranial vault revealed numerous curd-like tissue fragments varying in color from gray to tan to dark brown, filling a very enlarged epidural space. Removal of this material from the epidural space exposed a dark brown structure with the shape of a miniaturized brain, firmly adherent to the base of the skull. The dura demonstrated two localized defects bridged by meningeal and cerebral vessels. Subsequent study revealed the epidural space to be filled with brain tissue admixed with a small amount of blood. A widely distributed, very thin layer of subdural blood was also present. Internal brain architecture was largely obliterated, having been replaced by intradural fragmented brain tissue and blood similar to that present in the epidural space but much more tightly packed.

This very unusual type of disarrangement of intracerebral contents has rarely been reported in the forensic literature, and, to our knowledge, has been described only in burned bodies. This case shares some features resulting from prolonged exposure of tissues to high temperature with the reported burn cases, but is devoid of burn artifacts such as skin splitting, scalp charring or heat-induced skull fractures which are typically seen in the latter. The open cervical canal in our case excludes global increased intracranial pressure as a contributing factor. Our observations, combined with information derived from a confession by the suspect, are more consistent with this unusual artifact being the consequence of a combination of factors that must be (but apparently rarely are) simultaneously present. These factors may include: a sufficient amount of moist heat (e.g., by immersion or by continued presence of cerebrospinal fluid) delivered over a sufficiently long period; disproportionate shrinking of dura mater relative to brain parenchyma; increased friability of dura mater and brain tissue secondary to thermal effects; relatively weak adhesion (focally or diffusely) between dura mater and inner table of skull; development of a dural defect which allows escape of brain tissue into the newly created epidural space resulting from tissue shrinkage; and variable appearance of the resultant epidural brain tissue depending not only on the degree of brain tissue thermal damage but also the nature of the dural defect (e.g., size, and whether or not it is bridged by vessels and/or meningeal tissue creating a sieve-like orifice through which the brain tissue must pass before entering the epidural space). This hypothesis, if correct, may explain both the low incidence and atypical appearance of this type of heat-induced postmortem artifact.

Dismemberment, CNS, Thermal Artifact

G67 Detection of Chemical Signals by the Parasitic Wasp *Microplitis Croceipes*

Jeffery K. Tomberlin, PhD*, W. Joe Lewis, PhD, Marco D'Alessandro, BS, and Moukaram Tertuliano, PhD, Department of Biological and Agricultural Engineering, PO Box 748, Tifton, GA

The goals of this research project are to teach participants on the ability of insects to learn various chemicals of legal importance will be presented. We determined that the parasitoid wasp, *Microplitis Croceipes*, is an excellent candidate for the development of a biosensor for the detection of ultra-low levels of forensically important compounds.

Proposition: The wasp, *Microplitis croceipes*, can detect and learn various compounds of forensic importance at thresholds lower than that detectable by modern automated equipment.

Over the course of the past two years protocols for training the parasitoid wasp *M. croceipes* to learn and detect trace amounts of non-native chemicals have been developed. Behaviors associated with the detection of these odors, such as head bobbing, antennating, and complete rotation of their bodies over the source of the odor, have been identified.

Appetite can be used to teach wasps to learn and identify specific odors. Female wasps starved for 48 hours were provided 33% sugar-water solution on an approximately 2 mm² piece of filter paper immediately surrounded by 7-9 holes (each approximately 1 mm diameter) placed in an aluminum foil cover of a 3 cm plastic tube connected to a volatile collection chamber (containing the compound), a flow meter (18 ml per min flow rate), and a motor generating positive air flow. The wasps were allowed to feed on the sugar water for 10 seconds during three sessions, during which time they were also exposed to the chemical odor. Following these training sessions, it was determined that the wasps associate these odors with food and will enter a series of predictable behaviors attempting to locate a food resource when exposed to these compounds.

In order to determine level of learning and sensitivity, individual wasps were placed near a hole (1 mm diameter) in the center of a Teflon cap on a small glass cylinder. The compound was delivered to individuals using the system previously described, but at a much lower rate of 6-8 ml per minute. Percent response was recorded for various concentrations of each chemical examined. For a check, the trained wasps were exposed to air passed through a volatile collection chamber not containing the chemical. A positive response was defined as the wasp entering the hole or bobbing its head into the hole.

Results recorded for wasps trained to chemicals commonly used to train canines to locate human remains (i.e., putrescine and cadaverine) were investigated. To date, results recorded indicate that *M. croceipes* can detect concentrations of certain chemicals < 4 ppb, which are much lower than thresholds determined for a mechanical nose.

Current research is focusing on the development of a mass-training system for these wasps, as well as a system for housing the trained wasps, processing samples, and that signals investigators of a positive detection of a particular compound of interest. Additionally, the ability of *M. croceipes* to detect compounds released by explosives (i.e., 2,4 DNT, a major by-product released from landmines and other explosives), as well as narcotic metabolites, is being investigated.

Information gathered from this research may be used to develop biosensors utilizing the parasitic wasp *M. croceipes* to detect ultra-low concentrations of volatiles released from narcotics and explosives in airports or other locations deemed important. Additionally, such biosensors may be useful in locating human remains that have been buried for an extended period of time.

Associative Learning, Parasitoid, Biosensor

G68 Suicidal Air Rifle Wound of the Head

Jennie V. Duval MD*, Dallas County Medical Examiner's Office
Southwestern Institute of Forensic Science, Susan B. Allen BS, Dustin
S. Engel BA, Criminal Investigation Laboratory Firearms Section, and
Jeffrey J. Barnard MD, Dallas County Medical Examiner's Office,
5230 Medical Center Drive, Dallas, TX

The purpose of this paper is to report an unusual means of suicide and to increase awareness of the lethality of air-powered weapons.

Firearm deaths are extremely common in a busy medical examiner office. In 1999, the Dallas County Medical Examiner's Office (DCME) investigated 533 firearm deaths including 233 (44%) homicides, 283 (53%) suicides, 6 (1%) accidents and 9 (2%) undetermined causes of death. The majority of the firearms were handguns (75%), followed by shotguns (15%) and rifles (10%). Firearm injuries accounted for 283 (67%) of the 431 suicides investigated by the DCME in 1999. Though technically not firearms since they are powered by compressed air rather than gases produced by burning propellants, air guns and air rifles are capable of producing serious and, rarely, lethal gunshot wounds. A review of the computerized database of all cases investigated by the DCME from 1992 to the present revealed no previous deaths due to air weapons. The following is a case of a suicidal air rifle wound of the head.

A 33-year-old white male was discovered deceased by his mother on the living room floor of his locked apartment. Beside the body was a .177 caliber air rifle with an empty chamber. A mostly full, 250 count box of .177 caliber pellets was found in the same room. The mother had last spoken to her son by telephone the previous evening. The son had a medical history of hypertension and depression including two prior suicide attempts by drug overdose. He had recently been convicted of driving while intoxicated. Propranolol and Prilosec medications with recent prescription dates were found in the apartment. No suicide note was found.

Autopsy revealed a tiny round entrance wound in the left temple measuring approximately 1/16 inch in diameter surrounded by a thin rim of marginal abrasion. No muzzle abrasion was identified. No exit wound was present. Radiographs of the head revealed a single radiodense object in the right superolateral cranial cavity. Internal examination revealed perforation of the left temporalis muscle, the left squamous temporal bone, the left inferolateral parietal lobe, the body of the corpus callosum and penetration of the right parietal lobe. A tiny flattened lead pellet was recovered from the cerebral cortex of the right superior parietal lobe of the brain. The remainder of the autopsy examination was negative. Toxicology testing revealed 0.17% ethanol in postmortem femoral blood and 0.23% ethanol in vitreous fluid. The drug screen was negative.

The weapon was identified as a Benjamin and Sheridan Model 397PA Bolt Action Pump Air Rifle, a multi-stroke swinging-arm type of pneumatic airgun, manufactured by Crosman in August 2000. The ammunition was identified as Copperhead Model P177 (7.9 grain) Pointed Pellets. The advertised muzzle velocity for this air rifle is up to 800 fps (244 mps) which is comparable to the muzzle velocity of a .38 special handgun. Muzzle velocities of 150 fps and 200 fps are reportedly required to perforate skin and bone, respectively.

Review of the English literature since 1966 reveals several reports of air rifle and air gun injuries and fatalities. In fact, air weapons reportedly cause 30,000 injuries per year in the United States and are the main cause of ocular trauma and subsequent enucleation in children and young adults in Canada. Moreover, dozens of fatalities have been reported to the United States Consumer Product Safety Commission. Most of the reported injuries and deaths involve children with accidental penetrating wounds of the chest and head. Intracranial injuries are relatively rare and typically enter via the orbit, neck, the thin frontal bone of children or the squamous temporal bone of children and adults. Only two homicides and four suicides by air weapons have been previously reported. Three of the suicides and both homicides were the result of

intracranial injuries. This case report of a suicidal air rifle wound of the head again illustrates the commonly unrecognized lethal potential of air weapons.

Air Rifle, Suicide, Atypical Gunshot Wound

G69 Pediatric Injuries: Can CPR Related Injuries Mimic Inflicted Injuries?

Chitra Rao, MBBS*, Forensic Pathologist, Regional Forensic Pathology Unit, General Site -HHS, 237 Barton Street East, Hamilton, Ontario, L8L 2X2, Canada

The goals of this presentation are to help attendees understand what types of injuries CPR can cause and be able to differentiate them from inflicted injuries.

Medical experts are often asked whether CPR rendered either by the caretaker or medical personnel could have caused the injuries present in a case of child abuse. This prompted us to undertake a retrospective review of the autopsy findings of all pediatric deaths involving children 2 1/2 years of age and under done in our forensic unit over a 13-year period (1989 to June, 2001). Both clinical and autopsy reports were utilized in order to examine patient demographics, clinical findings, duration of CPR, person/persons administering CPR, cause and manner of death. 234 children were included in this study out of which 173 of them received CPR. The average duration of CPR was 40 minutes with the range being 6 minutes to 259 minutes. 15 out of 173 children sustained minor injuries attributed solely to CPR. Despite the lengthy resuscitative attempts by those with varying skills and levels of performance, there was not a single rib fracture.

No significant injuries were found in our series apart from minor chest contusions. There was one case of retinal hemorrhage and another case of small hemorrhage in the orbital fat without any other evidence of injury that were attributed to CPR.

Our study emphasized that child abuse should be considered in the presence of multiple and major injuries even after a history of prolonged CPR.

CPR, Inflicted Injuries, Pediatric

G70 When "Non-Terminal" Is Fatal—Medical Examiner Cases of Fibromyalgia Fatalities

Carolyn Bertrand, PhD, Forensic Psychology Research Fellow, County of San Diego, Mark J. Shuman, MD, MS*, Deputy Medical Examiner, County of San Diego, and Brian D. Blackbourne, MD, Chief Medical Examiner County of San Diego, San Diego, CA

The goal of this research project is to present medical examiner cases in which the decedents were young, female and had non-terminal illness as a primary diagnosis. The speaker will discuss the incidence and aspects of forensic pathology, investigation, psychology to assist in the future handling of similar cases nationwide.

The authors reviewed medical examiner cases with a history of Fibromyalgia (FM) for the 42 month period January 1998 through July 1, 2001. 17 cases were identified as containing enough historical and death scene detail for study. The mean age was 48, and all were female, though one decedent was undergoing gender change to male. Forty-seven percent were determined to be accidental deaths, nearly exclusively secondary to overdose with prescription medications dispensed to treat the symptoms of FM. Thirty-five per cent were classified as suicide. We found these cases to be complex, and required the utmost diligence in investigation by the medical examiner staff, toxicologists, and forensic pathologists. The high incidence of accidental and suicidal deaths, particularly by overdose of prescription medications, indicates that further study and education designed for the forensic community about chronic pain patients is necessary in obtaining the most

accurate cause and manner of death in future cases. Treating physicians may also benefit from additional education on the risks of polypharmacy and benefits of multidisciplinary pain management in this patient population.

Accidental Death, Fibromyalgia, Death Investigation

G71 Rapid Death From Phlegmonous Gastritis Associated With Lymphoma

Lakshmanan Sathyavagiswaran, MD*, Chief Medical Examiner, Coroner, Los Angeles County, 1104 North Mission Road, Los Angeles, CA

The goal of this research project is to make attendees aware of this rare pyogenic infection of the stomach and predisposing factors causing rapid death.

Acute phlegmonous gastritis is a serious illness, which fortunately is rare, with an estimated world incidence of 2.5 cases per year. It is a pyogenic infection of the stomach beginning as localized cellulitis which may either become a circumscribed abscess or a diffuse phlegmon. In 70% of cases hemolytic streptococci have been isolated. Other organisms including Ecoli, staphylococcus, anthrax bacillus have been cultured in some cases. Alcoholism, chronic gastritis, debility, peptic ulcer, previous gastric surgery and hypoacidity of gastric secretions are considered as predisposing factors to the disease. Prompt diagnosis is essential in view of high mortality without therapy. The case is hereby reported to renew awareness of the condition as a cause of death and its possible occurrence in compromised hosts with malignancy or steroid therapy.

Case Report: A 61-year-old female reported to the emergency room of a local hospital one December evening with complaints of continuous vomiting since that morning accompanied by a fever of 105. Denied hematemesis or diarrhea. Had a history of rheumatoid arthritis and prednisone therapy. In the emergency room she had a temperature of 102.6, pulse 100 R 32 BP 120/70 mmHg. Abdomen examination was benign. Chest examination revealed tubular type breath sounds in the bases. Arthritic deformities were seen in hands. Otherwise, physical examination was unremarkable. Chest x-ray showed right base infiltrate. White blood count was 11,600 with 76% polymorphs and 20% bands. Initial impression was gastritis and basilar pneumonia and she was discharged on Tylenol, ampicillin and Compazine. No cultures were done. At home, she apparently spent a restless night and was found unresponsive the following morning. She could not be resuscitated and was pronounced dead by the paramedics.

Medical Examiner autopsy findings revealed (1) rheumatoid arthritic deformities, hands, (2) enlarged mesenteric lymph nodes with firm white cut surface confirmed microscopically to be lymphoma, (3) fatty changes in the liver, (4) diverticulosis, sigmoid colon, (5) cholelithiasis, (6) edematous stomach wall with gray-brown purulent material extruding from pyloric cut surface from between the muscularis and mucosa. Microscopically neutrophilic infiltration of muscle and mucosa was present with microabscess formation. Since the body was embalmed, no culture could be done but gram stain revealed gram positive cocci in chains consistent with streptococci.

Conclusion: One should have a high index of suspicion for this condition especially in a patient with high fever, epigastric pain, vomiting, normal amylase in the absence of radiologic findings of perforated viscus and presence of nondistendible stomach on Barium studies with low incidence of mucosal abnormality. Therapy would be vigorous broad spectrum antibiotic therapy to include a penicillin type drug and prompt laparotomy.

If only antrum is involved, resection can be done; otherwise, a total gastrectomy may be necessary. Mortality rate is high with medical therapy alone.

Phlegmon, Gastritis, Immunocompromised State

G72 Victim-Offender Relationship in Florida Medical Examiner District 8

Shuala S. Martin, MA*, C A. Pound Human Identification Laboratory, University of Florida, 124 Fisherman Road, Satsuma, FL

The goals of this research project are to establish the correlation between victim-offender relationship and motive, weapon choice, and number of injuries inflicted for 57 homicide cases from Florida Medical Examiner District 8, 1992-1996. Relationship categories are clearly differentiated and new motive categories are introduced. All variables are established independently.

The study of victim-offender relationship is a young field and has received limited assessment. Nevertheless, research in this area has been integral in broadening our understanding of the interplay between victim and perpetrator during the crime event. Previous research of homicide victim-offender relationship has focused mainly on demographic variables of the victim and the offender. In addition, studies of victim-offender relationship with regard to homicide motive have sought mostly to differentiate homicides occurring in conjunction with other felonies, usually between strangers, from all other homicides. Thus, default associations have been created between relationship and motive. Motives have traditionally been denoted as either expressive in nature (as an expression of emotion) or instrumental in nature (occurring for gain, usually financial gain). However, such severely delineated motive categories fail to acknowledge impetuses for homicide that contain both emotional and instrumental aspects such as revenge. This paper seeks to expand upon and clarify previous research in the area of homicide victim-offender relationship by clearly differentiating relationship categories, introducing new motive categories that alleviate deficiencies introduced by motives that are both expressive and instrumental, and defining relationship and motive independently from each other. In addition, this paper will address areas that have received little attention, i.e., the association between victim-offender relationship, weapon choice, and number of injuries inflicted.

Methods: Relationships are divided into primary and secondary categories. Primary relationships include intimates, relatives, and friends. Secondary relationships include acquaintances and strangers. Primary and secondary relationship categories are differentiated based on the level of emotional attachment and positive interaction established between victim and offender. Motives are denoted as dispute/conflict, revenge, and felony type (representing all homicides committed in conjunction with other felonies). Disputes/conflicts are further differentiated between those of a romantic nature and those not of a romantic nature. Weapons are differentiated between firearms and all other weapons, or a combination of the two. Number of injuries inflicted is either singular or multiple.

The sample of 57 homicide victims stems from 177 total homicide cases processed in Florida Medical Examiner District 8 between 1992 and 1996. All state-mandated executions, victims of motor vehicular homicides, child victims of homicide, victims killed during law enforcement activity, homicides ruled accidental in nature, homicides involving suspected mental illness on the part of the offender, and homicides for which some or all information is unknown are excluded from the study. Offender data were collected from the files of the Office of the State Attorney, Florida Judicial Circuit 8.

Results: Significant correlation exists between victim-offender relationship and homicide motive ($p<.0001$). Sixty-three percent of disputes and conflicts occurred between people in primary relationships, and felony type homicides occurred with ten times more frequency between individuals in secondary relationships than in primary relationships. Revenge killings occurred in much higher frequency in secondary relationships. Despite a default association between romantic disputes and primary relationships, no bias is introduced. When subsuming all romantic disputes into a general dispute/conflict category, correlations remain significant ($p=.0012$). In addition, when all romantic disputes are removed ($n=47$), correlation occurs at the $p=.0375$ level. No correlation

is found between victim-offender relationship and either weapon choice or number of injuries inflicted ($p>.05$).

The new motive categories provide a clearer assessment of the variety of causes behind homicide while not introducing bias. In addition, all variables are determined independently, thus allowing for evaluation of the correlation between each of the variables without default associations. Further analysis of additional factors influencing weapon choice and number of injuries inflicted is needed to fully understand the interaction of these characteristics with victim-offender relationship.

Victim-Offender Relationship, Homicide, Victimology

G73 Medical Malpractice: A Case History Study by the Forensic Medicine Section From Bari

Nunzio Di Nunno, MD, Alessandro Dell' Erba, MD, Francesco Vinci, MD, Stanislao Mangiatordi, MD, Luigi Viola, MD, and Francesco Vimercati, MD, Sesione di Medicina Legale, Dipartimento di Medicina Interna e Medicina Pubblica, Bari University, Policlinico, Piazza G. Cesere n. 11, Bari, Italy*

The goal of this research project is to study the real entity of the medical malpractice phenomenon, the medical actions at risk and their incidence on the mortal event.

Legal actions arising from deaths derived from presumed malpractice and the autopsies arranged by the Judicial Authority, in cases of alleged of medical professional responsibility, are progressively increasing. This phenomenon reflects above all the distrust by the public for the medical community and towards public and private health care institutions. This feeling is amplified by the mass media which, seeking a larger audience, points out and emphatically chronicles single cases of real or presumed iatrogenic injury. In any event, the media are not disposed to reporting the ascertained cause of the danger. Moreover, the possibility of obtaining enormous compensation, increased above all by insurance, either by the single doctor or by the health offices, has decreased more and more the number of judicial proceedings often started on the basis of simple suspicion. On this basis, an important instrument to clarify the situation is surely represented by the autopsy. For this reason, highly qualified and experienced professionals who are able to point out the cause of death and to identify the possible wrong conduct and its exact consequences must carry out the autopsy. Only in this way is it possible to eliminate definitively any doubt about the doctor's action.

For the reasons reported above, it is easy to understand the utility of a study that verifies, with scientific precision, the real dimensions, characteristics and typology of the putative malpractice. To achieve this aim, we examined all data based on the single cases of autopsy occurring in the last decade in the Forensic Medicine Section of the Internal and Public Medicine Department of the University of Bari. We selected the malpractice cases and, among them, we identified the ones in which a death was attributed to a medical error. We differentiated them from the cases in which a death was not related to the medical conduct.

This work also permitted us to document the incidence of the malpractice and to identify the medical and surgical branches more frequently involved. We took into consideration the decade 1991–2000. In this period 2,123 autopsies were performed in our section and 364 of them involved cases in which the medical responsibility was implicated and for which a judicial proceeding was started. In this group we distinguished three different situations: 1) a medical error caused the death of the patient; 2) a medical error, by all accounts, was not directly attributed to the patient's decease or death; and 3) the medical conduct was correct.

In the sample concerning the 364 cases of presumed malpractice, females represented 48% and males, 52%.

A correlation between malpractice and patient death was demonstrated in 30% of the cases; conversely, the medical conduct was correct in 55% of the cases; the medical error could not be directly attributed to

the death of the patient in 15% of the cases. The cases of verified professional responsibility involved 84% of the public institutions, and for the remaining 16% private health care institutions. The highly specialized institutions involved were 31%. The remaining 69% were cases involving lesser-specialized institutions. The service occurred in a public hospital in 87% of the cases. Only 10% of the cases occurred during emergency situations and the 3% in public clinics. The surgical disciplines were involved in 52% of the cases; the medical ones in 41%; and, the anaesthesiology in the remaining 7%. Among these disciplines, obstetrics and gynaecology were involved in 16% of the cases; general surgery, in 14%; internal medicine, in 9%; orthopaedics, in 8%; first aid, 8%; anaesthesiology, in 7%; neurosurgery, in 5%; cardiology, in 4%; pediatrics, in 3%; ear, nose and throat medicine, in 2%; and, 24% in all other disciplines.

Another interesting aspect pointed out by our work is that the malpractice claim is not always linked to substandard conduct of a single doctor; in some cases, it was possible to notice and to distinguish other fundamental causes. These could be summarized as follows: 1) responsibility of the leading doctor in regard to the internal organization of the hospital stay department; 2) responsibility of the general director or of the medical director because one or both did not address in a timely and adequate manner the inefficiency, the insufficiency, the deficiency, of the defects of the institutions and/or the medical equipment; 3) responsibility of the local politicians and administrators connected to the institutions at the medical site and/or of medical equipment suitable and adequate for the population and the site.

The case history research must be considered to be partial, and, at the moment, in progress. In fact, we are aiming at a further, more intense investigation. It is a preliminary methodological approach to understand the malpractice phenomenon in Apulia where the current study has been limited to the autopsy case study of our Forensic Medicine Section.

Malpractice, Medical Error, Autopsies

G74 Nuclear and Mitochondrial DNA Analyses Following X- and Gamma-irradiation

J.C. Upshaw Downs, MD, Alabama Department of Forensic Sciences, PO Box 3510, Auburn, AL, S. Elaine Scott, MS, Alabama Department of Forensic Sciences, 2451 Fillingim Street, Mobile, AL, William Jones, Armed Forces Institute of Pathology, 2451 Fillingim Street, Mobile, AL, Robert Neyland, PhD, Maria Jacobsen, and Paul Mardikian, Warren Lasch Conservation Center; Former Charleston Naval Base 1250 Supply Street, Building 255, North Charleston, SC; Sudhir K. Sinha, PhD, ReliaGene, 5525 Moues Street, New Orleans, LA; and Douglas W. Owsley, PhD, National Museum of Natural History, Smithsonian Institution, Department of Anthropology, Washington, DC*

The goals of this research project are to determine if gamma- and/or x-irradiation adversely affect nuclear and/or mitochondrial DNA for identification purposes.

Identification of human remains is often accomplished by analysis of nuclear or mitochondrial DNA. Nuclear DNA (nDNA) allows a statistically more significant result while mitochondrial DNA (mtDNA) allows results in cases of advanced decomposition where nDNA identification is not possible. Because both methods, nDNA and mtDNA, are often used in cases of advanced decomposition, including skeletonization, the materials under study typically have been or require radiographic analysis for documentation, foreign body recognition/localization, skeletal assessment, and possible identification. Limited data are available regarding the effects of such ionizing radiation exposure on nDNA and mtDNA analysis.

In order to assess the effects of investigator applied ionizing radiation on DNA for identification purposes, 0.5 to 2.0 gram portions of vertebral body (from five co-mingled skeletal remains at 375 day post mortem interval), scalp hair (single living donor), and blood (single living donor),

were exposed to iridium 192 at 3 inches distance for 1 hour (7552r total) and 200 Kv at 4.5 ma x-irradiation at 7.5 inches distance for 2 minutes (7000r total). The exposed samples and matching non-exposed controls were subsequently analyzed by polymerase chain reaction (PCR) – short tandem repeat (STR) at 8 STR loci and amelogenin for nDNA and sex typing.

The fresh blood and hair samples gave consistent results at all eight loci by PCR-STR. The bone samples yielded positive results at up to two loci and positive amelogenin results. One vertebral body was analyzed for mtDNA at hypervariable regions I and II. Nine polymorphisms consistent between samples were identified in the control and x-irradiated specimens. The gamma-irradiated sample yielded no mtDNA results due to insufficient or excessively degraded mtDNA.

These results show that neither x- nor gamma-irradiation, in amounts typically employed in processing of skeletal remains, adversely affects nuclear or mitochondrial DNA for identification purposes.

Identification, DNA, Irradiation

G75 Recovery and Processing of Co-Mingled Remains Following Extended Submersion Period Facilitated by Computer Animation

J.C. Upshaw Downs, MD, Alabama Department of Forensic Sciences, PO Box 3510, Auburn, AL; and William R. Oliver, MD, Armed Forces Institute of Pathology, Washington, DC*

The goals of this research project are to utilize multi-disciplinary approach to successfully process co-mingled remains of multiple individuals while utilizing computer animation techniques and accident reconstructionists to allow for better lay understanding of the event.

The extrication of five sets of partially skeletonized human remains from the confines of the rear seat of a passenger vehicle is described. The case was highly emotionally charged and involved extensive press coverage and charges of racial bias.

Six young adults disappeared after last being seen at a nightclub in a rural area. Their whereabouts remained a mystery for five months until the vehicle was located in a local river. Due to the intense public interest and circumstances of the case, the unprocessed vehicle was placed on a flatbed truck and transported several hours away for examination.

On inspection, it was obvious that multiple sets of human remains were co-mingled in the back seat of the vehicle. These were accessed by removing the roof and block lifting proximate materials for evaluation.

The multi-disciplinary approach to this case included motor vehicle accident reconstructionists whose evaluation showed the car entered the water at a low rate of speed (<15 mph). In order to facilitate understanding of the dynamics of this crash, a computer animation of the event was created. The latter allowed interested laity to easily grasp the complexities of the crash and injuries related thereto.

The team approach allowed a rapid resolution to the case without incident, despite one lingering question – only five sets of remains were recovered.

Motor Vehicle Crash, Submersion, Recovery

G76 Comparison of Drug Concentration in Blowflies (Diptera: Calliphoridae) and Human Tissues

Mirella Gherardi, MD, Marina Caligara, PharmD, and Luca Sironi, PharmD, PhD, Institute of Legal Medicine - University of Milan, Via L. Mangiagalli, 37, Milan, Italy*

The goal of this research project is to help participants understand the uses of forensic entomotoxicology.

The renewed interest in forensic entomology, as reflected by the great number of recent publications and increasing incorporation of entomological evidence into the routine forensic investigation, has caused us to reconsider one of the more interesting applications: entomotoxicology.

Insects feeding on a decomposing body will introduce various xenobiotics present in that body in their own tissues. For this reason, Diptera and Coleoptera can be proven to be a valuable source of toxicological information for a body in an advanced stage of decomposition, when fluids and tissues normally used for analyses are not longer present.

The significance of this approach was recently underlined by a case in which the insect larvae showed positive for secobarbital while muscle tissues tested negative. Although the use of insects as alternate specimens for toxicological analyses has been well documented, there are still areas for further research, in particular, in the relationship between concentrations of xenobiotics in insects and the human tissues and fluids.

The results presented here deal with three cases from the Institute of Legal Medicine, University of Milan, where there was an insect infestation of the body with suspected drug involvement and 16 rearings of insects from cadaver tissues where there was a known drug intoxication. After a preliminary toxicological screening of blood and urine with EMIT® and GC/MS, samples of all available organs and biological fluids were collected. Samples of liver were removed from each case and exposed to insect activity. Colonizing species were *Lucilia sericata* (Fabricius) (Diptera: Calliphoridae) and *Sarcophaga haemorrhoalis* (Fallen) (Diptera: Sarcophagidae). Collections were made of 3rd instar and post-feeding 3rd instar larvae, and, in one instance, puparia was rearing of Diptera was also conducted on tissues from traumatic or natural death as controls.

Entomological samples from both cases having postmortem insect infestations and rearings from tissues control and known drug-related death were washed with deionized water and stored at -20°C. Additional samples were fixed in boiling water and preserved in 70% ETOH for species determinations.

Prior to toxicological analyses, larvae were again washed, dried, and homogenized with deionized water. Samples of humans organs were also homogenized. Drugs detections and quantifications were accomplished using GC/MS and ONLINE techniques (Roche©). In addition to opiates, cocaine, and/or benzoilecgonine and barbiturates, we were able to detect clomipramine, amitryptiline, nortryptiline, levopromazine, tioridazine and methadone from both human tissues and the insects analyzed. All xenobiotics were detected in both feeding and postfeeding 3rd instar larvae. In two of the questioned cases, analyses of Diptera puparia and Coleoptera larvae were positive. Controls were all negative for all drugs involved. From the quantitative point of view, differences were noted between real cases and experimental rearings. All xenobiotics were more concentrated in the entomological specimens from experimental rearings than in those from the real cases.

In most instances, the concentrations of the drugs were lower in the postfeeding 3rd instar larvae than for the feeding 3rd instar larvae. Exceptions for this pattern were encountered in clomipramine and levopromazine. Both these drugs were more concentrated in the postfeeding 3rd instar larvae. Additionally, while in most instances, drug concentrations were higher in liver tissues than in larvae, in four cases we encountered cocaine concentrations higher in the larvae than in liver tissues.

Our results confirm the reliability of entomotoxicological materials for the qualitative analyses of xenobiotics. Although additional case studies are indicated to further clarify quantitative aspects of entomotoxicology, it must be kept in mind that entomological materials are easy collectible, can be analyzed by unmodified routine techniques, and are free from contaminants due to putrefaction encountered in advanced stages of decomposition.

Forensic Entomology, Entomotoxicology, Blowflies

G77 Removing External Contamination of Maggots With a Bleach Solution Without Inhibiting Genetic Analysis of Maggot Crop Contents

Jason G. Linville, BS*, Department of Biology, and Jeffrey D. Wells, PhD*, Department of Justice Sciences, University of Alabama at Birmingham, Birmingham, AL

The goals of this research project are to understand (1) the procedure for dissecting a maggot and removing its crop for DNA analysis; (2) the effect washing maggots has on reducing the risk of external contamination; and (3) the effect washing maggots has on recovering vertebrate DNA from the maggot crop.

The type of corpse a maggot has been feeding on can be identified through mitochondrial DNA (mtDNA) analysis of the maggot crop contents. The crop is a diverticulum of the anterior end of the alimentary canal. Recently, Wells *et al.* identified several situations when this type of analysis would be useful in a forensic investigation (*J Forensic Sci* 46(3):685-687). DNA analysis could help investigators identify a missing victim if maggots are discovered at a suspected crime scene in the absence of a corpse. Maggot crop analysis could also provide a forensic entomologist with another way to associate a maggot with a victim when making a postmortem interval (PMI) estimation. If insect evidence is to be used for PMI estimation, it is assumed that the insect specimen's entire development took place on the victim. Maggot crop analysis could reveal that the maggot had moved onto the victim from a different nearby food source.

When amplifying mtDNA from a new source such as a maggot's crop, the forensic analyst must consider the risk of contamination. For maggot crop analysis, the analyst must be certain the recovered DNA is from the crop and not contaminant DNA from the maggot's exterior. In the case of identifying a missing victim, exterior contamination of human origin could lead to incorrect assumptions about the identity of the missing person. Exterior contamination would also interfere with making correct inferences about whether a maggot had been feeding on multiple food sources.

Removing external contamination could be accomplished through a simple washing of the maggot's exterior. The chosen wash method should reduce the amount of contaminant DNA located on the maggot's exterior, but should not interfere with the recovery of vertebrate DNA from the maggot's crop. In this study, we investigated the suitability of using a bleach solution to sterilize the external surface of a maggot prior to crop content analysis.

Soaking them in beef blood of a different genotype intentionally contaminated maggots raised on beef liver. A portion of these maggots was soaked overnight in a bleach solution. Before crop dissection, all maggots were briefly rinsed in water in order to recover a portion of any remaining outside contaminant. All maggots were dissected to remove the crop, which was then extracted. The water used to rinse each maggot was also extracted in order to detect whether the bleach wash had removed the external contaminant. A portion of cytochrome b was amplified from all extractions using newly developed primers designed to amplify most vertebrate DNA without amplifying insect DNA. Successful amplifications were sequenced using a PE-Biosystems (Foster City, CA) 310 genetic analyzer and BigDye Terminator® sequencing kit.

In all maggots, careful dissection of the crop led to the recovery of the food source DNA without any recovery of the external contaminant. Even maggots that were soaked in contaminant blood and not washed did not show any trace of the external DNA in the analyzed sequences from the crop. However, the maggots used in this study were well preserved and had large crops (6-8 mm in length). Further research is needed to assess the risk of contamination in maggots with near empty crops that have not been well preserved.

Soaking a maggot overnight in a bleach solution does not prevent the successful recovery of vertebrate DNA from the maggot crop. As previously mentioned, DNA from the food source was recovered from all of the analyzed maggot crops. The bleach wash appeared to have no effect on DNA recovery as all crop amplifications resulted in approximately the same quantity of amplified product.

Soaking a maggot overnight in a bleach solution does reduce the quantity of external contaminant. We were unable to recover contaminant DNA from the exterior of intentionally contaminated maggots that had been soaked in a bleach solution. This contaminant DNA was easily recovered from the exterior of intentionally contaminated maggots that had not been washed or washed only in water.

Our results demonstrate that a careful dissection process prevents contamination in maggot crop analysis even when dissecting heavily contaminated maggots. Also, soaking a maggot overnight in a bleach solution greatly reduces the quantity of external contaminant without compromising the ability to recover DNA from the maggot crop.

Forensic Entomology, Maggot Crop, Mitochondrial DNA

G78 The Child Abuse Works of Ambroise Tardieu...Had We Only Taken French

C. Ferraro, PhD, University of Long Island, Brookville, NY; and O'Brian C. Smith, MD*, Steven A. Symes, PhD, Cynthia D. Gardner, MD, and T.A. Campbell, MD, University of Tennessee, Memphis, 1060 Madison Avenue Memphis, TN

The goals of this research project are to help participants realize the value of two enduring quotes: 1) "In fine, nothing is said now that has not been said before." (Terence, ancient Rome); and 2) "Those who ignore history are condemned to repeat it." (anon.). All of this will pertain to our so-called recent advances in the diagnosis of child abuse.

In the middle of an eleven-year review of child deaths investigated by the University of Tennessee, Memphis, Division of Forensic Pathology, an advanced literature search regarding the recorded history of forensic involvement in child abuse uncovered the humbling works of Ambroise Tardieu. This general practice physician was born 1818 in France, and rose in stature to become the Dean of the prestigious Faculté de Médecine de Paris. His name is familiar to forensic pathologists world wide by his anatomical tombstone "Tardieu spots." With the recent heightened interest in the phenomenon of child abuse evidenced by Caffey(1946) and Kempe (1962), and more recently, by the Shaken Baby Syndrome, it was a humbling discovery to review Tardieu's seminal work entitled "A Forensic Study on Abuses and Maltreatment Exercised on Children" published in the Annales d' Hygiène Publique et de Médecine Légale (1860, 13: 361-398). Often referenced by only one or two sentences in forensic texts, radiologists like Silverman and now Brogdon come closest to appreciating what most English-speaking pathologists will come to regret: that Tardieu's works have not become required reading during their fellowships.

This treatise reflected his involvement with 32 cases of child maltreatment over a 14 year time-span, 18 fatal (with 16 autopsies) and 14 non-fatal. Tardieu differentiated between abuse by neglect and abuse by violence; emphasized the importance of establishing patterns and chronology of abuse; recognized torture and identified causality between the shaking of a baby and nerve damage with or without cranial hemorrhage; alerted the medical community to the discrepancy between parental explanation of trauma and clinical tableau; recognized sexual abuse; understood the judicial ramifications of his role as medical examiner; stressed the sociological, cultural and demographic context of abuse; and optimized autopsy techniques in fatal abuse cases. Yet, not confined by his practice only to the dead, he readily addressed the emotional crippling of abuse victims. Tardieu's extraordinary vision at a time when clinical diagnosis was not technologically dependent (the x-ray had yet to be

discovered) is truly humbling. No doubt Tardieu was a man of great intellect imbued with the concept of forensics in service to the community, capable of aiding the living as well as advocating for the dead. His great success was due in no small part to the French legal system that was already deeply committed to the welfare of its children with a sophisticated acknowledgement and understanding of child abuse. Of no less importance was the social and cultural readiness to accept his actions and intent, serving as a catalyst to his medical abilities and inherent humanitarianism. Meanwhile in New York City (1874), eight year-old Mary Ellen Wilson remained tied to a bed, malnourished and beaten, until the cruelty to animal laws were applied to her situation.

One hundred years have passed and we have re-invented the wheel. Since Dr. Kempe coined the term "battered-child syndrome" in 1962, abuse has been defined as physical, emotional and sexual abuse and abuse by neglect. The definitions are now clear; the challenge is to be as involved within the home to the same extent as Dr. Tardieu.

Translations of his observations will be presented through photos from our recent cases. A more daunting challenge may be his other 1200+ page work on toxicology.

Child Abuse, Forensics, Legal Medicine

G79 Coming of Age in Memphis... How Our Children Die

C. Ferraro, PhD, Long Island University, Brookville, NY; O'Brian C. Smith, MD, Steven A. Symes, PhD, Cynthia D. Gardner, MD, and T.A. Campbell, MD, University of Tennessee, Memphis, 1060 Madison Avenue Memphis, TN*

This paper reviews the fatalities between birth and 18 years of age investigated by the Shelby County, Tennessee Medical Examiner from 1991 to 2001. The goals of this project are: 1) to identify trends in natural, accidental, homicidal, and suicidal deaths, 2) to examine the circumstances surrounding each to understand the surrounding cultural and social environment, 3) to evaluate the validity of forensic investigators linking age with the behavior defined parameters of childhood.

This study reviews 1,363 cases. Manner of death indicated 43% were natural; 33%, accidental; 19%, homicidal; and 5%, suicidal.

Half of the 586 natural deaths were diagnosed as Sudden Infant Death Syndrome (SIDS). Black babies (79 %) were more likely to be affected than white (20%), male (60%) more than female (40%). Non-SIDS natural deaths represented a diverse pathology.

Of the 448 accidental deaths 70% were traffic, and 30% non-traffic. Vehicular accidents were 70% automobile, 2% motorcycle, 2% train and 1% bicycle. Seventy-three pedestrians (23%) were struck by automobiles, and 6 by train. Only males were casualties of train, motorcycle and bicycle accidents, with a higher median age of 15 years for 10 whites and 12 years for 5 blacks. A difference also existed among pedestrians. Black children made up 70 % of all pedestrian deaths with a median age of 5, white 29% with a median age of 10. The 219 automobile accidents affected males (61%) more than females (39%). There was a significant contrast in gender following repartition within age intervals. From birth to 14 years, the difference between genders is nil, but skews significantly in the 15-18 year interval with 66% male and 34% female. This contrast reflects a change among individuals still legally defined as children, but who no longer behave as such. Of 148 casualties between 15 and 18 years, 38% were drivers and 61% passengers. Males predominate with 74% driving, 60% riding, and a balanced distribution in relation to ancestry (54% white, 46% black driving, evenly divided for passengers). Alcohol or drug use was not found in any case through the age of 15. But results in 18% of all vehicular deaths in the 16 to 18 year age group, (24% of white male, 24% of black male, and 4% of white female but no black female) were positive.

Of the 136 non-traffic accidental deaths, 25% resulted from drowning, 21% asphyxia, 15% fire-related, 11% poisoning, 10% gunshot

wound, 9% blunt trauma, 3% hanging and 2% hyperthermia. Drowning under the age of 2 takes place within the home with gender and ancestry ratios nearly equal. Drowning of older children occurred outside the home, mostly while unsupervised (70% male, 30% female: 83% black, 17% white). Asphyxia in 28 cases was linked to various mechanisms. Aspiration of gastric content, 13 cases, was the leading cause, followed by 10 instances of positional asphyxia, 4 of overlying and 1 post-surgical. The highest incidence of gastric aspiration peaked around 2 years of age and primarily affects black boys, 12 cases (92%). Positional asphyxia (median age 6 months) and overlying (median age 4 months) affected even younger demographic groups. Racial distribution reveals a similar prevalence among blacks (71%). House fires resulting in burns or carbon monoxide inhalation victimized more blacks (81%) than whites (19%). Significant socio-economic unevenness between the various demographic segments may be reflected in these ratios. Poisoning (15 cases) was sorted out according to type. Chemical agents such as cleaning products were responsible for 3 deaths under the age of 2 years, 1 sniffing and 5 medication deaths between 2 and 15 years. Illicit drugs (MDMA, cocaine) overdose and sniffing affected 6 whites, (4 males and 2 females) between 16 and 18 years of age. Accidental gunshot wounds killed 12 males and 2 females, 10 blacks and 4 whites with a median age of 14 years. Accidental blunt trauma lead to the death of 12 children, 9 males and 3 females, 9 blacks and 3 whites; the median age was 2 years.

Death by suicide involved 75 children, gunshot wounds (83%) were the primary cause of death, followed by hanging (6%) and drug overdose (4%). Gender and ancestry showed 56 males (28 white, 25 black, 2 asian, 1 hispanic) and 19 females (14 white, 3 black and 2 hispanic). Although 2 were 12 years old, the greatest incidence of suicide was found at a median age of 17 years for gunshots, 16 for hanging and 18 for drug overdose. Circumstances surrounding suicides involved failing relationships, parental divorce, and/or family turmoil. Variation in incidence between genders, and among females suggests differential coping skills based upon gender, cultural and behavioral differences.

258 juvenile deaths were ruled homicide. Causes of death include 182 cases (70%) of gunshot wounds, 36 (14%) blunt trauma, 16 (6%) sharp force, 6 Shaken Baby Syndrome, 3 drowning, and 3 cases of maternal demise. It is imperative for any analysis of violent death to go beyond global statistical calculations. Overall, it appears that children are most often murdered by gunfire. However, taking into account age distribution, guns were used in 9 deaths (5%) in children under 10 years, all of them bystanders. By contrast, 173 (95%) homicides between 11 and 18 succumbed to gunshot wounds, with few bystanders. All gunshot wound victims under 10 years were black, with an even distribution between males and females. Older victims were predominantly black (94%) and male (95%). In many respects, circumstances leading to sharp force injuries were analogous to firearm deaths. Although the instrument of death varied, the demography did not. In contrast, while blunt trauma is responsible for only 14% of all juvenile homicides (36 cases); 86% (31 cases) of these occur under the age of 3. Whereas street violence and use of weapons kill the older, it is domestic violence using hands or instruments of convenience that kill the younger. These are children, acting like children, powerless as children, with a median age of 18 months, and a peak incidence at 2 years. From birth to 18 months, incidence among males (59%) was higher than among females (41%). The ratio, however, reversed in the interval between 18 month and 3 years (43% male and 57% female); blacks (81%) still remained more likely to be victimized than whites (19%). This latter distribution was found among the 6 cases of Shaken Baby Syndrome as well. Blunt trauma and Shaken Baby Syndrome can be taken as part of the same modality both in regard to circumstances and mechanisms of death. This conclusion is reflected in the frequent finding of both forms of injury in the same victim.

Although legally defined as children, analysis of how they die identifies behavioral differences within the first 18 years of life with a clear schism between youngsters who behave like children and those who assume adult conduct. Patterns of accidental, suicidal, and homicidal death

clearly reflect these behavioral differences. Realizing this difference is the first step to breaking down the concept of a homogeneous category of victims known as children. Focusing on specific age groups and their unique behaviors may provide the opportunity to design solutions to specific problem areas rather than emphasizing one solution for all.

Child Abuse, Homicide, Death

G80 Bruises in Infancy: How Many Are Too Many?

Betty S. Spivack, MD, University of Louisville, Kentucky Justice Cabinet, Office of the Chief Medical Examiner 810 Barret Avenue, Louisville, KY*

The goal of this research project is to emphasize the rarity of accidental contusions in infants less than nine months of age.

Bruises may be noted on young infants as incidental findings during well-child exams or at autopsy. The presenter will review several recent studies indicating that accidental bruises of any sort are rare in the first eight months of life. Bruises of the face, trunk, and upper extremity are even less common.

In 1999 Sugar et al (1) reported the results of 973 children under 36 months who were examined during well-child visits. The presence, site, and number of bruises were recorded. Developmental stage, particularly the ability to walk along furniture ("cruising") or independently, was noted. Children with known medical conditions causing easy bruising and children in whom abuse was suspected for any reason were excluded from the study. Only 2 of 366 children under 6 months of age (0.6%) and 8 of 473 children under 9 months of age (1.7%) had any bruises. Bruises were noted in only 2.2% of children who were not yet cruising, but in 17.8% of cruisers and 51.9% of walkers. Bruises of abdomen, buttocks, hands and feet were rare in all age groups. Bruises of trunk, upper arm and face were extremely rare in non-cruisers.

In 2001 Labbe and Caouette (2) reported the results of 2,040 examinations of 1,467 children aged 0 to 17 years who were seen at well-child visit or in a hospital emergency department. Children seen in emergency departments were excluded if they had presented because of trauma. Children were also excluded from the study if they had a neurologic disorder which affected mobility, medical conditions causing easy bruising, were deemed "unstable" or were suspected of having been abused. The majority of children older than 9 months (76.6%) had at least 1 recent skin injury; predominantly bruises. In contrast, only 11.4% of infants 0 – 8 months had any skin lesions; these were predominantly scratches. Only 3 of 246 infants under 9 months of age (1.2%) had any bruises.

Two recent cases in our office illustrate the importance of investigating bruises.

Case 1: A 5-week-old infant was brought to his pediatrician's office with a complaint that he "fell off the couch." He had a hematoma on the pinna of his left ear and a subconjunctival hemorrhage of the right eye. No report was made to child protective services. Two months later, the child was brought to a local hospital in full cardiorespiratory arrest. History provided was that the child was being fed and burped and then became lifeless. He was briefly resuscitated, but died of multiple organ system failure. Postmortem examination revealed multiple subgaleal hemorrhages, thin film subdural and epidural hemorrhages, a torn corpus callosum, severe cerebral edema with tonsillar herniation, bilateral diffuse retinal hemorrhages with retinoschisis and diffuse subdural hemorrhage of the spinal cord. Bruising was seen externally over the right face and pinna, extending onto the right scalp. A similar distribution of bruising was seen on infrared examination on the other side of the face.

Case 2: A 3-month-old child was noted to have multiple bruises while being bathed by her grandmother. She appeared otherwise well. She was brought to the hospital for evaluation. Pattern bruises were found to the abdomen, upper arm, neck and face. Skeletal survey revealed 3 ages

of rib fractures, and a compression fracture of L2. None of these skeletal injuries was suspected on physical examination.

In conclusion, the presence of any bruises in a child who is not yet walking along furniture is concerning. Bruises in unusual sites, such as the abdomen, face or upper arm, should lead to a child protection referral to investigate the possibility of inflicted trauma.

Contusions, Child Abuse, Skin Pathology

G81 Child Abuse Autopsy Technique... What Works for Us

O'Brian C. Smith, MD, Steven A. Symes, PhD, Cynthia D. Gardner, MD, Susan B. Patton, MNSc, and T. A. Campbell, MD, University of Tennessee, Memphis, 1060 Madison Avenue, Memphis, TN; and C. Ferraro, PhD, Long Island University, Brookville, NY*

The goals of this research project are to: 1) become familiar with the application of new autopsy techniques designed to enhance their ability to observe, record and present these findings, and 2) actual case studies will demonstrate how to perform these procedures.

Autopsies on victims of child abuse are more involved than most assault cases. The question of neglect, past physical abuses, torture, sexual abuse, instrumentality, timing or sequence of injury and dating of wounds is further complicated by the fact that children are not small adults. Growth and developmental processes from the epiphyseal plates in long bones, unfused sutures in cranial bones, degree of central nervous system myelination, susceptibility to certain forms of injury and basic considerations of size and weight are all differences requiring special or modified autopsy procedures. Over the years of autopsy service provided by the University of Tennessee, Memphis and the Regional Forensic Center, certain techniques have been employed to maximize the discovery, documentation, and demonstration of injuries. Some of these methods will be discussed using case based examples and include:

Epiluminescence is a dermatologist's aid utilizing the optical properties of oil applied to the skin surface to enhance the observation of injuries at or just below the epidermis.

Casting of the skin surface using elastomeric materials to preserve toolmark/bitemark impressions.

Angiography for the assessment of vascular patency and distribution. Post-mortem carotid catheterization and instillation of radio-opaque dye can be performed simply in the autopsy suite followed by standard x-ray views to record the vascular changes. Coronary angiographies may be performed *in situ* or *ex vivo* and x-rayed in any position.

Ocular Special procedures demonstrate retinal and optic nerve hemorrhages, *in situ* and by histology. Borrowing from eye donor protocols, circumferential incision of the limbus under suture traction allows gentle removal of the cornea followed by separate excision of the iris and lens. The vitreous is used to maintain the retina in place and utilize its optical properties to obtain clear photographs of the retina in place while maintaining the orientation of its landmarks. Hemorrhages and folds are readily demonstrated. Following this, the globe remnant is excised and retina and optic nerve removed for histological evaluation.

Skeletal assessment by physical examination techniques, radiographic protocols, anthropologic evaluation, histology and preservation as evidence. The rib cage is x-rayed using oblique views to enhance pre autopsy diagnostic accuracy. After thoracic evisceration, inspection and palpation are performed passively and under stress loading to identify well approximated and nearly bloodless fracture sites. The external surfaces are surgically freed to aid this. Injured ribs and those immediately adjacent are excised since occult fractures and green fractures are likely to escape any other method of detection. Fractures indicating any likelihood of age beyond immediately prior to death may be sectioned in part for histological dating with correlation by anthropological methods. All excised bone is processed for evidentiary retention by mild digestive techniques.

Wound dating or sequencing techniques correlate histological appearances with chronology or clinical history. The process of inflammation and repair is a phenomenon that proceeds along a well defined pathway, but progresses at a rate affected by its circulation, any interference with that blood supply, episodes of pre-existent shock, magnitude of the injury and area of injury examined and effects of decomposition.

Bronchoscopy evaluation of the airway in fire, asthma and pneumonia deaths. Persons receiving an endotracheal tube as a result of medical intervention prior to death are very amenable to bronchoscopic examination utilizing the lumen of the tube. Greater skill is required to examine the patient in rigor without a tube. Asthma patients show typical mucus plug formation; gastric aspiration is accompanied by a rapid onset mucosal erythema and pneumonia patients frequently exhibit purulent material. Smoke inhalation is easily diagnosed by the presence of soot deposits, while those dead before the fire have none.

Organ and tissue donor programs take precedence over medical examiner jurisdiction in Tennessee. As a result of good cooperation and mutual support of activities, no forensic autopsy has been compromised and tissue recovery has soared. The actual practice involves both parties, acting together in concert or sequentially to identify injuries prior to harvest and preservation of those areas of forensic interest. An exchange of pathology reports between donor agencies and the medical examiner completes the pathologic examination by our office while the donor agency determines suitability for transplant based in part upon our reports.

With these tools, the ability to record, describe and present injuries effectively is enhanced before families, attorneys and juries alike. Additionally, opposing experts get to review higher quality material that is less ambiguous.

Child Abuse, Autopsy, Organ Donor
